element has codes for several broad categories of fabrics and textiles, including unclassified and unknown types. For carpet constructed from manufactured fabric or fiber (code 71), you might be inclined to consider only those fires and a proportional share of fires coded as Type of Material First Ignited code 70 (unknown-type fabric, textile, fur, or hair) as well as fires coded as totally unknown. This would properly separate carpet fires from hardwood or unfinished floors (Type of Material First Ignited codes in the 60–69 range, which is wood and paper) and from vinyl floor coverings (Type of Material First Ignited codes in the 40–49 range, which is plastics, or perhaps code 81, which is linoleum, or codes 80 and 89, which are unclassified and unknown-type materials compounded with oil). But what about fires coded as cotton or rayon (code 72) or wool (code 73) or fur, silk, or other fabric (code 74)? If each of these possibilities corresponds to another real product—say, a type of rug or another type of carpet—then exclusion of these inappropriate codes makes sense. But any code that does not correspond to another real product is probably a miscoding and so is best treated as another type of partial or complete unknown, to be proportionally allocated and so added to the estimated number of total carpet fires.

For example, one of the most frequently reported Types of Material First Ignited for floor covering fires is gasoline, which clearly refers not to the floor covering but to a substance spilled or poured onto the floor covering. Should such fires be excluded because they clearly do not involve a true floor covering as the first item ignited? Or should they be included on the basis that the gasoline leads to accelerated early involvement of the real floor covering in fire, and so floor covering is the first true product involved in fire? Or should they be excluded on the basis that the burning properties of the floor covering are irrelevant to a fire started with gasoline? Or should they be included on the basis that the relative ability of different floor coverings to absorb gasoline could make a difference in fire development? No matter what the decision, it will not be a simple one.

The gasoline example illustrates another general point. It may be tempting, when constructing national estimates, to exclude certain types of fires as not being fair tests of the product or the building design. This practice is unsound, as all fires involving a product or occupancy are relevant to an overall description of the fire problem associated with it. Factors that make the fire challenge seem unfair can be properly addressed at the stage of analyzing how much fire probabilities can be reduced or interpreting whether a certain fire probability is acceptably low. But exclusions should occur at those points, not at the initial stages of analysis, or else the engineering analysis will be conducted against a misleadingly optimistic view of the size of the problem to be addressed.

At this stage, you may have achieved as detailed and appropriate an estimate of the incident rate as you can derive from NFIRS-based national estimates. It is not possible to ascertain, for example, age, style, specific materials, or specific burning properties of carpet from NFIRS. All types of carpets and rugs may still be inseparably combined in your estimates. In some cases, further refinement is possible based on differential patterns of usage and

their implications for areas of origin or for exposure to certain heat sources. For example, the same Equipment Involved in Ignition code is used for irons, hair dryers, and electric blankets. However, these devices are used in very different places and tend to ignite different burnable items because different items are close enough to each type of device to be ignited. Some heuristic estimates could be made. For carpets and rugs, however, there do not seem to be any differences in usage patterns that are clear-cut enough to use in analysis. More detail is needed from another data source.

Further progress depends on inference from a combination of incident data, usage data, and laboratory test data. The inference rules will be discussed after those types of data have been reviewed and discussed individually.

For now, let us return to the earlier statement that valid analysis of incident rates requires the use of a statistically representative database, like NFIRS and the NFPA survey. Many other databases exist that are much more detailed than NFIRS but are either known to be statistically unrepresentative or at best not known to be representative. To see why it is imperative that analysts not sacrifice statistical validity for detail, it may be useful to review a number of half-truths and widely held myths surrounding databases.

Data Half-Truths and Myths

“Someone must collect the data I need”: Why? Who would have that much interest? It takes time and resources to collect data. Any organization that collects data will have a reason to do so. And the data they collect will be the data *they* need.

Some databases were developed to serve diverse purposes and constituencies. In 1974, the National Fire Prevention and Control Act, Public Law 93-498, Section 9 established the National Fire Data Center to “provide an accurate, nationwide analysis of the fire problem, identify major problem areas, assist in setting priorities, determine possible solutions to problems, and monitor the effectiveness of programs to reduce fire losses.” This act established the U.S. Fire Administration and the National Fire Incident Reporting System (NFIRS).

The U.S. Consumer Product Safety Commission (CPSC) uses data from the sample-based National Electronic Injury Surveillance System (NEISS), which CPSC created, to develop estimates of the number of injuries associated with consumer products and treated at hospital emergency rooms.

NFIRS and NEISS are examples of event databases. Both were designed to help identify a very wide variety of problems and were not designed to “prove” a particular point.

When considering the use of data from a particular source, it is wise to consider why the data collection effort was undertaken in the first place. Who paid for it, and would the sponsors have a vested interest in a particular outcome? In some cases, data may be collected to promote an agenda, and may be virtually useless because of leading questions or other methodological flaws. It is often useful to review the survey instrument or form. Sometimes a data collection effort was designed to answer one

specific question, and the results would not be applicable in other settings. Rural and urban experiences may differ considerably from each other, so, for example, a study of big-city fire problems could not be applied to rural settings without refinement or reconfirmation.

It is not necessary, though, for biases to be inserted deliberately in order for serious biases to arise. Data collection budgets are typically small, and most databases are therefore limited to data that is easy to obtain. Both the accuracy of the data and the representativeness of the incidents captured must be considered highly suspect in any so-called opportunity sample. Even in a well-designed data collection system with no deliberate bias and no special shortage of funds, some biases arise because of the relative difficulty of obtaining reliable information and universal participation. For example, fires in fully sprinklered buildings or buildings with good detection/alarm systems are more likely to be discovered and controlled by on-site resources including the occupants. No data collection system based on third parties, like the fire service, can expect to capture unreported fires. The national estimates of fire problems that are produced by combining NFIRS data and the results of the NFPA survey only reflect data reported to municipal fire departments and exclude those handled by private federal brigades, federal fire-fighting organizations or the occupants themselves. Some occupancies, particularly high-hazard occupancies, are more likely to have fire brigades than others.

Suppose one asked for data on heat-release rates at key points during the fire. No one has the technology to measure or estimate such data outside a laboratory. Suppose one asked for readily observable change points in the fire, such as spread to a new room or floor. No one can expect to be in position to observe such change points at most fires, and fire fighters do not have the discretionary time during a fire to check specific times and record them. When seeking data, it is important to ask how the data collectors would be able to obtain the data and how reliable it would be.

“Anecdotes describe typical incidents”: This is often not true. *Anecdotes* are what statisticians call data points from a database that has not been designed to ensure statistical representativeness. The NFPA Fire Analysis and Research Division runs an anecdotal database called the Fire Incident Data Organization (FIDO). A clipping service identifies significant incidents (e.g., large loss, multiple deaths), and additional information is requested from the fire service and other sources. Because serious fires, with multiple deaths or millions of dollars in loss, tend to be widely reported, FIDO’s anecdotes can be used as a statistically representative (even complete) database for large fires. However, FIDO also captures well-documented fires on an opportunity basis, and for these fires FIDO is only anecdotal.

From early in the twentieth century until the mid-1970s, NFPA collected information on sprinkler activations.³ However, over time the easily available data sources became less and less reliable in capturing smaller fires. As FIDO’s representativeness for smaller fires de-

clined, so did its representativeness in capturing sprinkler successes. More and more such incidents were missed, and a disproportionate number of captured incidents therefore showed sprinkler problems.

Anecdotal information like that provided by FIDO, NFPA Fire Investigations, or CPSC’s In-Depth Investigations file can indicate the range and diversity of fires that *can* happen. Anecdotes cannot be used to estimate incident rates or probabilities.

“A rose is a rose is a rose”: Anecdotes are relevant but may not be representative. It is also possible to have representative data that are not relevant, even though they appear to be, because of differing definitions for the same terms. For example, definitions of data elements may differ in different countries or even different data collection systems. In fire incident databases, *space heater* refers to a heater for a relatively small area. The U.S. Department of Energy uses the term *space heater* to describe *all* heating systems, including furnaces and other central heating units. However, the term *heating equipment* in fire incident databases includes not only equipment to heat spaces but also water heaters.

“If data were collected, they must be available”: The analyst’s life would be easier if this statement were true. Unfortunately, it’s not. Some data, such as the detailed information collected by insurance companies, is proprietary and confidential. Corporations may maintain incident records when injuries or mishaps occur, but they are under no obligation to share that information with the general public. Information collected by the government *should* be available. The public can generally obtain copies of reports or files that already exist. However, data may not be kept indefinitely and older data may never have been entered into modern, electronically accessible media. Many computer systems have not been integrated, so analyses that are theoretically quite easy may be impossible without major conversion efforts.

These problems are usually not insurmountable. Some modifications may be needed and sources of uncertainty must be documented. Considerable data is available, as noted, which means estimates of sampling-based uncertainty can be readily constructed.

Field Observation Data

Switching now from fire incident data to other kinds of data based on observations in the field, Table 5-5.1 cites field observation data as relevant to reliability analysis, including instances of unavailability or failures to perform with full effectiveness when needed despite being available, and emergency evacuation analysis.

The chapter on reliability (Section 5, Chapter 3) elsewhere in this handbook provides an overview of issues in and mathematical methods for analyzing reliability. At present, data to support reliability analysis is very scarce. The five types of data sources identified are also relevant to other aspects of engineering analysis:

- Judgments and opinions
- Inspection and testing
- Simulations and laboratory studies
- Incident data
- Product life tracking systems

Judgments and Opinions

In the absence of any type of data from systematic field observations, one can use estimates from individuals whose work experience has provided them with a long period of nonsystematic field observations. There are methods like Delphi panels that try to eliminate bias from the group process of consolidating expert opinions into consensus estimates. (Modified Delphi panels have been used to specify many of the scoring parameters for NFPA 101A, the alternative evaluation scheme to NFPA's *Life Safety Code*.) But shared biases remain and are commonplace. In particular, the mix of observations that occur in the normal course of a job in fire suppression, fire reconstruction, design, and so forth, are subject to many biases that may not be recognized by the experts. (For example, new buildings are more likely to be designed for the affluent end of the general or business population, whereas fires are more likely to occur at the less affluent end, but neither tendency is absolute.)

In addition, there is a tendency for individuals to shade their recollections in favor of a pattern that is simpler than the often complex truth. Thus, a system or feature with relatively high reliability will have its reliability estimated even higher (sometimes called the *halo effect*), while a system or feature with relatively low reliability will have its reliability estimated even lower (sometimes called the *horns effect*).

Inspections and Testing

A program of routine inspection and testing can provide statistically representative data on failure frequencies and severities and is particularly useful for failures that are less than total or that otherwise may not draw attention to themselves when they occur. *Frequency* is how often failure occurs, and *severity* is how damaging failure is when it occurs, so frequency numbers are in fact relative to the level of severity of failure being tallied. However, inspection and testing-based databases are usually proprietary and so not available for routine engineering analysis. And even when available, they are subject to some critical gaps and biases.

First, the inspections that provide this kind of data tend to be part of a very advanced maintenance program, which provides the principal justification for the high cost of frequent inspection and testing. Frequent maintenance and inspection, in turn, are more likely to occur with a better-trained and more safety-conscious workforce, so the human error reliability problems, which tend to dominate mechanical and electrical problems for most systems and features in practice, are likely to be sharply lower. The resulting reliability figures will therefore tend to be much better than those achieved for more typical properties that lack the maintenance to achieve high reliability and the in-

spection and testing to measure their reliability. This is one reason why estimates of sprinkler reliability in Australia are so much higher than those in the United States.³ (Another reason is that Australian sprinkler systems are much more likely to have automatic alarm transmittal to the local fire brigades, which means small-fire successes are much more likely to be captured by the same people who create the national fire incident databases.)

Second, this form of data collection can miss transitory failure conditions, such as blocking a door open, or vulnerability to extremely rare external events, such as earthquakes. In both cases, the sampling in time represented by the inspections and tests may not be sufficient to identify an important problem, in the former case because the sampling points are too far apart and in the latter case because the sampling does not (and perhaps could not) cover a sufficiently long period of time.

Finally, the process of inspection and testing is itself subject to error. If inspection is limited to observation only, without more active involvement as with testing, the probability of error in observation can be quite significant. Most databases derived from inspections or tests do not consider this type of error.

Simulations and Laboratory Studies

Exit drills are a form of simulation or laboratory study that provide data on human reliability (and performance) with regard to a range of safety-related behaviors. They illustrate the larger point that simulations and related studies are particularly useful for studying human error reliability, a critical aspect that tends to be less well addressed by other controlled-study data sources.

Simulations may be less than realistic as a result of simplifications done to make the experiment repeatable and manageable, as well as those made to avoid undue risks to participants. A bench-scale fire test cannot be readily scaled up to real-scale fire effects and will avoid the high flux levels of a fully developed fire, in part to avoid harm to operators and equipment, but in so doing may create a misleadingly mild picture of real fire conditions. Even a room-scale test is unlikely to be set up with accelerants, high wind-speed ventilation, conditions promoting backdrafts, or some of the other conditions that can produce the most severe fire conditions. An evacuation drill may avoid bad-weather days to avoid injury to occupants, but this may paint an unrealistically optimistic picture of how slow and how hazardous real evacuations may be.

The field of ergonomics provides design solutions to many of the people-equipment interaction problems that studies and data like these identify.

Incident and Other Field Data on Systems Performance

In theory, the most appropriate database on reliability of a system or feature would be one that captured every naturally occurring test of its availability and performance (i.e., unwanted fires) and every other activation of the system (e.g., nuisance alarms). In practice, this requires constant monitoring, which is almost always too

expensive to be implemented. The attempts to approximate such a database using only fires reported to fire departments or, even worse, fires reported in the media, will miss most incidents and can give a misleadingly pessimistic picture of reliability.

For example, analyses of reported home fires consistently show roughly one-third of smoke alarms are nonoperational,⁴ but the last recent study of home installations in general found only one-fifth of smoke alarms are nonoperational.⁴ Part of the reason is that occupants who are not careful to maintain smoke alarm operability are more likely not to be careful to prevent fires. However, analysis of data from unreported fires suggests that a larger reason for the difference is the large number of home smoke alarm successes that keep fires small enough that fire departments are never notified.⁴

A similar story almost certainly applies to sprinklers, where analysis of data from reported fires indicates that sprinklers do not operate in one-sixth to one-fifth of the fires large enough to activate them (manufacturing facilities show only one-tenth).³ Real reliability, factoring in fires that are controlled so quickly they are never reported, could easily be well over 90 percent and yet be consistent with figures like these 80–86 percent figures derived from reported fires only.³ NFPA discontinued its sprinkler performance database in 1970 because of problems just like this.

The best databases, therefore, are those maintained by facilities or organizations that are equipped and committed to capture all fires and even all component failures. Such databases exist for process equipment (through the American Institute of Chemical Engineers, Center for Chemical Process Safety), for military equipment (through the Reliability Analysis Center in Rome, New York), and for the nuclear power industry (in documented probabilistic risk assessments for individual plants and through Science Applications International Corporation). (See contact information for some of these groups at the end of this chapter.)

All the databases described here tend to focus on active systems and other equipment. Passive fire protection features, such as fire walls, are less likely to be captured, in part because their failures tend not to be time-specific events (e.g., a smoke alarm has its battery removed, a sprinkler valve is shut off, both events occurring at defined points of time) but rather partial deficiencies in performance (e.g., a door is normally left slightly ajar, a wall has a hole in it). A poke-through hole in a wall, for example, is not a total failure of the wall and does not appear as an event in the course of the fire. Although it may have played a role in extension of the fire, it is unlikely to be identified in a postfire analysis. It also may not fit your definition of a reliability problem, but it is clearly a deviation from intended design that affects and degrades performance. No incident database routinely documents fire development and related factors in enough detail to capture this kind of problem.

Product Life Tracking System

This is the approach to data collection and reliability assurance underlying the extensive component reliability

data developed by the military, particularly for aircraft, including their onboard fire protection systems (and available from the Reliability Analysis Center, Rome, New York). It combines the inspection and testing approach with the incident data approach but is also organized by individual component, which supports very specific and targeted analysis, maintenance, redesign, and other uses.

Usage and Exposure Data

Usage and exposure data is necessary at several points in engineering analysis. First, if the analysis addresses fire risk, then usage or exposure data (e.g., number of units of product in use, number of establishments of a particular type, number of people using a product or occupying a building, number of square feet of space devoted to a type of occupancy) is needed to convert incident data to estimates of ignition probability or to convert failure event data to estimates of reliability. Many if not most engineering analyses, however, frame problems in ways that do not require explicit, quantitative treatment of ignition or reliability. Even these analyses still need some usage and exposure data in order to define and specify transitory conditions, such as the numbers, locations, and capabilities of occupants, that affect the achievement of fire safety objectives and so the performance of a design.

For risk calculation, the principal challenge is to find statistically representative data with enough detail and with a structure that matches the structure of the incident or other event data it is meant to be used with. A matrix of different types of home-heating equipment, in the categories for which the U.S. Department of Energy provides usage data, is displayed in Table 5-5.2.

Many, perhaps most, of the “not stated” entries can be reasonably filled in by someone with expert knowledge of available heating technologies, both current and past. However, other studies of usage have indicated significant usage of portable electric heaters for primary heating (which would be concealed here within the category of “other” devices or misclassified as primary heating) and have distinguished wood-burning fireplaces with and without inserts.

Fire incident databases such as NFIRS (through version 4.1) offer these device categories:

- Central heating unit
- Fixed-area space heater
- Portable space heater
- Fireplace
- Chimney
- Chimney connector
- Heat-transfer system
- Other

The last three specific types of equipment are part of distribution and are not linked to the devices they support. How would you apply these categories to a heat pump or a floor, wall, or pipeless gas furnace?

Table 5-5.2 *Types of Heating Equipment, by Fuel or Power, Local versus Central, Fixed versus Portable, Primary versus Secondary*

Fuel or Power	Type of Device	How Heat Is Distributed	Primary or Secondary Heating?
Natural gas	Central furnace	Forced warm air	Primary or secondary
	Not stated	Steam or hot water	Primary
	Floor, wall, or pipeless furnace	Not stated	Primary
	Room heater or other device	Not stated	Primary or secondary
	Fireplace	Not stated	Secondary
LP-gas	Central furnace	Forced warm air	Primary
	Room heater	Not stated	Primary
	Other	Not stated	Primary
	Not stated	Not stated	Secondary
Fuel oil	Central furnace	Forced warm air	Primary
	Not stated	Steam or hot water	Primary
	Other	Not stated	Primary
Kerosene	Not stated	Not stated	Secondary
	Not stated	Not stated	Primary or secondary
Electricity	Central furnace	Forced warm air	Primary
	Built-in units	Not stated	Primary or secondary
	Heat pump	Not stated	Primary
	Portable heater	Not stated	Secondary
	Other	Not stated	Primary or secondary
Wood	Heating stove	Not stated	Primary or secondary
	Fireplace	Not stated	Secondary
	Other	Not stated	Primary or secondary
Other	Not stated	Not stated	Primary or secondary

Source: *A Look at Residential Energy Consumption in 1997*, Energy Information Administration, Office of Energy Markets and End Use, U.S. Department of Energy, Washington, DC (November 1999).

For fuel or power, the Form of Heat of Ignition data elements in NFIRS (through version 4.1) will support categories like these:

- Gas-fueled equipment (natural gas and LP-gas not separated)
- Liquid-fueled equipment (fuel oil and kerosene not separated)
- Solid-fueled equipment (wood and coal not separated)
- Electric-powered equipment
- Fueled equipment with no information on type of fuel
- Match, lighter, ember, or other code suggesting fueled rather than electrical equipment but also somewhat in-

compatible with coding of heating equipment as heat source

- Light bulb or other code suggesting electrical rather than fueled equipment but also somewhat incompatible with coding of heating equipment as heat source
- Fireworks or other codes strongly incompatible with coding of heating equipment or heat source (and, fortunately, almost never used in combination with heating equipment)
- Codes providing no indication of fuel or power source but compatible with coding of heating equipment as heat source

This comparison will suffice to illustrate the point that even modestly detailed incident and usage databases can present a multitude of compatibility problems. Some problems can be solved by one-time special data collection efforts to devise assignment rules for estimation purposes. This is what is typically done to match chimney fires to wood stoves versus fireplaces, for example. Some problems can be solved by examination of the technology alternatives and by asking data collectors what rules they use to resolve questions in the field. Some problems can be addressed by expert judgment. And some problems create limits to the level of detail achievable in the data.

Another example has to do with occupancies. Occupancy refers to the use made of a space, and fixed property use is the NFIRS code that describes the use being made of a fixed property, which is to say a building or part of a building (such as a restaurant in a mall or on the ground floor of a high-rise multiuse building). U.S. Census Bureau codes for establishments are designed to classify the primary activity or line of the business that owns or occupies the building. In pursuit of its primary activity, a business may require and oversee many types of occupancies, from manufacturing to sales to office to storage to public assembly. The codes for businesses also distinguish retail from wholesale sales, whereas the codes for occupancies do not. Is a wholesale sales operation an office building or a mercantile occupancy? Or is it an office occupancy and a storage occupancy sharing a building? (Or the two parts might not be sharing a building.)

There are far more storage occupancies than there are buildings housing businesses whose defining purpose is storage. This means that no matter how one groups fires in storage occupancies, it is not clear that the data will match the data on establishments. Some storage occupancy fires will be in storage businesses, but many, perhaps most, will be in storage buildings associated with a store or a factory, on its complex.

Even when major categorization mismatches are not an issue, minor ones can be. The business codes identify gasoline service stations as a type of retail business. Fire incident database codes identify public service stations, but that category excludes private service stations (which the business codes may not recognize at all, since they classify a building, not the business that owns and runs the activity), excludes marine service stations (which may or may not be included in the business codes), and includes LP-gas dealers (who are probably listed separately under fuel dealers within miscellaneous retail for the business codes).

If all the matching issues are addressed, then one must still consider the measurement scales available. The business code categories are used to count establishments, which is probably the best measure of exposure but also mixes very large and very small buildings without distinction. A better measure for fire risk analysis would probably be square footage, but that data exists only for highly aggregated categories of buildings. Business-coded data also exist on numbers of employees and dollars of payroll, both already related to business size but not clearly relevant to exposure proportional to fire risk.

Current and previous versions of NFIRS (up to Version 4.1) used NFPA 901, *Uniform Coding for Fire Protection*, 1976 edition, as their starting point for data classification. Version 5.0 of NFIRS has reduced the number of fixed-property use codes dramatically. Separate fields are used to identify on-site materials, whether these materials are stored, processed, sold, or repaired at the facility, and building status. We have only begun to consider where and to what degree these extensive changes will make cross-matching business-coded data on establishments with occupancy-coded data on fire incidents more or less difficult.

Now consider occupant characteristics. Engineering analysis is done using scenarios, whether it is done in terms of fire hazard or full analysis of fire risk. Most fire safety objectives trace, directly or indirectly, to a goal of protecting people. Short of a highly conservative (and generally unachievable) objective of preventing any fire effects in any occupied area, engineering analysis will need to address the fates of occupants, explicitly and quantitatively. This, in turn, requires data on the occupants, effective when fire begins. How many are there, where are they, how will they act, and what are they capable of?

A wealth of information exists regarding household structures, which may be useful in defining *occupant sets*—alternative descriptions of occupants for analysis, analogous to fire scenarios—for homes. Information is much less detailed for occupants of any other occupancy, and these will tend to be the types of buildings where engineering analysis is sought. For those properties, one will need to seek data from industry sources and special surveys. Absent such data, it will be tempting, and possibly necessary, to use ad hoc, heuristic methods to shape subjective estimates. Certain cautions must be noted in so doing.

First, occupants do not respond in an ideal or perfectly efficient manner. They do not react immediately to the first cues of fire, they do not evacuate on the basis of perfect knowledge of conditions throughout the building, and they may evacuate in accordance with their normal patterns of movement rather than along rarely used paths best designed for quick, safe evacuation. Occupants may try to defend in place when they should not or try to evacuate when it would be safer to defend in place. None of this is a matter of panic or of irrational behavior or choices. It is not even unusual conservatism. It is simply a realistic view of how people respond to fire. Some evacuation models incorporate best available data on typical behavior and the time it takes. Optimizing models do not.

Second, the places that have fires differ, not in kind but to a significant degree, from the mix of places in

general. The former tend to be occupied by people (as residents, guests, workers, shoppers, etc.) who are poorer and less well educated, in buildings whose design, maintenance, and operation tend to be less fire safe, reflecting the limitations of their occupants, managers, and owners. Smokers and consumers of alcohol or other drugs are more likely to be present because their high-risk behavior makes fire more likely, as statistical studies of risk factors repeatedly show.^{5,6} There is little data on how best to reflect those patterns, and some of them may be moot for an engineering analysis of a well-designed new building, but analysts are advised to shade their assumptions and parameters toward less capability for occupants than the norm and much less capability than engineers see in their own lives, since engineers, like all professionals, are more affluent and better educated than the national average.

Third, there are far more people with limitations in the general population than ever before, if only because there are far more people in the older age groups. Buildings open to the general public will see more and more occupants with limitations of age. The Americans with Disabilities Act has facilitated access to workplaces and places of assembly for many more physically challenged individuals, while the deinstitutionalization of many people with chronic mental illness decades ago led to a larger share of occupants with mental or emotional limitations. The diversity of physical challenges is also increasingly recognized. Many people have some limitations (wear corrective eyeglasses or contact lenses, for example), and there may be less data with which to model the many moderately limited occupants than there is to model the much fewer severely limited occupants.

Fourth, occupant profiles can often be specified by linkage to time of day.⁷ In homes, during the day on weekdays, there will be fewer occupants, and they will represent a different mix of ages and roles than in the evening or at night. In the evening, people will tend to be awake, while at night, most will be asleep. In hotels, different times of day will find different mixes of occupants in the guest rooms, the small meeting rooms, the large function rooms, and the recreational facilities. Overall occupancy is rarely 100 percent, but there is data available to set estimated occupancy.⁸ In office buildings, the number, location, and other characteristics of occupants are clearly different during normal working hours than outside them.

Fifth, fire incidence and casualty data can and should be used as input to the process of setting occupant characteristics, but usually that data should not be used directly. For example, suppose you specified a household structure that reflected exactly the age distribution of deaths and injuries in home fires. That specification would not reproduce the observed age distribution of fire deaths and injuries, because the high-risk age groups will be disproportionately likely to suffer death or injury during fire.

On the other hand, it is useful to know that most fire risk in hotels and motels looks like fire risk in homes.⁵ It tends to be limited to the person or group in the guest room of origin, and the causes are much the same, after adjusting for the presence or absence of local heating or

cooking equipment. The very large death tolls in some hotel fires justify analysis of a property's vulnerability to extended fire development and smoke spread, but most risk will take place on a different scale and test different aspects of the property's fire safety provisions.

An even larger challenge to what many people may believe is the pattern in fatal office fires. The majority of fatal office fires occur outside business hours, and a large share involve fire spread to or from another occupancy (e.g., to or from an apartment in the same building or complex) or risks associated with dual use of the office property (e.g., the cot in the back room that makes the office into a residential property after hours).⁹ The classic concern in office buildings—the ability to safely evacuate large numbers of people faced with the threat of a rapidly growing fire—is almost never a factor in fatal office building fires.⁹ This does not mean it should not be part of the evaluation, only that the very different patterns of risk and hazard occurring after-hours or in multiuse properties need to be examined also.

Finally, it is dangerous to limit the challenge posed by occupant characteristics with an assumption of code compliance. The most deadly fires in eating and drinking establishments have involved serious code violations, including severe overcrowding. Many deadly fires have occurred in facilities that were not designed, operated, or licensed to provide health care, but that nevertheless proved to have occupants with severe limitations when a fire occurred.¹⁰ It is unreasonable to expect a building design to protect occupants from fire in the face of pervasive, serious code violations, but it is not unreasonable to conservatively plan for at least occasional, transitory, but possibly significant violations, such as overcrowding or deterioration of occupant capability below the minimum level that allowed them to be admitted for residency. Serious fires do not usually happen where everyone follows all the rules and best practices. A design should be robust enough to protect people even when challenged beyond the strict limits of what is supposed to be possible.

Laboratory Data

For laboratory data on physical properties of fire, products, buildings, and so on, you should start with the other chapters of this handbook, which identify the measures of interest, put them in context, and in many instances provide or reference best available data. Also, read the "Statistics" chapter (Section 1, Chapter 12) for general guidance on handling error and uncertainty in data, and consult. For guidance on error and uncertainty in data from particular test methods, consult precision and bias statements in the standards for those test methods, or consult ASTM E691, *Practice for Conducting an Interlaboratory Study to Determine the Precision of a Test Method*.

On a related point, read the other chapters closely for guidance, specific to each type of data, on what to do if your case does not exactly match the specifications for any available test data. For example:

1. Is it best to choose the closest documented case, or is extrapolation or interpolation better? How do you de-

termine what is the closest? How far outside tested values can you extrapolate with reasonable confidence?

2. What do you do if the tests do not align along any linear scale, making direct interpolation and extrapolation impossible? (For example, there may be one result for each of several materials.) Are there scaled characteristics that can be used as a legitimate, if unproven, basis for interpolation or extrapolation?
3. Is linear interpolation or extrapolation appropriate, or would another functional form be more appropriate?
4. In addition to the characteristics of the object or space for which you need data, are the fire conditions you anticipate the same as those used in the available tests? If not, do the differences matter and can they be adjusted for?
5. Scale matters. Results from bench-scale fire tests cannot be assumed to reflect full-scale performance.
6. Interactions also matter. Fire performance of products that are composites or layered combinations of materials cannot be predicted from test data on their constituent materials.¹¹
7. Time and usage change things. Products may change chemically or be altered physically, up to and including vandalism. All such changes may affect the applicability of test data on new products. This is even more true if the laboratory tests were on prototypes—or even prototypes with simplified design features—rather than on actual products ready for use.

In addition to direct use of laboratory test data, such data can be combined with incident data to provide greater detail. Consider the use of laboratory test data to build on the ignition probability estimates developed earlier for a specific product in the carpet and rug class. Under the section headed Incident Data, the discussion showed how to develop floor covering fire estimates, then fabric or textile floor covering fire estimates. Suppose this national estimates approach suffices to provide probabilities of ignition for a product class (e.g., carpet or rug) but not for any type, style, or brand of that product class.

First, the universe of products in use (not the universe of products currently offered for sale) must be divided into a small number of representative pieces such that every variation of product in use is represented by one of these reference pieces. Second, data must be developed on the share of current usage (not the current market share). Then, laboratory tests must be conducted to determine relative ignitability.

Let $i = 1, \dots, n$ be designations for n different representative pieces. Let u_i be the collective share of total usage accounted for by the i th piece and all the pieces represented by the i th piece. Let p' be the probability of ignition, derived from fire incident national estimates for the product in all its variations. Let p_i be the proportion of laboratory trials of the i th piece in which ignition occurred. Then (all variations of product are represented and none are double-counted)

$$\sum_{i=1}^n u_i = 1$$

The usage-weighted average frequency of ignition for the tested pieces is proportional to the experience-derived overall ignition probability for the product class.

$$\sum_{i=1}^n u_i p_i \propto p'$$

Therefore, the best estimate of the ignition probability for a piece of type i is

$$\frac{p' u_i p_i}{\sum_{i=1}^n u_i p_i}$$

This formula uses the incident data to calibrate the laboratory test data, or it uses the laboratory data to subdivide the ignition probability for the product class into more product-specific ignition probabilities.

Where Can the Data Be Obtained?

It is impossible to list all the data sources that may be useful for engineering analyses. However, a number of principal sources are listed below, and the organizations that provide those databases will often have leads to specialized databases for specific purposes.

Incident or Event Data

National (U.S.) estimates based on NFIRS and the NFPA survey of the frequency and severity of reported fires can be obtained from

One-Stop Data Shop
National Fire Protection Association
1 Batterymarch Park
Quincy, MA 02269-9101
Telephone: (617) 984-7450
Fax: (617) 984-7478
E-mail: osds@nfpa.org
Website: <http://www.nfpa.org/Research>

The National Fire Incident Reporting System (NFIRS) itself is administered by the U.S. Fire Administration. Specific questions about NFIRS may be addressed to

National Fire Data Center
U.S. Fire Administration
16825 South Seton Avenue
Emmitsburg, MD 21727
Telephone: (301) 447-1000
Fax: (301) 447-1052
Website: <http://www.usfa.fema.gov/nfdc>

Raw NFIRS data (not calibrated by the NFPA survey or anything else) may be ordered from

National Technical Information Service
Technology Administration
U.S. Department of Commerce
5285 Port Royal Road
Springfield, VA 22161
Telephone: (703) 605-6000 or (800) 553-6847
Website: <http://www.ntis.gov/>

Fire incident data from the fire brigades of the United Kingdom and results from the British Crime Survey's fire questions (about all fires, not just those that were reported) can be obtained from the address below. The United Kingdom collects information on time before discovery of fire and some other variables not collected by NFIRS.

Home Office
Research and Statistics Directorate
50 Queen Anne's Gate, Room 201
London, SW1H 9AT
United Kingdom
Telephone: 020 7273 2084
E-mail: rds.ho@gtnet.gov.uk
Website: <http://www.homeoffice.gov.uk/rds/index.htm>

Annual reports of fire losses in Canada may be ordered from

Council of Canadian Fire Marshals and Fire Commissioners
Alberta Labour
Room 601, IBM Building
10808-99th Avenue
Edmonton, Alberta T5K 0G5
Telephone: (403) 427-8392
Fax: (403) 427-5898

Four types of data can be ordered from the National Injury Information Clearinghouse, including

- Sample-based estimates of product-related injuries treated at hospital emergency rooms, from the National Electronic Injury Surveillance System (NEISS)
- Summaries of death certificate data on product-related fatalities
- In-depth investigations of product-related injuries or incidents, from CPSC's special studies and ongoing program of investigations
- Summaries, indexed by product, of CPSC Hotline reports, product-related newspaper accounts and medical examiner reports

The NEISS data and the death certificate data could be used for event data.

National Injury Information Clearinghouse
U.S. Consumer Product Safety Commission (CPSC)
Washington, DC 20207-0001
Telephone: (301) 504-0424
Fax: (301) 504-0025
Website: <http://www.cpsc.gov/about/clrnghse.html>

Injury data may also be obtained for other countries.

Injury data for the Nordic countries of Denmark, Finland, Iceland, Norway and Sweden can be obtained from

Nordic Medical Statistical Committee
Sejerøgade 11
DK-2100 Copenhagen Ø
Telephone: +45 39 17 39 91
Fax: +45 39 18 51 22
E-mail: nom-nos@inet.uni2.dk
Website: <http://www.nom-nos.dk/nomesco.htm>

Australian injury data can be obtained from

The National Injury Surveillance and Prevention Project
Research Centre for Injury Studies
Flinders University of South Australia
Mark Oliphant Building
Laffer Drive
Bedford Park, South Australia
Australia
Telephone: +61 8 8374 0970
Fax: +61 8 8374 0702
E-mail: nisu@flinders.edu.au
Website: <http://www.nisu.flinders.edu.au>

Reliability databases are available from a few sources. Some industries maintain reliability databases of incidents in their own facilities. For example, the American Institute of Chemical Engineers coordinates the Process Equipment Reliability Database for the hydrocarbon and chemical process industries and the Process Safety Incident Database. Participants provide data and share the costs of maintaining the databases. In return, they obtain access to the data. Additional information may be obtained from

Science Applications International Corporation (SAIC)
10260 Campus Point Drive
San Diego, CA 92121
Telephone: (858) 826-6000
Website: <http://www.saic.com>

Center for Chemical Process Safety
American Institute of Chemical Engineers
3 Park Avenue
New York, NY 10016-5991

H. W. Marryat
Fire: A Century of Automatic Sprinkler Protection in Australia and New Zealand, 1886-1986
Australian Fire Protection Association
Melbourne, Australia

Some data exists from periodic special studies by nationally prominent organizations such as Factory Mutual Global. For example, a June 1992 study (code # FMRC J.I. 0T1R6.RE) displays public-domain failure probability data for automatic fire detection and suppression systems. However, much of the data held by such organizations is proprietary, and the trend has been toward making an even larger share of data and reports proprietary. This reduces the availability of data from this source to the ordinary practicing engineer.

Usage and Exposure Data

Every year, the Bureau of the Census releases an updated *Statistical Abstract of the United States*. This publication contains close to 1500 tables on demographics and economic activity and is a compilation of data collected by the U.S. Census and other entities. Some of the data would help establish usage and exposure. The *State and Metropolitan Area Data Book* and the *County and City Data Book* contain similar data on their respective jurisdictions. All three are available in print and electronically. Ordering information can be obtained from

Customer Services
U.S. Bureau of the Census
Washington, DC 20233
Telephone: (301) 457-4100
Fax: (888) 249-7295 (orders only)
Inquiry Faxes to (301) 457-4714
Website: <http://www.census.gov/statab/www>

Sources for data in the *Statistical Abstract* are often worth checking for possible additional information that may or may not be published elsewhere.

The Bureau of the Census and the U.S. Department of Housing and Urban Development (HUD) together produce the *American Housing Survey*. Data sets on housing can be obtained from <http://huduser.org/datasets/pdrdatas.html>.

Demographic and economic (exposure and usage) data from countries in the European Union can be obtained from Eurostat at <http://europa.eu.int/comm/eurostat/>. The site also has links to other countries' web pages.

The U.S. Department of Energy's Energy Information Administration (EIA) conducts energy consumption surveys of residential, commercial, and industrial users. These surveys provide valuable information on equipment and fuel usage. The EIA will also be conducting surveys on alternative-fueled vehicles. Information can be obtained by contacting the

Energy Information Administration EI30
1000 Independence Avenue, SW
Washington, DC 20585
Telephone: (202) 586-8800
E-mail: infoctr@eia.doe.gov
Website: <http://www.eia.doe.gov/emeu/consumption/>

Data from more than 100 agencies has been compiled and is accessible through FedStats. Many databases may be downloaded by the user at <http://www.fedstats.gov/>.

Laboratory Data

The National Institute of Standards and Technology's (NIST's) Building and Fire Research Laboratory (BFRL) maintains the website *Fire on the Web* at <http://fire.nist.gov/>. It includes the following resources:

- Data from fire tests on various topics, both from NIST and from industrial donors
- Online BFRL publications

- FireDoc, an online card catalog of NIST fire-related publications
- Fire modeling software

CHAPTER 6

Measuring Fire Consequences in Economic Terms

G. Ramachandran, Revised by John R. Hall, Jr.

Introduction

In any fire risk analysis or risk-based assessment, valid measurements of the severity of the fire hazard—the consequences of fire, if it occurs—are of paramount importance. Most analyses are limited to simple outcome measures, such as numbers of deaths or injuries or direct property damage, defined as direct harm to property requiring repair or replacement.

Consequences have to be expressed in monetary values if the purpose of the analysis is to permit a decision maker to express and compare all relevant costs and benefits of different choices, in comparable terms that truly capture what is important to the decision maker or the group he or she represents (such as the general public).

The rapidly growing use of performance-based fire protection design is an example in which these advanced methods of consequence measurement are needed at the level of an individual building or product, while the growing number of countries demanding cost-benefit analysis of proposed new national regulations provides an example of the need for these methods of measurement at the level of national policy.

This chapter describes some of the oft-neglected aspects of consequence measurement in support of economic decisions about fire protection engineering choices. Specifically, this chapter offers:

- An overview of the total cost of fire and of efforts to prevent or mitigate fire
- A discussion of how the relevant costs and benefits for the same choices may vary, depending on whether

they are analyzed from the point of view of an individual, an organization, or society as a whole

- An overview of the ways in which costs and benefits are treated for insurance purposes
- Methods for translating nonmonetary consequences— notably deaths and injuries—into monetary equivalents for purposes of analysis
- Methods for estimating indirect losses—mainly business interruption costs—caused particularly by large fires
- Utility theory and its role in capturing people's preferences for certainty in outcomes

Principles of life-cycle costing are relevant but are covered at length in this section in Chapter 7, "Engineering Economics." Chapter 7 also provides additional material relevant to many of the subjects covered in this section. A more extensive treatment of the above topics, with a range of examples, can be found in *The Economics of Fire Protection* by G. Ramachandran.¹

Components of Total National Fire Cost

For more than two decades, the World Fire Statistics Centre (WFSC) has issued periodic studies with comparative statistics from 15–20 countries on the total cost of fire.² Their methods are the starting point for most national analyses, including more detailed analyses that have taken place in the United States and Canada.³ The WFSC methodology tracks deaths and injuries, which are not converted to monetary equivalents, but focuses on four core economic components:

- Damages due to fire, whether reported or unreported (for a fire service database), insured or uninsured (for an insurance database), direct or indirect (where indirect loss includes business interruption losses—also called consequential loss), temporary lodging, missed work, and other costs or lost income associated with recovery from a fire

Dr. G. Ramachandran retired in November 1988 as head of the Operations Research Section at the Fire Research Station, U.K. Since then he has been practicing as a consultant in risk evaluation and insurance. He is a visiting professor at the universities of Manchester and Leeds. His research has focused on statistical and economic problems in fire protection and actuarial techniques in fire insurance.

- Costs of fire-fighting organizations, typically dominated by or limited to the costs of municipal career fire service organizations
- Incremental construction costs for buildings attributable to fire safety requirements or concerns
- Administrative costs of fire insurance, including profits

Table 5-6.1 shows these costs from 1980 through 1997 for the United States.⁴ The reports of the World Fire Statistics Centre show comparable figures for many other countries, primarily in Europe but including Japan and Canada. Comparisons are made easier because all loss figures are also shown as percentages of national gross domestic product (GDP). The total U.S. percentage for these core components typically runs about 1 percent of the GDP. The United States tends to have one of the lower percentages for fire damage and fire insurance administration (although the latter is especially hard to calculate and has proven quite volatile from year to year). The United States tends to have one of the higher percentages for costs of fire-fighting organizations and for fire-related costs of building construction (although the latter is a subjective estimate, based on some special studies).

Table 5-6.2 shows the relative importance of the four core components of total cost and how that relative importance has changed over the 18 years studied. The costs of fire-fighting organizations and building construction for fire protection—where the U.S. figures tend to represent one of the higher GDP percentages—are by far the two dominant components of the total cost core, and their dominance has been growing. Not shown in Tables 5-6.1 and 5-6.2 are two other important points. First, in every

country except Switzerland providing indirect loss figures, indirect losses tend to be less than 25 percent of direct damages. (The figure for Switzerland is 40 percent.) Second, the U.S. fire death rate, relative to national population, consistently ranks among the highest rates in the countries studied by the World Fire Statistics Centre.

Indirect Loss Estimation—NFPA Approach to U.S. Losses

NFPA did a special study to provide a better basis for calculating indirect loss for properties other than homes. They found that indirect loss varied considerably as a fraction of direct damage, from one type of property to another. Based on their analysis of 109 fires from 1989, indirect losses (principally business interruption costs) add the following amounts to direct loss, based on property class:

- 65 percent for manufacturing and industrial properties
- 25 percent for public assembly, educational, institutional, retail, and office properties
- 10 percent for residential, storage, and special-structure properties
- 0 percent for vehicle and outdoor fires

These percentages may appear low to anyone whose sense of indirect loss is based primarily on a few well-publicized incidents where indirect losses were much larger than direct damages. From a statistical standpoint, however, such incidents are more than offset by the far more numerous incidents where indirect loss is either small or nonexistent.

Table 5-6.1 Estimated Core Total Cost of Fire in the United States (in billions of dollars)

Component of Cost	1980	1981	1982	1983	1984	1985	1986	1987	1988
Economic losses	7.9	8.5	8.1	8.3	8.4	9.1	8.3	8.9	10.5
Reported	6.3	6.7	6.4	6.6	6.7	7.3	6.7	7.2	8.4
Unreported	0.3	0.4	0.3	0.3	0.4	0.4	0.4	0.4	0.4
Indirect	1.3	1.4	1.3	1.4	1.3	1.4	1.2	1.3	1.8
Career fire departments	5.7	6.3	7.0	7.6	8.2	8.5	9.6	10.5	11.8
Net fire insurance	4.1	3.9	4.6	4.8	5.6	4.5	5.0	5.7	4.2
Building construction for fire protection	10.6	11.5	11.6	12.1	14.7	16.9	17.2	17.6	18.4
Total	28.2	30.2	31.3	32.9	36.9	38.9	40.1	42.6	44.9
Component of Cost	1989	1990	1991	1992	1993	1994	1995	1996	1997
Economic losses	11.1	9.6	11.5	10.5	10.5	10.1	11.3	11.5	10.4
Reported	8.7	7.8	9.5	8.3	8.5	8.2	8.9	9.4	8.5
Unreported	0.5	0.4	0.5	0.4	0.5	0.4	0.5	0.5	0.5
Indirect	2.0	1.4	1.5	1.7	1.5	1.5	1.9	1.6	1.5
Career fire departments	11.9	13.2	13.8	14.4	15.4	16.1	17.0	17.7	19.4
Net fire insurance	3.8	4.9	3.1	4.5	4.8	6.7	5.9	6.1	7.0
Building construction for fire protection	20.6	24.0	18.0	17.6	21.1	23.0	24.7	27.4	31.4
Total	47.5	51.7	46.4	47.0	51.8	55.9	58.9	59.0	68.2

Sums may not equal totals because of rounding error. Figures are not adjusted for inflation; they are the figures reported in those years. Some figures for earlier years have been changed from earlier total cost reports to reflect revisions shown in published sources.

Sources: NFPA survey; *Statistical Abstract of the United States, Property/Casualty Insurance Facts*, and telephone conversations with their data sources; formulas from special studies.

Table 5-6.2 Changes in Components of Core of Total Cost of Fire in the United States, 1980–1997

Component of Cost	Percent Change 1980–1997	1980 Percent Share	1997 Percent Share
Economic loss	+32	28	16
Career fire departments	+223	20	28
Net fire insurance	+71	14	11
Building construction for fire protection	+181	38	45
Total	+133	100	100
Consumer price index ^a	+95	—	—

^aIn other words, \$1.00 in 1980 consumer goods would have cost \$1.95 in 1997. The increase in dollars estimated for the core of the total cost of fire is more than the increase due to inflation.

Sums may not equal totals because of rounding error.

Sources: Table 5-6.1; consumer price index data from *U.S. Bureau of the Census, Statistical Abstract of the United States 1999*, Washington, DC (1999).

There remains the problem of quantifying indirect loss associated with properties that never reopen. Here again, the overall pattern is much more modest than some figures that have circulated. Each year, an estimated 2 percent of reported nonresidential structure fires, excluding fires in storage facilities and special structures (e.g., vacant properties, properties under construction, structures that are not buildings), result in business closings. For NFPA's analysis of indirect losses in the United States, a closing is estimated to imply indirect losses equal to four times the reported direct loss in the fire.

These very rough calculations suffice to estimate indirect loss for purposes of a national analysis of total cost from society's point of view. They clearly are not sufficient to produce estimates suitable for insurance purposes or any other decision making at the level of an individual firm. Also, detailed estimates of consequential losses to the national economy should reflect several economic factors, including level of employment or unemployment, level of capacity utilization, volume of exports and imports, exchange rates, and performance of national and international competitors. Due to the interactions of these factors, a detailed evaluation of consequential losses to the national economy is a complex problem requiring the application of econometric models, such as input-output analysis. These national factors do not apply to analysis at the level of an individual firm.

The effects of a fire on the earning capacity of a firm can be measured in terms of loss of profits during the period of interruption following the damage until the resumption of the activity in which the firm was engaged before the fire. Loss of profits is usually expressed as a percentage of loss of turnover. A cover against this loss can be obtained by purchasing a consequential loss insurance policy, the premium for which is a function of the period of indemnity. Loss of profits sustained by a supplier or customer of the firm that suffered the fire (called the "fire-hit firm" from here on) can be covered by a normal consequential loss policy based on reduction in turnover.

The form of insurance policy in more general use in the United States is known as business interruption insurance (BII). BII operates on lines similar to the United Kingdom's contract of consequential loss insurance (CLI) with a turnover specification, though there are some differences. For private sector level insurance firms transacting BII or CLI, there are useful sources of data for estimating consequential losses due to fires in industrial and commercial premises. Organizations such as the Insurance Information Institute in the United States compile consequential loss data furnished by major insurance firms.

Indirect Loss Estimation—Unpublished U.K. Study

Returning to national- and society-level analyses of indirect or consequential loss, some now-old studies done in the United Kingdom illustrate how a more detailed analysis can be done. The U.K. government's Home Office carried out two research studies between 1970 and 1980 on consequential losses to the national economy. The first study adopted an input-output-type model in which all losses were considered output losses.⁵ Losses were either (1) losses in the type of output actually hit by fire or (2) losses in some other output, because production factors (e.g., fixed assets, entrepreneurial effort, or labor) have been less effectively employed as a result of the fire. The effects of a fire were assumed to have the most impact on the fire-hit firm, the supplying firm, the purchasing firm, the parallel firm, and the rest of the economy. A fire-hit firm was defined as a compartment of production covering just that type of output that had been hit by a fire and no other output. A parallel firm was defined as the compartment of a firm that produced in parallel to the fire-hit compartment (which might be in the same firm or in another firm). Any effects in a parallel firm or somewhere else in the rest of the economy were assumed to be included in the calculation of the effects in a fire-hit firm, in a supplying firm, or in a purchasing firm.

In this Home Office study, consequential losses were measured by the net present values of streams of annual outputs lost by the fire-hit firm, supplying firms, and purchasing firms. In regard to the fire-hit firm, it was necessary to determine a length of time over which fixed assets destroyed by fire were assumed not to be replaced by extra investment in the economy. This time choice had to depend on a view of the future course of the economy, which depended on unknown events and influences. Hence, alternative calculations were produced that were based on the remaining lives of the assets and on a number of shorter periods. The net present values were corrected for offsetting influences within the fire-hit firm, supplying firms, and purchasing firms. These influences were due to two factors. First, some production factors affected by fire might be used elsewhere in the economy. Second, production factors already employed elsewhere might be used more intensively. The extent to which such offsetting influences would operate would depend largely on the level of employment and the pressure of demand in the economy. Separate calculations were made for three alternative cases—slack, middle, and tight conditions in the economy. Results were given for each of 15

industries, including a factor by which a fixed assets valuation should be multiplied to give the sum of all the corrected output losses.

In order to verify the assumptions employed and results obtained in the study mentioned above, the Home Office commissioned field research aimed at an in-depth investigation of a small sample of fires.⁶ This study involved direct contact with fire-hit firms and concentrated on direct, consequential, and, hence, the total loss to the U.K. economy from industrial, distributive, and service sector fires. Consequential losses were considered to arise from loss of exports, extra imports, the diversion of resources from other productive activities, and reduction in the efficiency of resource use following the fire. The study assumed that there was full-capacity utilization of resources and that market values of the resources reflected their true worth. Insurance estimates of losses were used as measures of the assets destroyed in fires. By application of national capital output ratios, these asset losses were translated into losses of output from fire. Allowances were made for the secondary impact on suppliers and customers of fire-hit firms and for the impact of the level of capacity utilization. A correction factor was applied to account for the ability of the economy to "make good" the losses of the fire-hit firm by other firms.

The analysis produced estimates of the ratios of consequential to direct losses to the economy for "off-peak" and "peak" years and for each industry and service sector. The main conclusion was that most fires, except those in chemical and allied industries, produced no consequential losses to the national economy. Only in one sector (chemicals) was evidence found of a statistical link between consequential losses and direct losses. The study failed to estimate this link for other sectors and a number of other possible effects on consequential losses. Note the similarity of this conclusion to the results of the much smaller, rougher, and more recent NFPA study, leading to the indirect loss parameters still used in the United States.

Indirect Loss Estimation—Private Sector Level

A study by Hicks and Liebermann deals with costs and losses from the community and private perspective as they impact the fire victim.⁷ The property class categories addressed in this study were commercial occupancies only, separated into four types: (1) mercantile, (2) non-manufacturing, (3) manufacturing, and (4) warehouses. The authors considered first the following expression, based on a convenient formulation of the Cobb-Douglas production function:⁸

$$IL = ke^{rT}E^aX^{1-a} \tag{1}$$

where

- IL = indirect loss
- k = constant
- r, a = regression coefficients
- E = expenditure for fire protection (-)
- X = number of fires (+)
- T = time (surrogate for technological advance) (-)

The signs in parentheses relate to the expected values of the coefficients for the independent variables. The term ke^{rT} is a scalar factor in which r measures increases in fire department efficiency due to technological advances in suppression equipment, training, or facilities as well as altered building codes, smoke alarms, and the like. Equation 1 can be converted to a multiple-regression model by taking logarithms of terms on both sides.

In principle, the parameters r and a can be estimated but, in practice, sufficiently detailed statistics typically are not available. The authors therefore adopted the following, much more simplified, form:

$$IL = c(DL)^b \tag{2}$$

where DL is the direct loss and c and b are constants. Equation 2 is based on the assumption that very small fires typically generate small indirect losses while large fires produce larger indirect losses. If $b = 1$, this model reduces to the earlier-cited approach used by NFPA, wherein indirect losses are estimated as proportional to direct damages.

The results obtained by Hicks and Liebermann⁶ are given in Table 5-6.3. Note that all values of the parameter b are near 1, which means the deviations from the even simpler model used by NFPA are modest. Statistical tests of significance showed that the regression model fitted well with the data in all the cases except warehouses. Since nationally aggregated data were utilized, it was recommended that the occupancy-specific models be used only at the national level and that any desired analysis of local impacts be accomplished using a local model. The value of parameter b has been estimated to be greater than unity for local and national levels and less than unity for the occupancy levels. For any increase in direct loss, the ratio of indirect to direct loss would increase if $b > 1$, and decrease if $b < 1$. The ratio would be a constant if $b = 1$. From the information given in the study, it was not possible to test whether the value of b was significantly different from unity for any of the six levels.

Indirect Loss—Illustrations from Some Major U.S. Fires

It is not difficult to identify large, well-publicized fires in which the cost of business interruption far exceeds di-

Table 5-6.3 Relationship between Direct and Indirect Fire Loss Model Parameters⁷

Level	Parameters (from Equation 2)	
	<i>c</i>	<i>b</i>
Local	0.203	1.146
National	0.015	1.245
Mercantile	0.109	0.889
Nonmanufacturing	0.069	0.874
Manufacturing	0.135	0.890
Warehouse	0.047	0.804

rect property loss. One type of fire where this can happen involves a property that offers lodging or workspace and suffers so much damage that the slack capacity of the facility or even the community is not sufficient to absorb the displaced demand. An example is the MGM Grand Hotel fire, where the hotel claimed total direct damage and business interruption costs of \$211 million, while NFPA's best information placed direct damage at \$30–50 million.⁹

Sometimes, though, it can be difficult to determine what the true net loss due to business interruption is—what constitutes an “interruption.” Compare two large high-rise office building fires.^{10,11} Fire destroyed four floors of the 62-story First Interstate Bank building in Los Angeles in 1988 but also took the entire building out of service for six months—a true business interruption, because the property reopened after repairs.

By contrast, the 1991 One Meridian Plaza fire destroyed more floors in a shorter high-rise office building (38 stories) and the building never reopened. The dozens of firms, occupying nearly a million square feet of office space, had to seek new permanent homes, but the real estate community estimated, a year after the fire, that vacancy rates would still be 11–12 percent *after* every displaced firm had been absorbed.

One Meridian Plaza represented an estimated 2.5 percent of Philadelphia's office space, while the MGM Grand represented a larger share of Las Vegas area hotel rooms. These are all factors in determining how easily a market can compensate for interruption of capacity from one provider. Similar concerns arise for fires in any type of large multiunit residential or health care occupancy.

The most clear-cut examples of widespread vulnerability involve critical elements of the nation's infrastructure. Fears of great damage from a widely distributed computer virus have so far not materialized, and two major interruptions to the northeast electrical power grid in the last third of the twentieth century were not due to fire. However, there have been two fire examples involving telephone exchanges, the more recent in Hinsdale, Illinois, in 1988.¹²

A total of 38,000 customers were served by the Hinsdale office. The majority were still without service five days after the fire, and some did not regain service until nine days after the fire. An estimated 9000 businesses were affected, including a nationwide hotel chain's reservation service, a florist delivery service networked to 12,500 florists around the country, and communications between a Federal Aviation Administration control tower and both of Chicago's major commercial airports. The most conservative estimate of the costs of the associated delays and lost business would exceed the estimated \$40–60 million in direct damage.

Economic Costs Not Usually Calculated within the Core

Several cost components have been estimated by Meade but cannot be readily estimated each year.³ They totaled \$27.8 billion in 1991 and consist of the following:

- Costs of meeting fire grade standards in the manufacture of equipment, particularly electrical systems

equipment and “smart” equipment with its greater use of computer components (\$18.0 billion)

- Costs of fire maintenance, defined to include system maintenance, industrial fire brigades, and training programs for occupational fire protection and fire safety (\$6.5 billion)
- Costs of fire retardants and all product testing associated with design for fire safety (\$2.5 billion)
- Costs of disaster recovery plans and backups (\$0.6 billion)
- Costs of volunteer and paid activities involved in preparing and maintaining codes and standards (\$0.2 billion)

The largest piece by far is the first one. Meade's study developed estimates, by industry, firm, or individual making the estimate, that ranged over two orders of magnitude, from 20 to 2000 percent add-on cost. He settled on 30 percent, which seems conservative. However, out of the fraction of equipment that could be affected by these costs, his estimate of the share that is built to these more demanding standards is not conservative. His estimate raises the concern that the fire safety spending habits of industry's most fire-conscious companies have been treated as typical of all industry.

Based on the Consumer Price Index, the \$27.8 billion estimated by Meade for 1991 would translate to \$32.8 billion in 1997 in the United States.

Costs and Benefits Based on Level

The previous discussion noted that the calculation of indirect loss is done differently if the focus is on an individual firm or on the entire society. Any calculation of costs and benefits associated with fire, fire prevention, or mitigation activities and decisions will show differences based on level, because costs and benefits do not fall equally on all parties.

A fire that interrupts or destroys the ability of a single firm to offer its goods or services to the market results in devastating indirect loss to that firm. Society, however, may experience no discernable effect, provided that

1. The firm represents a small part of its industry, so that neither price nor availability for its products or services is affected by the removal of the firm.
2. The firm represents a small part of the employment opportunities in its community, so that its employees are able to find comparable work and income quickly and easily.

Conversely, a fire that results in little on-site damage but creates devastating environmental damage on the surrounding area, through air or water pollution, may represent a negligible cost to the firm, provided it is able to disown the off-site costs and pay minimal legal costs to do so. Meanwhile, the cost to society is enormous.

The second example cited above involved direct damage to property, and its central premise—that the firm could disavow off-site damages if they were sufficiently difficult to measure and to trace to an event on the firm's site—is probably far-fetched in today's world. The

first example cited above involved a major type of indirect loss, sometimes called business interruption loss or consequential loss, and that example is not at all unusual.

Analysis can be done at many different levels—the individual person, the individual firm, the individual community, the individual industry, the individual state or province, the individual industry plus all industries strongly dependent on it, the individual nation, the entire world—but for purposes of analyzing business interruption or consequential loss, it may be useful to focus on two major levels of economic activity. These are (1) private sector and community level and (2) national and societal level. The first level includes the fire-hit firm and the firms supplying to or purchasing from the fire-hit firm's materials, components, or services. Costs associated with moving, temporary accommodation, and lost profits are valid costs at the private sector level but not at the national level.

At the national level, the loss of a specific unit of productive capacity may be spread among the remaining capacity in the nation such that competitors may seize the opportunity to enter the market and maintain the national rate and volume of manufacture. In such cases, there may be little or no incremental loss to the national economy as a result of a fire in the premises of, for example, a manufacturing firm. Several studies by the now-defunct Insurance Technical Bureau (ITB) in the United Kingdom provide an indication of the various special factors one should consider in the evaluation of consequential losses due to fires and other hazards.

A small number of the total number of production lines in a plant manufacturing pharmaceutical products may generate a very large proportion of total gross profits.¹³ Regulatory restrictions may limit possibilities for shifting manufacture to other plants or even to other lines in the same plant. Natural raw materials may be irreplaceable or out of season, creating another source of delay in recovery or another obstacle to meeting demand during the recovery process. Specialized plant equipment (e.g., tailor-made driers or centrifuges) may involve long delays for replacement. Loss of laboratory facilities may seriously interrupt testing and quality control programs.

The aerospace industry is another example where innovation driven by research creates a very short cycle time for the introduction of new products. In such cases there may be little redundancy in the supply of prototypes or other essential elements needed to keep the program on schedule.¹⁴ Examples might include a new aircraft prototype assembly, untried or unproven research and development projects, or specimens for fatigue testing of aircraft structures. Loss of any of the above could result in a significant interruption to the program. In addition, the effect of delays in the development or supply of components or assemblies from specialist equipment manufacturers can be serious. The interactions of the many activities and firms involved in the manufacture of aerospace products makes for involved consequential loss considerations.

An example from the other end of the spectrum of industries would be resin, paint, and ink manufacture, which would not normally be expected to give rise to unduly high consequential loss.¹⁵ Facilities are generally dis-

persed in small units throughout a given country, and there may be sufficient manufacturing capacity to absorb temporary loss at individual sites. Also few, if any, products are so special that they cannot be made elsewhere in the industry. Consequential loss, therefore, hinges primarily on the time for reinstatement of the plant and the ability of management to arrange for the supply of goods from other sources, pending a return to full production. Loss of raw materials or finished goods normally results in relatively short interruption periods. However, longer periods may be required for the replacement of tanks and pumps destroyed by fires, and for other hazards, such as explosion.

Due to high investment costs, specialized equipment (e.g., electronically or computer-controlled equipment) is generally used at full capacity in some industrial processes. Continuous operation of these processes may reduce the chance of a fire spreading, but provides no scope for making up for lost production following a fire. Specialized equipment, if damaged by fire, cannot be replaced easily or quickly, since either they or spare parts for them may have to be imported. Industries using such equipment are liable to sustain high consequential losses.

Measurement Approaches in the Insurance Industry

Statistical (actuarial) techniques are well developed for calculating the insurance premium for loss of profits due to fire. (For example, see Benckert.¹⁶)

The risk premium is a function of the period of indemnity, and is generally expressed as the product of the loss frequency and the mean amount of loss. The loss frequency is assumed to be independent of the period of indemnity. The frequency function of the period of interruption following a fire has a log-normal distribution.^{16,17}

An insurance company generally adds two types of loading to the risk premium to calculate the premium payable by a policyholder. First, a safety loading is added toward chance fluctuations of loss beyond the expected loss. Second, another loading is imposed to cover the insurer's operating costs, which include profits, taxes, and other administrative expenses. A number of texts have been published on different types of insurance and claims concerned with consequential losses. (For example, see Riley.¹⁸)

Monetary Equivalents for Nonmonetary Costs and Consequences

Deaths and Injuries

Damage to life or health in terms of injuries and deaths is an important consequence in fire risk assessment and is usually the first priority consequence cited in national codes or regulations. Its importance is not in question. What is difficult is identifying a valid and acceptable method for estimating and comparing monetary equivalents of consequences of this type with costs and with monetary equivalents of consequences of other

types, such as property damage or indirect/consequential loss.

Insurance claims provide some data for the valuation of injury, though they are likely to be limited to costs mediated by the marketplace, such as treatment costs and the value of work time lost. Other costs, such as pain and suffering, are more difficult to evaluate.

The specification of a dollar equivalent for human losses, particularly for loss of life, remains an extremely controversial subject. It is important to emphasize that no one intends to suggest that there is an acceptable price for losing one's life. Rather, these figures are intended to reflect a social consensus on the value of changes in the risk of death by fire. For example, if most people say they would be willing to pay \$1500 to reduce their lifetime risk of dying in a fire from, say, one chance in 500 to one chance in 1000, then a simple way of restating that is that people value a life saved at \$1500 for 1/1000 of a life, or \$1.5 million per life.

Four approaches to valuing human life have been identified. The first method is concerned with gross output based on goods and services that a person can produce if not deprived, by death, of the opportunity to do so. Sometimes gross productivity is reduced by an amount representing consumption (net output). Discounted values are generally taken to allow for the lag with which the production or consumption occurs. The output approach usually gives a small value for life, especially if discounted consumption is deducted from discounted production. This must be so since the community as a whole consumes most of what it produces. It is argued that when a person dies, although the community loses that person's future output, it also saves concurrent future consumption. The person's own consumption or the utility that would be derived if the person were alive is not counted as a loss. This approach received considerable emphasis, say, 30 years ago, but not today. A variation of this approach is called the "livelihood approach."¹⁹

The second approach assumes that if an individual has a life insurance policy for x £, then he or she implicitly values his or her life at x £. Collection of necessary data from insurance companies is not a difficult task, and this is the major advantage in adopting the insurance method. There are, however, two drawbacks to this method. First, a decision whether or not to purchase insurance and the amount of insurance is not necessarily made in a manner consistent with one's best judgment of the value of his or her life. This decision depends largely on the premium the insured can bear from his or her income, taking into account family expenditures. Second, purchasing an insurance policy does not affect the mortality risk to an individual. This action is not intended to compensate fully for death or to reduce the risk of accidental death. Hence in insuring life it is not exactly a value tradeoff that is considered between mortality risks and costs.

The third method for assessing value of life involves court awards to heirs of a deceased person as restitution from a party felt to be responsible for the fatality. Here again, collection of necessary data is not a problem. Assessment of values of life could also be expected to be reasonably accurate since lawyers and judges have a massive professional expertise in the ex post analysis of accidents.

The object of such an analysis is to discover whether the risk could have been reasonably foreseen and whether the risk was justified or unreasonable.

There are, however, a few problems in using court awards for valuing human life. The court should ideally be concerned with the assessment of suitable sums as compensation for an objective loss (e.g., loss of earnings of the deceased) as well as for a subjective loss (e.g., damages to spouse and children for their bereavement and grief). In some countries damages can include a subjective component for pain and suffering of survivors, but certain courts are generally against such compensation for subjective losses to persons who are not themselves physically injured, believing that bereavement and grief are not losses which deserve substantial compensation. It is also difficult to value the quality of a life that has been lost. People who themselves suffer severe personal injury, of course, qualify for substantial damages for subjective losses. Resource costs such as medical and hospital expenses are significantly higher for obvious reasons in serious injury cases than in fatal cases; hence, awards for subjective losses tend to be much larger and more important in serious nonfatal cases than in fatal cases. Some courts have also limited to very low levels the damages that may be awarded for reductions of life expectancy. Last, in court awards risks to individuals are considered relative to the plaintiff and costs to the defendant. However, value judgments are likely to vary according to whether the individuals making these judgments are associated with the plaintiff, the defendant, or the court.

The fourth approach is the one most widely adopted for valuing life. The willingness to pay is based on the money people are willing to spend to increase their safety or reduce a particular mortality risk.^{20,21} It is difficult to differentiate between the benefit from increasing people's feeling of safety and that from reducing the number of deaths. Anxiety is a disbenefit even if the risk is much smaller than believed. Likewise, if a person dies from something of whose risk he or she is unaware, he or she still suffers a loss.

This approach to value of life rests on the principle that living is a generally enjoyable activity for which people would be willing to sacrifice other activities, such as consumption. The implied value of life revealed by a willingness-to-pay criterion would depend on a number of factors. The acceptable expenditure per life saved for involuntary risks is likely to be higher than the acceptable expenditure for voluntary risks, as people are generally less willing to accept involuntarily the same level of risk they will accept voluntarily. The sum people are prepared to pay to reduce a given risk will also depend on the total level of risk, the amount already being spent on safety, and the earnings of the individuals.

The theoretical superiority of the willingness-to-pay method begins with its connection to the principle of consumer sovereignty, which says goods should be valued according to the value individuals put on them. Despite this individual-oriented underpinning, this approach can also be used to develop a general figure for a typical person, based on consensus patterns in the values individuals select. This, in turn, permits analysis of societal decisions using the willingness-to-pay principle.

Surveys have shown variability and inconsistencies in responses, because individuals have difficulty in answering questions involving very small changes in their mortality risks.^{22,23,24} Due to insufficient knowledge about the risk, most people find it difficult to accurately quantify the magnitude of a risk. Also, the benefits are often intangible (e.g., enjoyment, peace of mind). It is difficult to put a monetary value on these factors.

Economists therefore use a variety of inferential methods to develop value of life and value of injury averted estimates for purposes of analysis. These include examination of patterns from the other three approaches—foregone future earnings, insurance policy amounts, and especially court judgments. It is also possible to develop an inferred value of life risk reduction from any action that has a cost and achieves such a reduction. Studies have been done of the implied value of life associated with hundreds of safety- and health-related regulatory actions. Studies could be done based on the price and demand curves for safety-oriented products, such as smoke alarms and child-resistant lighters.

It is useful to keep in mind the very wide variation in the estimates and valuations and the implied uncertainty as to what values are reasonable. For example, a landmark 1981 study cited sources for values of statistical life ranging from \$50,000 to \$8 million.²⁵ More recent valuations have been higher generally but still vary widely.

Economists at the U.S. Consumer Product Safety Commission have an ongoing program of studies of injury costs. Periodically, they review the literature, including their own studies, and select dollar values for use in policy analysis of fire safety and other product hazard analysis. The NFPA studies of the total cost of fire in the United States use values of \$5 million per death and \$166,000 per injury as 1993 values, then use the Consumer Price Index to calculate corresponding values for later years *for injuries only*, all in accordance with the practices of CPSC economists.

The total dollar equivalent for reported and unreported fire deaths and injuries in the United States, calculated in this way, was \$42.5 billion in 1997.⁴

It is beyond the scope of this chapter or this handbook to review, even briefly, the many nuances, methods, and applications of value of life estimation. For those who wish to pursue the subject in more detail, several listed references are recommended.²⁶⁻³³

The Value of Donated Time

In the United States, the largest block of donated time for fire safety consists of the donated time of the roughly 800,000 volunteer fire fighters, who provide municipal fire protection to a sizeable fraction, mostly rural, of the U.S. population. One approach to valuing their donated time is to assume that costs are generated primarily by the workload of responding to fires. (This means assuming fire fighting and response and return involve many more total person-hours for volunteers than do training, maintenance, inspections, fire prevention, etc.)

Fire departments that are (all or mostly) volunteer protect 43 percent of the population, but it is a mostly rural population with a much higher fire rate per capita.³⁴

Therefore, volunteers respond to the majority of fires. After further allowing for the fact that the U.S. Census Bureau figures for expenditures on local fire protection include nonpersonnel expenditures by both career and volunteer fire departments—which are typically about 13 percent of a career department's total budget—the estimated dollar equivalent for donated volunteer fire fighter time would be roughly the same as the total reported expenditures for local fire protection. (This includes career personnel and nonpersonnel costs for career and volunteer fire departments.)*

This approach ignores services such as response to nonfire emergencies (e.g., medical aid, hazardous materials spill), fire prevention programs, code enforcement and inspection activity, and the like, all of which are more often provided by career than by volunteer fire departments. These services may contribute to costs. Also, this approach ignores differences that may affect the cost of servicing fires, such as special hazards (e.g., large industrial plants, high-rise buildings) that not only require more resources for suppression if fire occurs but also require more equipment and more training to prepare for fires. This approach ignores differences in pay scales and work weeks, which affect the cost of running a fire department. It is not clear whether these factors would tend to raise or lower the average cost of a volunteer fire department that found it had to pay for the time it had previously been given free.

A second approach to valuing time is to assume that costs are generated not so much by the workload of emergencies as by the need to provide coverage and readiness to respond for a certain area, that is, the ability to provide an effective response in a certain response time. If this approach is used, the primary factor in costs would not be workload, but geographical area. The low-density rural areas covered by volunteer fire departments would then require more personnel than would more compact areas of equal population covered by career fire departments.

Communities seeking to set such fire protection coverage at an appropriate level might begin with a response time objective. The part of response time that is most related to resource decisions is travel time, which may be treated as proportional to travel distance. If one thinks of a typical response area as a circle with the fire station in the middle, one can see that travel distance is proportional to the square root of area. For example, if the distance from the fire station to the edge of the response area doubles, that is equivalent to doubling the radius of a circle, whose area then is quadrupled. This also means that if the same population is spread out over an area four times as large, it will need twice as many fire stations to provide equivalent travel times, which means the needed

*Since 1986, the International City Management Association's annual *Municipal Year Book* has included figures on average per capita expenditures on personnel, capital, and other items for municipal fire departments. The sum of these three components is always higher than the indicated total, possibly because of problems with incomplete responses on the survey. Based on comparing the personnel cost to the sum, the personnel share is usually 87 percent, so the rest is usually 13 percent.

number of fire fighters may be treated as inversely proportional to the square root of the population density.

In 1996, the metropolitan statistical areas of the United States had 79.9 percent of U.S. population in 19.9 percent of the area. If one assigns all the remaining area and population to volunteers (which is a rough approximation), then the metropolitan population density (proportional to 79.9 percent divided by 19.9 percent) exceeds the nonmetropolitan population density (proportional to 20.1 percent divided by 80.1 percent) by a factor of 16. The square root is 4.0, which is not too far from the actual ratio in fire fighters (3 : 1 in 1996). (If the figures were more properly adjusted to address career versus volunteer communities and to exclude areas under federal or state jurisdiction, the 4.0 ratio would fall and be even closer to the three-to-one ratio of fire fighters.)

Using the three-to-one to four-to-one ratios for personnel needed, assuming their costs would be the same as in career fire departments, and again adjusting for non-personnel costs included in reported local fire expenditures, the result is a range of \$48–64 billion in 1997 for the value of time donated by volunteer fire fighters.

If this estimate of the value of donated time by volunteer fire fighters is combined with the earlier estimates of the core components of total cost of fire, the other economic components estimated from data that is not updated yearly, and the estimated monetary equivalent of deaths and injuries associated with fire, the resulting total is \$160 to \$206 billion for the United States in 1997. This is 2–3 percent of the total U.S. gross domestic product, a figure that fully justifies appeals from the fire protection engineering community for more support for research into ways of reducing the total, either through improved safety or through sustained safety at reduced cost.

Utility Theory

Even after all costs and benefits (e.g., risk reduction) have been converted to monetary equivalents, an important aspect of people's preferences may be overlooked if expected-value techniques are used directly in a cost-benefit analysis of fire safety measures to include the certainty-equivalent of uncertain costs and benefits.

Suppose a person is offered a choice between \$5 or a 50/50 coin toss wager between \$10 and nothing. The expected values of the two choices are equal, assuming a fair coin. A person who prefers the sure thing is called *risk averse*. Most people are somewhat risk averse in some situations. Just how risk averse a person is can be measured by determining how low the sure-thing offer can be set before the person will choose the wager with the \$5 expected value.

Fire loss is never a sure thing, and so people's risk preferences are always relevant to assessing their preferences for choices involving fire risk.

People differ not only in their degree of risk aversion but also as a function of the type of choice being offered. Some people may prefer to take risks in most situations. It also is not unusual to find that a person is a *risk preferer* for ventures involving small losses but a *risk avoider* for those involving large values.

Any pattern of risk preferences can be quantified by the use of *utility functions*. *Disutility*, the negative counterpart of utility, is the appropriate term in an analysis involving negative outcomes such as fire loss, cost of fire protection, and insurance premiums.

Consider a few more examples based on participation in a game of chance. Suppose a person is offered the following bet on toss of a coin—to win \$100 if the coin comes up heads, and lose \$75 if the coin comes up tails. If the coin is a fair coin, the probability of heads or tails coming up is one-half. The expected payoff is

$$\frac{1}{2}(\$100) + \frac{1}{2}(-\$75) = \$12.5$$

if the person playing the game takes the bet and \$0 if he or she does not take the bet. According to the expected value criterion, the bet should be accepted because its expected value is greater than the expected value of not taking the bet.

Now suppose the amounts involved are \$1,000,000 and \$750,000 rather than \$100 and \$75. The expected payoff is now \$125,000 if the bet is taken and \$0 if the bet is not taken. Every value has been multiplied by 10,000. According to the expected value criterion, the bet should still be taken and is even more attractive. But would you take this bet? Probably not, unless you are wealthy enough that you could afford to lose \$750,000. The possible gain of \$1,000,000 is tempting, but losing could be devastating or even intolerable.

As another example, consider a choice between two bets. In the first bet, the person playing the game wins \$2 million if a coin comes up heads and wins \$1 million if the coin comes up tails. In the second bet \$8 million can be won if the coin comes up heads, but nothing will be won if the coin comes up tails. The expected payoffs of the two bets are \$1.5 and \$4 million, respectively. The second bet has a much larger expected payoff than the first, and hence should be chosen on the basis of the expected value criterion. However, many would choose the first bet because they focus on the larger minimum gain—the closest thing to the “sure thing” in a choice between two bets. With the first bet, you are assured of at least \$1 million. With the second bet, there is a 50 percent chance of winning nothing.

Consider a third example, defined more directly in terms of fire safety. Suppose the owner of a home or other building faces a probability, p , of fire occurring in the coming year and a loss, L , in the event of a fire. (In this simplified example, only one kind and severity of fire is possible.) The expected annual loss due to fire in that building is pL , and it is a two-outcome bet, like a coin toss.

The sure-thing alternative, from the owner's point of view, can be achieved through insurance. The property owner has two options—to insure or not insure the building. The expected loss (cost) is equal to the insurance premium (call it I) if insured, and pL if not insured.

On the basis of the expected value principle, the owner should choose the insurance option only if I is less than pL . This condition will never be satisfied since an insurance firm would determine the premium, I , for a risk category by adding to the risk premium, pL , two loadings—a safety loading and another loading to cover

the operating costs of the firm which include profits, taxes, and other administrative expenses. From the insurance company's point of view, it should offer the insurance only if I is greater than pL . How is it that insurance even exists under these conditions?

The risk aversion of most people provides the foundation for breaking this dilemma. Based on risk aversion, the building owner will accept a sure-thing loss of I even if I is greater than pL . The difference is typically large enough not only to make a mutually acceptable deal possible, but to allow I to be large enough to cover the two loadings mentioned above.

In practice, many different sizes and severities of fire are possible. For the smallest fires, the building owner's risk aversion will probably be much less pronounced, and insurance may seem unattractive. The creation of a deductible threshold solves that problem by allowing the insurance to be limited to losses large enough for the owner's risk aversion to be strong. If a very large fire occurs, the insurance company may be unable to cover the loss. This leads to reinsurance markets, particularly for properties with the potential for more than one very large loss in a short period of time. For smaller losses, the safety loadings on the risk premium would provide a safety margin for the insurance company, depending on its calculations of the probability distribution for the fire loss. There may also be an upper bound set on the maximum loss the insurance company can cover.

The preference for a small fixed loss over a risk of large loss originates primarily from an aversion to the psychological state of uncertainty. For the reasons mentioned previously, the expected monetary value is not a satisfactory criterion for decisions involving potential losses in ranges where risk aversion is an issue for many people. Note that the ranges of risk aversion can depend on the size of the decision maker's resource base—how large a loss can be sustained at all, and how large a loss can be absorbed without serious inconvenience or harm—and on the number of "bets" undertaken. An insurance purchaser has one bet (at least one per year) going, so he or she is exposed to the full uncertainty of the risk. An insurance company with many customers has many bets going, so the company's annual loss experience will fit a much narrower range around the expected value, except in certain circumstances. If many customers are exposed to a common risk, such as will happen if many customers live in the same hurricane-prone region, the range of probable outcomes for the insurance company will be much wider. If the insurance company's evaluation of the probabilities and consequences is seriously deficient or simply outdated, then its exposure may be quite different than it believes.

Utility and Disutility

For positive outcomes (gains), *utility* means a measurement scale for desirability.³⁵ It is a number measuring the attractiveness of a consequence—the higher the utility, the more desirable the consequence. A utility function translates monetary consequences into a scale for which expected-value calculations accurately reflect the preferences of an individual, a firm, or a decision maker. For

negative outcomes (losses and costs), *disutility* is a measurement scale for undesirability—the higher the disutility, the less desirable the consequence.

The examples given earlier illustrate the fact that, for a specific person, firm, or decision-making entity, the value of gaining x dollars (or consequence of losing x dollars) is not necessarily x multiplied by the value of gaining a single dollar (or consequence of losing a single dollar). Issues of certainty and of the ability to accept loss can cause substantial deviations from the simple multiplicative relationship.

If it were possible to measure the true relative values to the decision maker of the various possible payoffs in a problem of decision making under uncertainty, expected values could be calculated in terms of these true values instead of the monetary values. The theory of utility seeks to develop such values, permitting choices to be analyzed using the decision-making rule—the maximization of expected utility or minimization of expected disutility. Utility theory provides a means of encoding risk preferences in such a way that the risky venture with the highest expected utility or lowest expected disutility is preferred. Symbolically, if the monetary value of the i th outcome is X_i , the utility corresponding to a gain X_i is $U(X_i)$; the disutility corresponding to a loss X_i may be denoted by $D(X_i)$.

Utility Functions

The mathematical structure of the function $U(X)$ is central to the application of utility theory. Figure 5-6.1 graphically shows three typical utility functions that are usually encountered in this analysis.³⁶ The utility function represented by the straight line A is appropriate for a decision maker operating on an expected monetary value (EMV) basis. This line satisfies the equation $U(X) = X$ and represents risk neutrality. The concave curve B corresponds to a risk-averse (or risk-avoiding) decision maker, and the convex curve C to a risk-prone (or risk-taking) decision maker. For a decision maker who is more risk prone than the EMV individual or who prefers a risk, the utility of a fair game exceeds the utility of not gambling and hence a fair game will always be played. On the other hand a decision maker who is more risk averse than the EMV person is does not like or cannot afford risks and is a risk avoider.

Some individuals could have a sigmoid form of utility function as illustrated by Figure 5-6.2. Such a person is a risk preferer for small values of X but a risk avoider for larger values.

Consider now a game with a 50 percent chance of winning £100 and a 50 percent chance of winning nothing, which has the expected value £50. The expected value line A in Figure 5-6.1 connects the points $[0, u(0)]$ and $[100, u(100)]$. To find the utility of the game for the risk avoider (curve B), find the utility value corresponding to the point on the straight line above the expected £50 value of the game. By reading to the left, cutting curve B , this value is equal to $U(£20)$ so that the decision maker's cash equivalent (CE) for the game is £20. He or she would be willing to pay up to £20 to be able to participate in the game. This is still below the EMV of £50 since the utility function B is that of a risk avoider.

Figure 5-6.1. Typical utility functions.

Figure 5-6.2. Sigmoid utility function.

The difference between the EMV and CE is the *risk premium*, which is £30 in this example. The decision maker would be willing to pay £30 to avoid the risk involved in participating in the game.

In the case of the risk taker denoted by curve C, the utility of the game is equal to $U(£70)$, so £70 is the cash equivalent for the game. Although the expected value is only £50, the risk taker is willing to pay up to £70 to be able to participate in the game. Hence the risk premium is –£20. It is negative because the decision maker, instead of being willing to pay a premium to avoid the risk in the game, is willing to pay a premium (above and beyond the expected value) to be able to participate in the game.

The risk premium, RP, discussed above is the amount which a decision maker, on the basis of his or her utility function, is willing to pay to avoid or participate in a risky activity. For increasing utility functions such as those

shown in Figure 5-6.1, the risk premium for any risky venture is defined as

$$RP = EMV - CE \quad (3)$$

where EMV is the expected monetary value and CE the cash equivalent. The parameter CE is also referred to as *certainty monetary equivalent*, CME, in the literature on utility theory.³⁷

For a risk avoider whose increasing utility function is concave, the risk premium RP given by Equation 3, for any situation in which the outcome is uncertain, is positive (EMV is greater than CE). For a risk taker whose increasing utility function is convex, RP is negative. For a risk neutral person whose utility function is linear, RP is always zero (EMV = CE).

The CE is defined mathematically as

$$U(CE) = E[U(x)] = \bar{U} \quad (4)$$

where the right-hand side is the expected value of the utility over the range of values taken by x . If x_1, x_2, \dots, x_n are the values (consequences) with probabilities p_1, p_2, \dots, p_n

$$\bar{U} = E[U(x)] = \sum_{i=1}^n p_i U(x_i) \quad (5)$$

If x is a continuous variable with probability density function $h(x)$, the expected utility is given by

$$\bar{U} = \int_x U(x)h(x) dx \quad (6)$$

The CE or CME of a risky venture, V , is an amount, \hat{x} , such that the decision maker is indifferent between the risky venture, V , and the certain amount, \hat{x} . Put another way, \hat{x} is the value for which $U(\hat{x})$, the utility function on \hat{x} , is equal to the expected value of the utility function on the full range of possible outcomes.

The expected value of a random variable, x , is given by

$$\bar{x} = E(x_i) = \sum_{i=1}^n p_i x_i \quad (7)$$

or by

$$\bar{x} = \int_x xh(x) dx \quad (8)$$

in the continuous case.

To illustrate the procedure for calculating a CE or CME, consider, as an example, the specific utility function

$$U(x) = -e^{-cx} \quad (9)$$

Suppose the decision maker is faced with a venture with two possible outcomes: x_1 with probability $\frac{1}{2}$ and x_2 with probability $\frac{1}{2}$. The expected value of the venture is

$$\bar{x} = \frac{x_1 + x_2}{2}$$

The certainty equivalent (CE) is therefore the solution to this equation:

$$U(\hat{x}) = -e^{-c\hat{x}} \\ = -\frac{e^{-cx_1} + e^{-cx_2}}{2}$$

It may be verified that for $c = 1$, $x_1 = 10$ and $x_2 = 20$, the certainty equivalent is

$$\hat{x} = 10.69$$

The expected value is

$$\frac{(10 + 20)}{2} = 15$$

Consider a second example in which the risky venture has a continuous range of outcomes, ranging from 0 to 20, with an exponential probability density function

$$f(x) = e^{-x}$$

The expected value is

$$\bar{x} = \int_0^{20} xe^{-x} dx = 1$$

Suppose we further assume a utility function as

$$U(x) = -e^{-2x}$$

The certainty equivalent is given by \hat{x} such that

$$-e^{-2\hat{x}} = -\int_0^{20} e^{-2x}e^{-x} dx \\ = -\int_0^{20} e^{-3x} dx = -\frac{1}{3} \quad \hat{x} = 0.55$$

Specific Probability Distributions for Utility Analysis of Fire Safety Choices

Based on the formulations just discussed, a utility analysis requires a probability distribution function for the outcomes of a risky choice and a utility function on those same outcomes. For a risky choice where fire loss is the source of risk, the key variable in differentiating the outcomes is the size of the fire loss (in monetary terms). Let that be defined as x .

Consider a property owner with an asset value of W . If a loss of x is incurred in a fire, the asset value would be reduced to

$$X = W - x \quad (10)$$

The property owner's utility function will be defined in terms of the reduced asset value, rather than the fire loss, because the reduced asset value reflects the owner's wealth and ability to absorb a loss. An appropriate utility function in terms of positive X would be

$$U(X) = -e^{-\theta X}, \quad \theta > 0 \quad (11)$$

which is an increasing risk averse utility function.³⁹

Although the extent of risk aversion quantified by θ is constant for all X , this exponential utility function is widely used in view of its computational simplicity.

Next, in order to match the form of the utility function to the form of a distribution on probabilities of fire loss size, Equation 11 should be rewritten as

$$U(x) = -W'e^{\theta x} \quad (12)$$

where $W' = e^{-\theta W}$ and W' is a constant. As discussed earlier, the certainty equivalent \hat{x} is given by solving the following equation for \hat{x} :

$$-W'e^{\theta \hat{x}} = -W' \int_x e^{\theta x} v(x) dx \quad (13)$$

where $v(x)$ is the probability density function of fire loss, x .

As x increases from zero, $U(x)$ decreases from a value of $-W'$. A larger loss means a lower adjusted asset value and hence lower utility.

According to statistical studies carried out by Ramachandran,³⁸⁻⁴⁰ Shpilberg,⁴¹ and other authors, loss in a fire has a skewed (nonnormal) probability distribution. Ramachandran has concluded that a good fit is obtained from an exponential-type distribution applied to the logarithm, z , of fire loss size, x (i.e., $z = \log x$ follows an exponential distribution). Among distributions of this type, a normal distribution for z or a log-normal distribution for x is commonly used. An exponential distribution for z or a Pareto distribution for x has also been considered by some actuaries.

If the probability distribution function for fire loss is expressed in terms of z ($= \log x$) instead of x , it will be computationally necessary to have a utility function expressed in terms of z as well. Ramachandran⁴² has argued that z ($= \log x$) may be used in Equation 12 instead of x so that the utility function is

$$U(z) = -e^{\theta z} \quad (14)$$

which is equivalent to

$$U(x) = -x^{\theta} \quad (15)$$

The utility function in Equation 15 is a decreasing function with $\theta = 1$ representing risk neutrality. The value of θ should be greater than unity to express a risk averse attitude. The degree of risk aversion increases with θ .

Consider a property worth total financial value V belonging to a risk category with fire loss x having a log-normal distribution. If μ and σ are the mean and standard deviation of z ($= \log x$), following the method described by Ramachandran,¹ the certainty equivalent for the range $(0, V)$ is given by

$$\hat{x}^{\theta} = \frac{1}{G(k)} \frac{1}{\sqrt{2\pi}\sigma} \int_{-\infty}^{\log V} \exp \left[-\frac{1}{2} \left(\frac{z - \mu}{\sigma} \right)^2 \right] e^{\theta z} \\ = \frac{G(k - \sigma\theta)}{G(k)} \exp \left(\mu\theta + \frac{\sigma^2\theta^2}{2} \right) \quad (16)$$

where

$$k = (\log_e V - \mu) / \sigma$$

$$G(k) = \frac{1}{\sqrt{2\pi}} \int_{-\infty}^k \exp\left(-\frac{t^2}{2}\right)$$

$$G(k - \sigma\theta) = \frac{1}{\sqrt{2\pi}} \int_{-\infty}^{k - \sigma\theta} \exp\left(-\frac{t^2}{2}\right)$$

and $G(t)$ is the standard normal distribution. The expected monetary value of the loss is given by $\theta = 1$ in Equation 16, because risk neutrality means utility is linearly related to loss. For a decreasing utility function (or increasing disutility function) such as Equation 15, the certainty equivalent, CE, is greater than the EMV.

For a property with a given level of fire protection, the CE corresponding to a given degree (θ) of risk averse attitude of the owner is the maximum insurance premium the owner will be willing to pay to meet the uncertain consequences of a fire. The CE will increase with θ ; an owner more risk averse than another will be prepared to spend more money on insurance.

Both EMV and CE will decrease with increasing levels of fire protection. Hence, by adopting efficient fire protection measures, a property owner with a given degree of risk aversion can reduce the cost of the insurance premium. He or she can also obtain a further reduction in the premium by taking self-insurance for small losses.

CHAPTER 7

Engineering Economics

John M. Watts, Jr., and Robert E. Chapman

Introduction

Engineering economics is the application of economic techniques to the evaluation of design and engineering alternatives.¹ The role of engineering economics is to assess the appropriateness of a given project, estimate its value, and justify it from an engineering standpoint.

This chapter discusses the time value of money and other cash-flow concepts, such as compound and continuous interest. It continues with economic practices and techniques used to evaluate and optimize decisions on selection of fire safety strategies. The final section expands on the principles of benefit-cost analysis.

An in-depth treatment of the practices and techniques covered in this compilation is available in the ASTM compilation of standards on building economics.² The ASTM compilation also includes case illustrations showing how to apply the practices and techniques to investment decisions.

A broader perspective on the application of engineering economics to fire protection engineering can be found in *The Economics of Fire Protection* by Ramachandran.³ This work is intended as a textbook for fire protection engineers and includes material and references that expand on several other chapters of this section of the SFPE handbook.

Cash-Flow Concepts

Cash flow is the stream of monetary (dollar) values—costs (inputs) and benefits (outputs)—resulting from a project investment.

Dr. John M. Watts, Jr., holds degrees in fire protection engineering, industrial engineering, and operations research. He is director of the Fire Safety Institute, a not-for-profit information, research, and educational corporation located in Middlebury, Vermont. Dr. Watts also serves as editor of NFPA's *Fire Technology*.

Dr. Robert E. Chapman is an economist in the Office of Applied Economics, Building and Fire Research Laboratory, National Institute of Standards and Technology.

Time Value of Money

The following are reasons why \$1000 today is “worth” more than \$1000 one year from today:

1. Inflation
2. Risk
3. Cost of money

Of these, the cost of money is the most predictable, and, hence, it is the essential component of economic analysis. Cost of money is represented by (1) money paid for the use of borrowed money, or (2) return on investment. Cost of money is determined by an interest rate.

Time value of money is defined as the time-dependent value of money stemming both from changes in the purchasing power of money (inflation or deflation) and from the real earning potential of alternative investments over time.

Cash-Flow Diagrams

It is difficult to solve a problem if you cannot see it. The easiest way to approach problems in economic analysis is to draw a picture. The picture should show three things:

1. A time interval divided into an appropriate number of equal periods
2. All cash outflows (deposits, expenditures, etc.) in each period
3. All cash inflows (withdrawals, income, etc.) for each period

Unless otherwise indicated, all such cash flows are considered to occur at the end of their respective periods.

Figure 5-7.1 is a cash-flow diagram showing an outflow or disbursement of \$1000 at the beginning of year 1 and an inflow or return of \$2000 at the end of year 5.

Notation

To simplify the subject of economic analysis, symbols are introduced to represent types of cash flows and

Figure 5-7.1. Cash-flow diagram.

interest factors. The symbols used in this chapter conform to ANSI Z94;⁴ however, not all practitioners follow this standard convention, and care must be taken to avoid confusion when reading the literature. The following symbols will be used here:

- P = Present sum of money (\$)
- F = Future sum of money (\$)
- N = Number of interest periods
- i = Interest rate per period (%)

A complete list of the ANSI Z94 symbols is given in Appendix A to this chapter.

Interest Calculations

Interest is the money paid for the use of borrowed money or the return on invested capital. The economic cost of construction, installation, ownership, or operation can be estimated correctly only by including a factor for the economic cost of money.

Simple interest: To illustrate the basic concepts of interest, an additional notation will be used:

$$F(N) = \text{Future sum of money after } N \text{ periods}$$

Then, for simple interest,

$$F(1) = P + (P)(i) = P(1 + i)$$

and

$$F(N) = P + (N)(P)(i) = P(1 + Ni)$$

For example: \$100 at 10 percent per year for 5 yr yields

$$\begin{aligned} F(5) &= 100[1 + (5)(0.1)] \\ &= 100(1.5) \\ &= \$150 \end{aligned}$$

However, interest is almost universally compounded to include interest on the interest.

Compound interest

$$F(1) = P + (P)(i) = P(1 + i)$$

is the same as simple interest,

$$F(2) = F(1) + F(1)(i)$$

Interest is applied to the new sum:

$$= (F(1))(1 + i) = P(1 + i)^2$$

$$F(3) = F(2)(1 + i) = P(1 + i)^3$$

and by mathematical induction,

$$F(N) = P(1 + i)^N$$

EXAMPLE:

\$100 at 10 percent per year for 5 yr yields

$$\begin{aligned} F(5) &= 100(1 + 0.1)^5 \\ &= 100(1.1)^5 \\ &= 100(1.61051) \\ &= \$161.05 \end{aligned}$$

which is over 7 percent greater than with simple interest.

EXAMPLE:

In 1626 Willem Verhulst bought Manhattan Island from the Canarsie Indians for 60 florins (\$24) worth of merchandise (a price of about 0.5 cents per hectare [0.2 cents per acre]). At an average interest rate of 6 percent, what is the present value (2001) of the Canarsies' \$24?

$$\begin{aligned} F &= P(1 + i)^N \\ &= \$24(1 + 0.06)^{375} \\ &= \$7.4 \times 10^{10} \end{aligned}$$

Seventy-four billion dollars is a reasonable approximation of the present land value of the island of Manhattan.

Interest Factors

Interest factors are multiplicative numbers calculated from interest formulas for given interest rates and periods. They are used to convert cash flows occurring at different times to a common time. The functional formats used to represent these factors are taken from ANSI Z94, and they are summarized in Appendix B to this chapter.

Compound Amount Factor

In the formula for finding the future value of a sum of money with compound interest, the mathematical expression $(1 + i)^N$ is referred to as the *compound amount factor*, represented by the functional format $(F/P, i, N)$. Thus,

$$F = P(F/P, i, N)$$

Interest tables: Values of the compound amount, present worth, and other factors that will be discussed shortly, are tabulated for a variety of interest rates and number of periods in most texts on engineering economy. Example tables are presented in Appendix C to this chapter. Although calculators and computers have greatly reduced the need for such tables, they are often still useful for interpolations.

Present Worth

Present worth is the value found by discounting future cash flows to the present or base time.

Discounting: The inverse of compounding is determining a present amount which will yield a specified future sum. This process is referred to as discounting. The equation for discounting is found readily by using the compounding equation to solve for P in terms of F :

$$P = F(1 + i)^{-N}$$

EXAMPLE:

What present sum will yield \$1000 in 5 yr at 10 percent?

$$\begin{aligned} P &= 1000(1.1)^{-5} \\ &= 1000(0.62092) \\ &= \$620.92 \end{aligned}$$

This result means that \$620.92 “deposited” today at 10 percent compounded annually will yield \$1000 in 5 yr.

Present worth factor: In the discounting equation, the expression $(1 + i)^{-N}$ is called the *present worth factor* and is represented by the symbol $(P/F, i, N)$. Thus, for the present worth of a future sum at i percent interest for N periods,

$$P = F(P/F, i, N)$$

Note that the present worth factor is the reciprocal of the compound amount factor. Also note that

$$(P/F, i, N) = \frac{1}{(F/P, i, N)}$$

EXAMPLE:

What interest rate is required to triple \$1000 in 10 years?

$$P = \frac{F}{3} = (P/F, i, 10)$$

therefore,

$$(P/F, i, 10) = \frac{1}{3}$$

From Appendix C,

$$(P/F, 10\%, 10) = 0.3855$$

and

$$(P/F, 12\%, 10) = 0.3220$$

By linear interpolation,

$$i = 11.6\%$$

Interest Periods

Normally, but not always, the interest period is taken as 1 yr. There may be subperiods of quarters, months, weeks, and so forth.

Nominal versus effective interest: It is generally assumed that interest is compounded annually. However, interest may be compounded more frequently. When this occurs, there is a *nominal interest* or annual percentage rate and an *effective interest*, which is the figure used in calculations. For example, a savings bank may offer 5 percent interest compounded quarterly, which is not the same as 5 percent per year. A nominal rate of 5 percent compounded quarterly is the same as 1.25 percent every three months or an effective rate of 5.1 percent per year. If

$$r = \text{Nominal interest rate,}$$

and

$$M = \text{Number of subperiods per year}$$

then the effective interest rate is

$$i = \left(1 + \frac{r}{M}\right)^M - 1$$

EXAMPLE:

Credit cards usually charge interest at a rate of 1.5 percent per month. This amount is a nominal rate of 18 percent. What is the effective rate?

$$\begin{aligned} i &= (1 + 0.015)^{12} - 1 \\ &= 1.1956 - 1 \\ &= 19.56\% \end{aligned}$$

Continuous interest: A special case of effective interest occurs when the number of periods per year is infinite. This represents a situation of *continuous interest*, also referred to as continuous compounding. Formulas for continuous interest can be derived by examining limits as M approaches infinity. Formulas for interest factors using continuous compounding are included in Appendix B. Continuous interest is compared to monthly interest in Table 5-7.1.

EXAMPLE:

Compare the future amounts obtained under various compounding periods at a nominal interest rate of 12 percent for 5 yr, if $P = \$10,000$. (See Table 5-7.2.)

Series Payments

Life would be simpler if all financial transactions were in single lump-sum payments, now or at some time in the

Table 5-7.1 Continuous Interest (%)

Nominal %	Effective	
	Monthly	Continuous
5	5.1	5.1
10	10.5	10.5
15	16.1	16.2
20	21.9	22.1

Table 5-7.2 Example of Continuous Interest $N = 5$ yr, $r = 12\%$

Compounding	M	i	NM	F/P	F
Annual	1	12.000	5	1.76234	17,623.40
Semi-annual	2	12.360	10	1.79085	17,908.50
Quarterly	4	12.551	20	1.80611	18,061.10
Monthly	12	12.683	60	1.81670	18,167.00
Weekly	52	12.734	260	1.820860	18,208.60
Daily	365	12.747	1825	1.821938	18,219.38
Hourly	8760	12.749	43,800	1.822061	18,220.61
Instantaneously	∞	12.750	∞	1.822119 ^a	18,221.19

^a F/P (instantaneous) = $e^{Ni} = e^{5(0.12)} = e^{0.6}$.

future. However, most situations involve a series of regular payments, for example, car loans and mortgages.

Series compound amount factor: Given a series of regular payments, what will they be worth at some future time? Let

A = the amount of a regular end-of-period payment

Then, note that each payment, A , is compounded for a different period of time. The first payment will be compounded for $N - 1$ periods (yr):

$$F = A(1 + i)^{N-1}$$

and the second payment for $N - 2$ periods:

$$F = A(1 + i)^{N-2}$$

and so forth. Thus, the total future value is

$$F = A(1 + i)^{N-1} + A(1 + i)^{N-2} + \dots + A(1 + i) + A$$

or

$$F = \frac{A[(1 + i)^N - 1]}{i}$$

The interest expression in this equation is known as the *series compound amount factor*, ($F/A, i, N$), thus

$$F = A(F/A, i, N)$$

Sinking fund factor: The process corresponding to the inverse of series compounding is referred to as a *sinking fund*; that is, what size regular series payments are necessary to acquire a given future amount?

Solving the series compound amount equation for A ,

$$A = F \left\{ \frac{i}{[(1 + i)^N - 1]} \right\}$$

Or, using the symbol ($A/F, i, N$) for the *sinking fund factor*

$$A = F(A/F, i, N)$$

Here, note that the sinking fund factor is the reciprocal of the series compound amount factor, that is, ($A/F, i, N$) = $1/(F/A, i, N)$.

Capital recovery factor: It is also important to be able to relate regular periodic payments to their present worth; for example, what monthly installments will pay for a \$10,000 car in 3 yr at 15 percent?

Substituting the compounding equation $F = P(F/P, i, N)$ in the sinking fund equation, $A = F(A/F, i, N)$, yields

$$A = P(F/P, i, N)(A/F, i, N)$$

And, substituting the corresponding interest factors gives

$$A = P \frac{[i(1 + i)^N]}{[(1 + i)^N - 1]}$$

In this equation, the interest expression is known as the *capital recovery factor*, since the equation defines a regular income necessary to recover a capital investment. The symbolic equation is

$$A = P(A/P, i, N)$$

Series present worth factor: As with the other factors, there is a corresponding inverse to the capital recovery factor. The *series present worth factor* is found by solving the capital recovery equation for P .

$$P = A \frac{[(1 + i)^N - 1]}{[i(1 + i)^N]}$$

or, symbolically

$$P = A(P/A, i, N)$$

Other Interest Calculation Concepts

Additional concepts involved in interest calculations include continuous cash flow, capitalized costs, beginning of period payments, and gradients.

Continuous cash flow: Perhaps the most useful function of continuous interest is its application to situations where the flow of money is of a continuous nature. *Continuous cash flow* is representative for

1. A series of regular payments for which the interval between payments is very short
2. A disbursement at some unknown time (which is then considered to be spread out over the economic period)

Factors for calculating present or future worth of a series of annual amounts, representing the total of a continuous cash flow throughout the year, may be derived by integrating corresponding continuous interest factors over the number of years the flow is maintained.

Continuous cash flow is an appropriate way to handle economic evaluations of risk, for example, the present value of an annual expected loss.

Formulas for interest factors representing continuous, uniform cash flows are included in Appendix B.

Capitalized costs: Sometimes there are considerations, such as some public works projects, which are considered to last indefinitely and thereby provide perpetual service. For example, how much should a community be willing to invest in a reservoir which will reduce fire insurance costs by some annual amount, A ? Taking the limit of the series present worth factor as the number of periods goes to infinity gives the reciprocal of the interest rate. Thus, *capitalized costs* are just the annual amount divided by the interest rate. When expressed as an amount required to produce a fixed yield in perpetuity, it is sometimes referred to as an *annuity*.

Beginning-of-period payments: Most returns on investment (cash inflows) occur at the end of the period during which they accrued. For example, a bank computes and pays interest at the end of the interest period. Accordingly, interest tables, such as those in Appendix C, are computed for end-of-year payments. For example, the values of the capital recovery factor ($A/P, i, N$) assume that the regular payments, A , occur at the end of each period.

On the other hand, most disbursements (cash outflows) occur at the beginning of the period (e.g., insurance premiums). When dealing with beginning-of-period payments, it is necessary to make adjustments. One method of adjustment for beginning-of-period payments is to calculate a separate set of factors. Another way is to logically interpret the effect of beginning-of-period payments for a particular problem, for example, treating the first payment as a present value. The important thing is to recognize that such variations can affect economic analysis.

Gradients: It occasionally becomes necessary to treat the case of a cash flow which regularly increases or decreases at each period. Such patterned changes in cash flow are called *gradients*. They may be a constant amount (linear or arithmetic progression), or they may be a constant percentage (exponential or geometric progression). Various equations for dealing with gradient series may be found in Appendix B.

Comparison of Alternatives

Most decisions are based on economic criteria. Investments are unattractive, unless it seems likely they will be recovered with interest. Economic decisions can be divided into two classes:

1. Income-expansion—that is, the objective of capitalism
2. Cost-reduction—the basis of profitability

Fire protection engineering economic analysis is primarily concerned with cost-reduction decisions, finding the least expensive way to fulfill certain requirements, or minimizing the sum of expected fire losses plus investment in fire protection.

There are four common methods of comparing alternative investments: (1) present worth, (2) annual cost, (3) rate of return, and (4) benefit-cost analysis. Each of these is dependent on a selected interest rate or discount rate to adjust cash flows at different points in time.

Discount Rate

The term *discount rate* is often used for the interest rate when comparing alternative projects or strategies.

Selection of discount rate: If costs and benefits accrue equally over the life of a project or strategy, the selection of discount rate will have little impact on the estimated benefit-cost ratios. However, most benefits and costs occur at different times over the project life cycle. Thus, costs of constructing a fire-resistive building will be incurred early in contrast to benefits, which will accrue over the life of the building. The discount rate then has a significant impact on measures such as benefit-cost ratios, since the higher the discount rate, the lower the present value of future benefits.

In view of the uncertainty concerning appropriate discount rate, analysts frequently use a range of discount rates. This procedure indicates the sensitivity of the analysis to variations in the discount rate. In some instances, project rankings based on present values may be affected by the discount rate as shown in Figure 5-7.2. Project A is preferred to project B for discount rates below 15 percent, while the converse is true for discount rates greater than 15 percent. In this instance, the decision to adopt project A in preference to project B will reflect the belief that the appropriate discount rate is less than or equal to 15 percent.

Figure 5-7.2. Impact of discount rate on project selection.

A comparison of benefits and costs may also be used to determine the payback period for a particular project or strategy. However, it is important to discount future costs or benefits in such analyses. For example, an analysis of the Beverly Hills Supper Club fire compared annual savings from a reduction in insurance premiums to the costs of sprinkler installation. Annual savings were estimated at \$11,000, while costs of sprinkler installation ranged from \$42,000 to \$68,000. It was concluded that the installation would have been paid back in four to seven years (depending on the cost of the sprinklers). However, this analysis did not discount future benefits, so that \$11,000 received at the end of four years was deemed equivalent to \$11,000 received in the first year. Once future benefits are discounted, the payback period ranges from five to eleven years with a discount rate of 10 percent.

Inflation and the discount rate: Provision for inflation may be made in two ways: (1) estimate all future costs and benefits in constant prices, and use a discount rate which represents the opportunity cost of capital in the absence of inflation; or (2) estimate all future benefits and costs in current or inflated prices, and use a discount rate which includes an allowance for inflation. The discount rate in the first instance may be considered the real discount rate, while the discount rate in the second instance is the nominal discount rate. The use of current or inflated prices with the real discount rate, or constant prices with the nominal discount rate, will result in serious distortions in economic analysis.

Present Worth

In a *present worth* comparison of alternatives, the costs associated with each alternative investment are all converted to a present sum of money, and the least of these values represents the best alternative. Annual costs, future payments, and gradients must be brought to the present. Converting all cash flows to present worth is often referred to as *discounting*.

EXAMPLE:

Two alternate plans are available for increasing the capacity of existing water transmission lines between an unlimited source and a reservoir. The unlimited source is at a higher elevation than the reservoir. Plan A calls for the construction of a parallel pipeline and for flow by gravity. Plan B specifies construction of a booster pumping station. Estimated cost data for the two plans are as follows:

	Plan A Pipeline	Plan B Pumping Station
Construction cost	\$1,000,000	\$200,000
Life	40 years	40 years (structure) 20 years (equipment)
Cost of replacing equipment at the end of 20 yr	0	\$75,000
Operating costs	\$1000/yr	\$50,000/yr

If money is worth 12 percent, which plan is more economical? (Assume annual compounding, zero salvage value, and all other costs equal for both plans.)

$$\begin{aligned} \text{Present worth (Plan A)} &= P + A(P/A, 12\%, 40) \\ &= \$1,000,000 + \$1000(8.24378) \\ &= \$1,008,244 \end{aligned}$$

$$\begin{aligned} \text{Present worth (Plan B)} &= P + A(P/A, 12\%, 40) \\ &\quad + F(P/F, 12\%, 20) \\ &= \$200,000 + \$50,000(8.24378) \\ &\quad + \$75,000(0.10367) \\ &= \$619,964 \end{aligned}$$

Thus, plan B is the least-cost alternative.

A significant limitation of present worth analysis is that it cannot be used to compare alternatives with unequal economic lives. That is, a ten-year plan and a twenty-year plan should not be compared by discounting their costs to a present worth. A better method of comparison is annual cost.

Annual Cost

To compare alternatives by annual cost, all cash flows are changed to a series of uniform payments. Current expenditures, future costs or receipts, and gradients must be converted to annual costs. If a lump-sum cash flow occurs at some time other than the beginning or end of the economic life, it must be converted in a two-step process: first moving it to the present and then spreading it uniformly over the life of the project.

Alternatives with unequal economic lives may be compared by assuming replacement in kind at the end of the shorter life, thus maintaining the same level of uniform payment.

	System Cost	Insurance Premium	Life
Partial system	\$ 8000	\$1000	15 yr
Full system	\$15,000	\$250	20 yr

EXAMPLE:

Compare the value of a partial or full sprinkler system purchased at 10 percent interest.

$$\begin{aligned} \text{Annual cost (partial system)} &= A + P(A/P, 10\%, 15) \\ &= \$1000 + \$8000(0.13147) \\ &= \$2051.75 \end{aligned}$$

$$\begin{aligned} \text{Annual cost (full system)} &= A + P(A/P, 10\%, 20) \\ &= \$250 + \$15,000(0.11746) \\ &= \$2011.90 \end{aligned}$$

The full system is slightly more economically desirable. When costs are this comparable, it is especially important to consider other relevant decision criteria, for example, uninsured losses.

Rate of Return

Rate of return is, by definition, the interest rate at which the present worth of the net cash flow is zero. Computationally, this method is the most complex method of comparison. If more than one interest factor is involved,

the solution is by trial and error. Microcomputer programs are most useful with this method.

The calculated interest rate may be compared to a discount rate identified as the "minimum attractive rate of return" or to the interest rate yielded by alternatives. Rate-of-return analysis is useful when the selection of a number of projects is to be undertaken within a fixed or limited capital budget.

EXAMPLE:

An industrial fire fighting truck costs \$100,000. Savings in insurance premiums and uninsured losses from the acquisition and operation of this equipment is estimated at \$60,000/yr. Salvage value of the apparatus after 5 yr is expected to be \$20,000. A full-time driver during operating hours will accrue an added cost of \$10,000/yr. What would the rate of return be on this investment?

@ 40% present worth

$$\begin{aligned} &= P + F(P/F, 40\%, 5) + A(P/A, 40\%, 5) \\ &= -\$100,000 + \$20,000(0.18593) \\ &\quad + (\$60,000 - 10,000)(2.0352) \\ &= \$5,478.60 \end{aligned}$$

@ 50% present worth

$$\begin{aligned} &= P + F(P/F, 50\%, 5) + A(P/A, 50\%, 5) \\ &= -\$100,000 + \$20,000(0.13169) \\ &\quad + (\$60,000 - \$10,000)(1.7366) \\ &= -\$10,536.40 \end{aligned}$$

By linear interpolation, the rate of return is 43 percent.

Benefit-Cost Analysis

Benefit-cost analysis, also referred to as cost-benefit analysis, is a method of comparison in which the consequences of an investment are evaluated in monetary terms and divided into the separate categories of benefits and costs. The amounts are then converted to annual equivalents or present worths for comparison.

The important steps of a benefit-cost analysis are

1. Identification of relevant benefits and costs
2. Measurement of these benefits and costs
3. Selection of best alternative
4. Treatment of uncertainty

Identification of Relevant Benefits and Costs

The identification of benefits and costs depends on the particular project under consideration. Thus, in the case of fire prevention or control activities, the benefits are based on fire losses prior to such activities. Fire losses may be classified as direct or indirect. Direct economic losses are property and contents losses. Indirect losses include such things as the costs of injuries and deaths, costs incurred by business or industry due to business interruption, losses to the community from interruption of services, loss of payroll or taxes, loss of market share, and loss of reputation. The direct costs of fire protection activities include the costs of constructing fire-resistive buildings, installation costs of fire protection systems, and the

costs of operating fire departments. Indirect costs are more difficult to measure. They include items such as the constraints on choice due to fire protection requirements by state and local agencies.

A major factor in the identification of relevant benefits and costs pertains to the decision unit involved. Thus, if the decision maker is a property owner, the relevant benefits from fire protection are likely to be the reduction in fire insurance premiums and fire damage or business interruption losses not covered by insurance. In the case of a municipality, relevant benefits are the protection of members of the community, avoidance of tax and payroll losses, and costs associated with assisting fire victims. Potential benefits, in these instances, are considerably greater than those faced by a property owner. However, the community may ignore some external effects of fire incidents. For example, the 1954 automobile transmission plant fire in Livonia, Michigan, affected the automobile industry in Detroit and various automobile dealers throughout the United States. However, there was little incentive for the community to consider such potential losses in their evaluation of fire strategies, since they would pertain to persons outside the community. It might be concluded, therefore, that the more comprehensive the decision unit, the more likely the inclusion of all relevant costs and benefits, in particular, social costs and benefits.

Measurement of Benefits and Costs

Direct losses are measured or estimated statistically or by a priori judgment. Actuarial fire-loss data collected nationally or for a particular industry may be used, providing it is adequately specific and the collection mechanism is reliable. More often, an experienced judgment of potential losses is made, sometimes referred to as the *maximum probable loss* (MPL).

Indirect losses, if considered, are much more difficult to appraise. A percentage or multiple of direct losses is sometimes used. However, when indirect loss is an important decision parameter, a great deal of research into monetary evaluation may be necessary. Procedures for valuing a human life and other indirect losses are discussed in Ramachandran.³

In the measurement of benefits, it is appropriate to adjust for utility or disutility which may be associated with a fire loss.

Costs may be divided into two major categories: (1) costs of private fire protection services, and (2) costs of public fire protection services. In either case, cost estimates will reflect the opportunity cost of providing the service. For example, the cost of building a fire-resistive structure is the production foregone due to the diversion of labor and resources to make such a structure. Similarly, the cost of a fire department is the loss of other community services which might have been provided with the resources allocated to the fire department.

Selection of Best Alternative

There are two considerations in determining benefit-cost criteria. The first pertains to project acceptability, while the second pertains to project selection.

Project acceptability may be based on benefit-cost difference or benefit-cost ratio. Benefit-cost ratio is a measure

of project worth in which the monetary equivalent benefits are divided by the monetary equivalent costs. The first criterion requires that the value of benefits less costs be greater than zero, while the second criterion requires that the benefit-cost ratio be greater than one.

The issue is more complicated in the case of project selection, since several alternatives are involved. It is no longer a question of determining the acceptability of a single project, but rather selecting from among alternative projects. Consideration should be given to changes in costs and benefits as various strategies are considered. Project selection decisions are illustrated in Figure 5-7.3. The degree of fire protection is given on the horizontal axis, while the marginal costs and benefits associated with various levels of fire safety are given on the vertical axis. As the diagram indicates, marginal costs are low initially and then increase. Less information is available concerning the marginal benefit curve, and it may, in fact, be horizontal. The economically optimum level of fire protection is given by the intersection of the marginal cost and marginal benefit curves. Beyond this point, benefits from increasing fire protection are exceeded by the costs of providing the additional safety.

A numerical example is given in Table 5-7.3. There are five possible strategies or programs possible. The first strategy, A, represents the initial situation, while the remaining four strategies represent various fire loss reduction activities, each with various costs. Strategies are arranged in ascending order of costs. Fire losses under each of the five strategies are given in the second row, while the sum of fire losses and fire reduction costs for each strategy is given in the third row. The sum of fire losses and fire reduction costs of each strategy is equivalent to the life-cycle cost of that strategy. Life-cycle cost analysis is an alternative to benefit-cost analysis when the outcomes of the investment decision are cost savings rather than benefits per se. Additional information on life-cycle cost analysis is found in Fuller and Petersen.⁵

Figure 5-7.3. Project selection.

Table 5-7.3 Use of Benefit-Cost Analyses in Strategy Selection

Category	Strategy				
	A	B	C	D	E
Fire reduction costs	0	10	25	45	70
Fire losses	100	70	50	40	35
Sum of fire reduction costs and fire losses	100	80	75	85	105
Marginal benefits	0	30	20	10	5
Marginal costs	0	10	15	20	25
Marginal benefits minus marginal costs	0	20	5	-10	-20
Marginal benefit-cost ratio	—	3.0	1.33	0.5	0.2

Data in the first two rows may then be used to determine the marginal costs or marginal benefits from the replacement of one strategy by another. Thus, strategy B has a fire loss of \$70 compared to \$100 for strategy A, so the marginal benefit is \$30. Similarly, the marginal benefit from strategy C is the reduction in fire losses from B to C or \$20. The associated marginal cost of strategy C is \$15. Declining marginal benefits and rising marginal costs result in the selection of strategy C as the optimum strategy. At this point, the difference between marginal benefits and marginal costs is still positive.

Marginal benefit-cost ratios are given in the last row. It is worth noting that, while the highest marginal benefit-cost ratio is reached at activity level B (as is the highest marginal benefit-cost difference), project C is still optimum, since it yields an additional net benefit of \$5. This finding is reinforced by examining changes in the sum of fire losses and fire reduction costs (i.e., life-cycle costs). Total cost plus loss first declines, reaching a minimum at point C, and then increases. This pattern is not surprising, since as long as marginal benefits exceed marginal costs, total losses should decrease. Thus, the two criteria—equating marginal costs and benefits, and minimizing the sum of fire losses and fire reduction costs—yield identical outcomes.

Treatment of Uncertainty

A final issue concerns the treatment of uncertainty. One method for explicitly introducing risk considerations is to treat benefits and costs as random variables which may be described by probability distributions. For example, an estimate of fire losses might consider the following events: no fire, minor fire, intermediate fire, and major fire. Each event has a probability of occurrence and an associated damage loss. The total expected loss (EL) is given by

$$EL = \sum_{i=0}^3 p_i D_i$$

where

p_0 = probability of no fire

p_1 = probability of a minor fire

p_2 = probability of an intermediate fire

p_3 = probability of a major fire

D_n = associated damage loss, $n = 0,1,2,3$

Expected losses may be computed for different fire protection strategies. Thus, a fire protection strategy that costs C_3 and reduces damage losses of a major fire from D_3 to D'_3 will result in an expected loss

$$EL = p_0D_0 + p_1D_1 + p_2D_2 + p_3D'_3 + C_3$$

Similarly, a fire control strategy that costs C_2 and reduces the probability of an intermediate fire from p_2 to p'_2 has an expected loss

$$EL = p_0D_0 + p_1D_1 + p'_2D_2 + p_3D_3 + C_2$$

A comparison of expected losses from alternative strategies may then be used to determine the optimal strategy.

Use of expected value has a limitation in that only the average value of the probability distribution is considered. Discussion of other procedures for evaluating uncertain outcomes is given by Anderson and Settle.⁶

Appendix A: Symbols and Definitions of Economic Parameters

Symbol	Definition of Parameter
A_j	Cash flow at end of period j
A	End-of-period cash flows (or equivalent end-of-period values) in a uniform series continuing for a specified number of periods
\bar{A}	Amount of money (or equivalent value) flowing continuously and uniformly during each period, continuing for a specified number of periods
F	Future sum of money—the letter F implies future (or equivalent future value)
G	Uniform period-by-period increase or decrease in cash flows (or equivalent values); the arithmetic gradient
M	Number of compounding periods per interest period ^a
N	Number of compounding periods
P	Present sum of money—the letter " P " implies present (or equivalent present value). Sometimes used to indicate initial capital investment.
S	Salvage (residual) value of capital investment
f	Rate of price level increase or decrease per period; an "inflation" or "escalation" rate
g	Uniform rate of cash flow increase or decrease from period to period; the geometric gradient
i	Effective interest rate per interest period ^a (discount rate), expressed as a percent or decimal fraction
r	Nominal interest rate per interest period, ^a expressed as a percent or decimal fraction

^aNormally, but not always, the interest period is taken as 1 yr.

Subperiods, then, would be quarters, months, weeks, and so forth.

Appendix B: Functional Forms of Compound Interest Factors^a

Name of Factor	Algebraic Formulation	Functional Format
<i>Group A. All cash flows discrete: end-of-period compounding</i>		
Compound amount (single payment)	$(1 + i)^N$	$(F/P, i, N)$
Present worth (single payment)	$(1 + i)^{-N}$	$(P/F, i, N)$
Sinking fund	$\frac{i}{(1 + i)^N - 1}$	$(A/F, i, N)$
Capital recovery	$\frac{i(1 + i)^N}{(1 + i)^N - 1}$	$(A/P, i, N)$
Compound amount (uniform series)	$\frac{(1 + i)^N - 1}{i}$	$(F/A, i, N)$
Present worth (uniform series)	$\frac{1 - (1 + i)^{-N}}{i}$	$(P/A, i, N)$
Arithmetic gradient to uniform series	$\frac{(1 + i)^N - iN - 1}{i(1 + i)^N - i}$	$(A/G, i, N)$
Arithmetic gradient to present worth	$\frac{(1 + i)^N - iN - 1}{i^2(1 + i)^N}$	$(P/G, i, N)$
<i>Group B. All cash flows discrete: continuous compounding at nominal rate r per period</i>		
Continuous compounding compound amount (single payment)	e^{rN}	$(F/P, r, N)$
Continuous compounding present worth (single payment)	e^{-rN}	$(P/F, r, N)$
Continuous compounding present worth (single payment)	$\frac{e^{rN} - 1}{e^{rN}(e^r - 1)}$	$(P/A, r, N)$
Continuous compounding sinking fund	$\frac{e^r - 1}{e^{rN} - 1}$	$(A/F, r, N)$
Continuous compounding capital recovery	$\frac{e^{rN}(e^r - 1)}{e^{rN} - 1}$	$(A/P, r, N)$
Continuous compounding compound amount (uniform series)	$\frac{e^{rN} - 1}{e^r - 1}$	$(F/A, r, N)$
<i>Group C. Continuous, uniform cash flows: continuous compounding</i>		
Continuous compounding sinking fund (continuous, uniform payments)	$\frac{r}{e^{rN} - 1}$	$\bar{A}/F, r, N$
Continuous compounding capital recovery (continuous, uniform payments)	$\frac{re^{rN}}{e^{rN} - 1}$	$\bar{A}/P, r, N$
Continuous compounding compound amount (continuous, uniform payments)	$\frac{e^{rN} - 1}{r}$	$F/\bar{A}, r, N$
Continuous compounding present worth (continuous, uniform payments)	$\frac{e^{rN} - 1}{re^{rN}}$	$P/\bar{A}, r, N$

^aSee Appendix A for definitions of symbols used in this table.

Table C-7.2 Capital Recovery Factor (Changes P to A)

Yr.	2%	4%	6%	8%	10%	12%	15%	20%	25%	30%	40%	50%
1	1.020	1.040	1.060	1.080	1.100	1.120	1.150	1.200	1.250	1.300	1.400	1.500
2	.5150	.5302	.5454	.5608	.5762	.5917	.6151	.6545	.6944	.7348	.8167	.9000
3	.3468	.3603	.3741	.3880	.4021	.4163	.4380	.4747	.5123	.5506	.6294	.7105
4	.2626	.2755	.2886	.3019	.3155	.3292	.3503	.3863	.4234	.4616	.5408	.6231

CHAPTER 8

Extreme Value Theory

G. Ramachandran

Introduction

The theory of extreme values, as generally known, deals with the statistical properties of the maximum or minimum value of a random variable. The theory has found practical applications in fields such as structural engineering, aeronautics, and meteorology. A comprehensive treatise on the extreme value theory and its applications was presented by Gumbel.¹ Further theoretical developments and applications are contained in *Statistical Extremes and Applications*, edited by Tiago de Oliveira.²

Fire protection is one such area, where figures for financial losses are generally available for large fires which, in the United Kingdom, for example, are currently defined as fires costing £50,000 or more in property damage. To make the best use of limited data provided by a small sample of large-loss fires, Ramachandran³ has developed a general mathematical framework, the extreme order theory, which includes the largest loss as a particular case.

The *object* of this chapter is to explain the basic features of extreme order statistics and show how data on financial losses in large fires can be used for

1. Predicting the behavior of the tail (large losses) of the probability distribution of fire loss
2. Estimating the average loss in all fires, large and small, in a particular building or group of buildings with similar fire risks, and
3. Assessing the probable reduction in loss due to a fire protection measure

A few other possible applications of extreme value theory in the fire protection field are also discussed briefly.

Dr. G. Ramachandran retired in November 1988 as head of the operations research section at the Fire Research Station, United Kingdom. Since then he has been practicing as a consultant in risk evaluation and insurance. He is a visiting professor at the Universities of Manchester and Leeds. His research has focused on statistical and economic problems in fire protection and actuarial techniques in fire insurance. In October 1998 he published a book on the Economics of Fire Protection.

These include statistical analysis of test results, fire severity, and fire resistance.

Extreme Order Distributions

The probability distribution of fire loss (x) is skewed, and, in general, the variable $z (= \log x)$ has a distribution belonging to the "exponential type." (See Ramachandran⁴⁻⁶ and Shpilberg.⁷) Among distributions of this type, normal for z (which is the same as log-normal for x) has been recommended widely for modeling fire insurance claims. Exponential for z or Pareto for x has been considered by some actuaries. The (cumulative) distribution function of z may be denoted by $F(z)$ and its density function by $f(z)$.

The logarithms of losses in n fires during a defined period of time constitute a sample of observations generated by the "parent" distribution $F(z)$. If these figures are arranged in decreasing order of magnitude, the m th value in this arrangement may be denoted by $z_{(m)n}$, which is the logarithm of the m th loss $x_{(m)n}$. For the largest value, the subscript m takes the value 1 (first rank).

In a series of samples (periods), each with a large number n of observations (fires), the values pertaining to $z_{(m)n}$ have a probability distribution with density function approximately given by

$$\frac{m^m a_{(m)n}}{(m-1)!} \exp[-my_{(m)} - m \exp(-y_{(m)})] \quad (1)$$

$$-\infty \leq z_{(m)n} \leq \infty$$

$$y_{(m)} = a_{(m)n}[z_{(m)n} - b_{(m)n}] \quad (2)$$

where $a_{(m)n}$ and $b_{(m)n}$ are solutions of

$$F[b_{(m)n}] = 1 - (m/n) \quad (3)$$

$$a_{(m)n} = (n/m)f[b_{(m)n}] \quad (4)$$

The parameter $b_{(m)n}$ is the modal value of $z_{(m)n}$. Ramachandran³ has discussed different methods of estimating the parameters $a_{(m)n}$ and $b_{(m)n}$.

Behavior of Large Losses

Let $\bar{z}_{(m)n}$ and $s_{(m)n}^2$ be the mean and variance of $z_{(m)n}$, respectively, in N samples. For large N , the values of these two parameters tend to

$$\mu_{(m)z} = b_{(m)n} + \left[\frac{1}{a_{(m)n}} \right] \bar{y}_{(m)} \tag{5}$$

$$\sigma_{(m)z}^2 = \frac{\sigma_{(m)y}^2}{a_{(m)n}^2} \tag{6}$$

where

$$\bar{y}_{(m)} = 0.5772 + \log_e m - \sum_{v=1}^{m-1} \left(\frac{1}{v} \right) \tag{7}$$

$$\sigma_{(m)y}^2 = 1.6449 - \sum_{v=1}^{m-1} \left(\frac{1}{v^2} \right) \tag{8}$$

The value of $z_{(m)n}$ for any probability level, p , is given by

$$z_{(m)np} = b_{(m)n} + \left[\frac{1}{a_{(m)n}} \right] y_{(m)p} \tag{9}$$

where $y_{(m)p}$ is the value of $y_{(m)}$ corresponding to the probability level, p . The values of $y_{(m)p}$ for selected probability levels have been tabulated by Gumbel.⁸

Consider, as an example, the analysis carried out by Ramachandran⁴ using the top 17 fire losses ($m = 1$ to 17) in the U.K. textile industry during the 21-year period ($N = 21$) from 1947 to 1967. The losses (in units of £1000) were first corrected for inflation by adjusting them to 1947 values. Base e was used for calculating the logarithms of losses. The linear method (Ramachandran³) was then applied to the logarithms of the corrected losses for estimating the parameters $a_{(m)n}$ and $b_{(m)n}$. Since the number of fires, n , per year varied over the period, the following approximate correction was included in the estimation process:

$$b_{(m)n_j} = b_{(m)n} + \left[\frac{1}{a_{(m)n}} \right] \log_e \left(\frac{n_j}{n} \right) \tag{10}$$

where $b_{(m)n_j}$ is the modal value of $z_{(m)}$ for the year with n_j fires. The results, reproduced in Table 5-8.1, pertain to a sample size of 465 fires, the frequency experienced in the base year 1947.

Figure 5-8.1 has been drawn on a log scale and shows the relationship between the annual frequency of fires in the textile industry and the probable loss, at 1947 prices, of the 1st ($m = 1$), 7th ($m = 7$), and 16th ($m = 16$) largest fires in a year. For each of these three ranks, the modal sizes of the losses are shown with confidence bands. For an estimated number of fires in any year, an ordinate erected at the corresponding point on the x-axis would intersect the upper and lower confidence lines at points giving the corresponding confidence limits. The probability of exceeding the upper or falling short of the lower limit is 0.1. For example, if the number of fires expected in a year in the textile industry is 1000, the most probable value of the largest loss would be £260,000, with upper and lower confidence limits of £700,000 and £180,000; all figures are at 1947 money values.

Table 5-8.1 Textile Industry Top Fire Losses from 1947 to 1967, U.K.

Extreme (m)	$a_{(m)n}$	$b_{(m)n}$
1	2.247	5.214
2	1.785	4.829
3	1.626	4.534

13	0.886	2.832
14	0.924	2.749
15	0.937	2.680
16	0.950	2.583
17	1.002	2.537

Figure 5-8.1. Fire frequency and large losses.

The confidence lines represent a control chart based on the current trend. The increase in the frequency, n , of fires may be partly due to the inadequacy of fire prevention measures. In addition, if some or all of the actual large losses corrected for inflation exceeded the corresponding upper limits, it may be concluded that general

changes in fire fighting and fire protection methods or in the industrial processes are taking place to alter the picture for the worse. If the losses are less than the lower limits, then the changes are for the better. These arguments and the data on losses and number of fires for the period 1968 to 1978 suggested that protection measures were coping well with fire outbreaks in the U.K. textile industry. (See Ramachandran.³) This observation is true to some extent for the later period, as well.

Average Loss

If fire loss, x , is assumed to have a log-normal probability distribution, the expected or average loss is given by

$$\bar{x} = \exp\left(\mu + \frac{\sigma^2}{2}\right)$$

where μ and σ are the mean and standard deviation, respectively, of $z = \log_e x$. Estimation of the parameters μ and σ is a simple statistical problem if loss figures are available for all the n fires in a sample. If loss figures are available only for large losses above a threshold level, extreme value techniques can provide reasonably good estimates of μ and σ . The basic features of these techniques are as follows:

If $z (= \log x)$ has a normal distribution, the standard variable

$$t = \frac{(z - \mu)}{\sigma}$$

has also a normal distribution with distribution function $G(t)$ and density function $g(t)$. As defined earlier, if $z_{(m)n}$ is the logarithm of the m th loss $x_{(m)n}$ from the top, the variable

$$t_{(m)n} = \frac{[z_{(m)n} - \mu]}{\sigma} \quad (11)$$

follows the extreme order distribution shown in Equation 1 with

$$y_{(m)} = A_{(m)n}[t_{(m)n} - B_{(m)n}] \quad (12)$$

instead of Equation 2. As in Equations 3 and 4, the parameters $A_{(m)n}$ and $B_{(m)n}$ are given by

$$G[B_{(m)n}] = 1 - \left(\frac{m}{n}\right) \quad (13)$$

$$A_{(m)n} = \left(\frac{n}{m}\right)g[B_{(m)n}] \quad (14)$$

The values of $B_{(m)n}$ for the standard normal distribution have been well tabulated by, for example, Fisher and Yates.⁹ The corresponding values of $A_{(m)n}$ can then be obtained for Equation 14. From Equation 12 the expected value of $t_{(m)n}$ is

$$\bar{t}_{(m)n} = B_{(m)n} + \left[\frac{1}{A_{(m)n}}\right]\bar{y}_{(m)} \quad (15)$$

with $\bar{y}_{(m)}$ given by Equation 7. From Equation 11, the expected values of $z_{(m)n}$ is

$$\bar{z}_{(m)n} = \mu + \sigma\bar{t}_{(m)n} \quad (16)$$

The value of $z_{(m)n}$ in a single sample or its mean value over N samples (each with n fires) will provide an estimate of $\bar{z}_{(m)n}$.

If figures for losses are available for, say, r large fires ($m = 1$ to r), the straight line in Equation 16 can be used to obtain rough estimates of μ and σ by plotting the r pairs of values $[\bar{z}_{(m)n}, \bar{t}_{(m)n}]$ and drawing the best line, or by the method of least squares. However, this method is somewhat imprecise, since the residual errors in Equation 16 arise from ranked variables and, hence, vary with m (not constant) and are correlated (not independent). For dealing with this problem, Ramachandran^{3,10} has developed a generalized least squares method that provides the best and unbiased estimates of μ and σ but requires the use of a complex computer program. Ramachandran also described a maximum likelihood method in these studies which involves simple calculations for estimating μ and σ for each sample.

Economic Value of Fire Protection Measures

The economic value of a fire protection measure depends on the reduction in loss that could be expected due to the satisfactory operation of the measure in the event of a fire. This reduction could be assessed in terms of the difference in the expected (average) loss in two groups of buildings with similar fire risks—one group equipped with the fire protection measure and the other not equipped. The reduction in loss or gain is one of the main components in a cost-benefit analysis of a fire protection measure.

Consider, as an example, the investigation carried out by Rogers¹¹ in regard to the effect of sprinkler protection of buildings. Rogers applied the generalized least square method mentioned in the previous section, assuming specifically that fire loss has a log-normal probability distribution. Table 5-8.2 contains some interesting results obtained by Rogers for average loss in all fires (estimated from large losses). The figures in Table 5-8.2 relate to fires that survived "infant mortality"; very small fires were excluded from the total sample size (n), since their inclusion would distort the shape of the loss distribution, particularly at the upper tail. It is apparent that sprinklers reduce the loss expected in multistory buildings to a considerable extent. Sprinklers also reduce the probability of loss in a fire exceeding a large amount (see Figure 5-8.2), based on the parameters μ and σ estimated from large losses in connection with the results in Table 5-8.2. (The parameters in Figure 5-8.2 pertain to $z = \log_{10} x$.)

Factors Affecting Fire Damage

A full assessment of fire risk ought to consider all the relevant factors affecting fire damage and evaluate their

Table 5-8.2 Average Loss per Fire at 1966 Prices (£ × 000)

	Sprinklered Single Story	Sprinklered Multistory	Nonsprinklered Single Story	Nonsprinklered Multistory
Textiles	2.9	3.5	6.6	25.2
Timber and furniture	1.2	3.2	2.4	6.5
Paper, printing, and publishing	5.2	5.0	7.1	16.2
Chemical and allied	3.6	4.3	4.3	8.2
Wholesale distributive trades	—	4.7	3.8	9.4
Retail distributive trades	—	1.4	0.4	2.4

Line	Subpopulation	Parameters
1	Sprinkler/single story	$\mu = -0.616$ $\sigma = 1.024$
2	Sprinkler/multistory	$\mu = -1.419$ $\sigma = 1.340$
3	Nonsprinkler/single story	$\mu = -0.334$ $\sigma = 1.062$
4	Nonsprinkler multistory	$\mu = 0.401$ $\sigma = 0.992$

$F(Z)$ (cumulative distribution for Z) = probability of loss less than or equal to Z

$V(X)$ (cumulative distribution for X) = probability of loss less than or equal to X

Survivor probability = $1 - F(Z) = 1 - V(X)$ = probability of loss exceeding X or Z

Figure 5-8.2. The survivor probability distribution of fire loss for each class in the textile industry.

independent contribution to the damage. A full assessment is possible by performing a multiple regression analysis. The problem is to estimate the regression parameters, using large observations of the dependent variable, logarithm of loss. (Factors affecting the damage, assigned numerical values, will be independent variables.) For tackling this problem, a multiple regression model, based on extreme order theory, has been developed by Ramachandran.^{3,12} Using large losses, this model

gives estimates of regression parameters approximately equivalent to estimates that would be obtained if loss figures were available for all the fires and were utilized in the calculations.

Consider, for example, the expected loss which has a “power relationship” with the size of a building such that

$$z = \alpha + \beta \log A \tag{17}$$

where z is the logarithm of loss, and A is the total floor area of a building.

The linear relationship in Equation 17 was incorporated in an investigation concerned with the trade-offs between sprinklers and structural fire resistance (Ramachandran³). Based on the information about buildings given in the reports on fires furnished by the fire brigades, industrial buildings were classified into two broad groups—high and low fire resistance. Each of these groups was further divided into single story and multistory and sprinklered and nonsprinklered. The parameters α and β were estimated for each of the eight subgroups and for each industry using large-loss figures. As an example, expected losses for two hypothetical multistory buildings engaged in textile manufacture are given in Table 5-8.3.

Analysis of Test Results

In some fire tests, observations recorded are extreme values (maximum or minimum). In such cases, classical methods of analysis of variance, although normally carried out, are not strictly applicable. Extremes, particularly the maximum and the minimum, have highly skewed

Table 5-8.3 Textile Industry, Multistory Buildings Expected Loss (£) at 1978 Prices

Building Category	Floor area (ft ²)	
	100,000	1,000,000
Sprinklered		
High fire resistance	4080	5790
Low fire resistance	6460	23,070
Nonsprinklered		
High fire resistance	19,910	38,260
Low fire resistance	31,510	152,410

probability distributions and, hence, are not normally distributed. In these problems, the following approach may be used to test the difference between two maximum values. (For a similar test for minimum values, see Ramachandran and Rogers.¹³)

If the reduced variable of the maximum is written as

$$y_{(1)} = a_{(1)}[z_{(1)} - b_{(1)}] \tag{18}$$

and

$$u_{(1)} = \exp[-y_{(1)}] \tag{19}$$

the variable $2u_{(1)}$ has a chi square distribution with 2 degrees of freedom. It follows, therefore, that $\exp[y_{(1)2} - y_{(1)1}]$ has an "F" distribution with (2, 2) degrees of freedom. The reduced maximums, $y_{(1)1}$ and $y_{(1)2}$, belong to two independent samples from exponential-type parents, with $z_{(1)1}$ and $z_{(1)2}$ as the maximum observations in the samples. From Equation 18

$$y_{(1)1} = a_{(1)1}[z_{(1)1} - b_{(1)1}] \tag{20}$$

$$y_{(1)2} = a_{(1)2}[z_{(1)2} - b_{(1)2}] \tag{21}$$

and from Equation 19

$$u_{(1)1} = \exp[-y_{(1)1}]$$

$$u_{(1)2} = \exp[-y_{(1)2}]$$

As in the "F" test, the values $y_{(1)1}$ and $y_{(1)2}$ should be so denoted that $u_{(1)1}$ is greater than $u_{(1)2}$. The variable

$$z = \frac{1}{2} \log \left[\frac{u_{(1)1}}{u_{(1)2}} \right] = \frac{1}{2} [y_{(1)2} - y_{(1)1}] \tag{22}$$

has the z distribution, the probability points of which have been tabulated by Fisher and Yates.⁹ It may be verified that the α percent point of z in this particular case is given by the following formula derived by Ramachandran and Rogers.¹³

$$z = \frac{1}{2} \log_e \left(\frac{1 - \alpha}{\alpha} \right) \tag{23}$$

Significant difference in $y_{(1)2} - y_{(1)1}$ at α level would occur if the observed value of z given by Equation 22 is greater than the value of z given by Equation 23.

Consider, as an example, large-scale tests conducted at the Fire Research Station, U.K., to assess the products due to combustion of plastics. The three factors investigated were (1) crib load, (2) weight of the plastic (PVC), and (3) width of ventilation opening. The observations recorded were maximum temperature, maximum concentrations of carbon dioxide and carbon monoxide, and minimum oxygen; a graphic analysis revealed that variables as such (without any log transformation) approximate an exponential-type distribution.

Table 5-8.4 Maximum Temperature at Vent Position

Levels of other factors (kg)		Vent width levels				z
		240 mm		700 mm		
Load	PVC	Max Temp.	y	Max Temp.	y	
120.5	0	870	-0.6533	925	-0.8340	0.0904
120.5	95	950	0.4587	975	-0.1390	0.2989
241	0	960	0.5977	1100	1.5985	0.5004
241	95	1010	1.2927	1020	0.4865	0.4031
103.5						
137.5	0	960	0.5977	1070	1.1815	0.2919

For purposes of illustration, the results for maximum temperature at vent position are reproduced in Table 5-8.4. (See Ramachandran and Rogers¹³ for full details of the statistical analysis.) It was assumed that the scale parameter $a_{(1)}$ was the same for all the 10 maximum observations arising from 10 independent samples. The standard deviation, σ_z , of these observations was 68.06. According to Gumbel,¹ the standard deviation, σ_y , of $y_{(1)}$ is 0.9497 for $N = 10$. Hence, from Equation 18, an estimated value of $a_{(1)}$ was given by

$$a_{(1)} = \frac{\sigma_y}{\sigma_z} = 0.0139$$

The averages of the maximum temperatures \bar{z}_{240} and \bar{z}_{700} for the two vent width levels were 950 and 1018. For $N = 5$, the mean $[\bar{y}_{(1)}]$ of $y_{(1)}$ was found to be 0.4588. From Equation 18, the values of parameters $b_{(1)}$ were estimated as

$$b_{240} = \bar{z}_{240} - \left[\frac{\bar{y}_{(1)}}{a_{(1)}} \right] = 917$$

$$b_{700} = \bar{z}_{700} - \left[\frac{\bar{y}_{(1)}}{a_{(1)}} \right] = 985$$

For each pair of observations, the y values and the z test statistic were calculated using Equations 20 through 22. From Equation 23, for $\alpha = 0.10$ (10 percent point), the theoretical value of z was 1.0986. In all the five cases, the observed z values in Table 5-8.4 were less than 1.0986. This implied that there was no significant difference between the maximum temperature at the vent position for the two ventilation levels for any fixed level of the other two factors, load and PVC. At present, it is not possible to test the interactions between factors and the differences between overall means, such as $(\bar{z}_{240} - \bar{z}_{700})$.

Fire Severity and Fire Resistance

For the design of a fire-resistant building, knowledge of the expected fire severity is essential. The fire severity in a room will vary with the quantity of combustible material (fire load), the area of ventilation, and the dimensions of the room. Fire severities, however, may differ from room to room in a building, because the furnishings

in a building are seldom everywhere equal and may also change with time. Thus, it is difficult to predict whether a fire in a given building will be ventilation controlled. For the reasons mentioned above, fire severity must be regarded as a random variable with a probability distribution. This distribution can be assumed to be exponential such that the probability of fire severity being greater than S is given by $\exp(-\lambda_s S)$, with the variable S measured in time units, say, minutes. (See, for example, Sara-Coward.¹⁴)

There are no data available at present to estimate the probability distribution of the fire resistance, R , of a room or a complete building. It might be possible to determine this distribution from the fire resistance of structural elements and the plan of a building showing the connections between rooms, corridors, floors, and so forth, using, in addition, data on factors such as doors and windows which affect the fire resistance. Purely from heuristic reasoning, exponential or log-normal distribution has been suggested for the fire resistance of a structural element. Log-normal was assumed in a statistical analysis of fire resistance of laminated timber columns (Ramachandran.¹⁵)

In a fire, failure of the structure of, for example, a room occurs if the fire resistance, R , of the room is less than the fire severity, S , both the variables expressed in units of time. The probability of this failure event can be evaluated from the probability distributions of R and S , if this information is available.

What is ideally required is the probability of minimum fire resistance, R_p , being less than the maximum possible fire severity, S_q . If this probability is denoted by ϑ such that

$$\text{Prob}(R_p < S_q) = \vartheta \quad (24)$$

then ϑ should be a small value which is allowable or acceptable, depending on the consequences of failure in terms of damage to life and property. From a political point of view, it might be possible to tolerate a certain number of deaths and injuries and a certain amount of property loss resulting from the failure of building structures due to fires. For any type of building, the acceptable level of ϑ depends on the number of buildings of this type at risk and the fire damage (life and property) experienced by these buildings.

It must be recognized that both R_p and S_q are random variables and not constants. Since fire resistance has an exponential-type distribution, the reduced variable

$$y_p = a_p(R_p - b_p) \quad (25)$$

has the probability distribution of the smallest (minimum) value with distribution function

$$1 - \exp[-\exp(y_p)] \quad (26)$$

and density function

$$\exp[y_p - \exp(y_p)] \quad (27)$$

The parameters a_p and b_p can be estimated from the parent distribution of fire resistance, if the exact nature of this distribution is known together with its location and scale parameters. In the case of the minimum, if $U(R)$ is the parent cumulative distribution function,

$$U(b_p) = \frac{1}{n} \quad (28)$$

such that the probability of fire resistance being less than b_p is $(1/n)$. The value of n may be so chosen that Equation 28 gives a small value which is acceptable. The parameter a_p is given by $v(b_p)$, where $u(R)$ is the density function corresponding to $U(R)$.

Since fire severity has an exponential-type distribution, the maximum fire severity S_q , with $m = 1$ in Equation 1, has the density function

$$\exp[-y_q - \exp(-y_q)] \quad (29)$$

and distribution function

$$\exp[-\exp(-y_q)] \quad (30)$$

where

$$y_q = a_q(S_q - b_q) \quad (31)$$

If $V(S)$ is the distribution function of fire severity, the parameter b_q , from Equation 3, is given by

$$V(b_q) = 1 - \left(\frac{1}{n}\right) \quad (32)$$

such that the probability of fire severity exceeding b_q is $(1/n)$. Then, from Equation 4, $a_q = nv_{(b_q)}$, where $v(s)$ is the density function of fire severity.

Having defined the probability distributions and parameters of minimum fire resistance and maximum fire severity, it follows to study the random behavior of the variable

$$d_{RS} = R_p - S_q \quad (33)$$

which will enable the evaluation of the probability given by Equation 24. This problem is the subject of a current research investigation by the author. In conclusion, the fire resistance of the structural elements of a building should be such that the fire safety level specified in Equation 24 will be satisfied.

CHAPTER 9

Computer Simulation for Fire Protection Engineering

William G. B. Phillips, Revised by Douglas K. Beller and Rita F. Fahy

Introduction

Fire protection engineers are required to deal with a complex fire scenario that includes human reactions and behavior, in addition to the physical and chemical fire processes. Operations research (OR) pioneered the application of the scientific method to the management of organized systems in which human behavior is a key element. Fire protection engineering could be defined as the application of operations research to the fire system.

Systems involving human beings are difficult to study because realistic experiments may be impossible and neither past experience nor the available data provide sufficient insight. Operations research overcomes these difficulties by the use of simulation models. Simulation models are widely used in science, engineering, and mathematics to study problems that involve ordinary and partial differential equations (either overtly or implicitly). In fire science, for example, simulation models have been used to handle phenomena such as smoke movement and absorption of toxic substances. Both computational fluid dynamics (CFD) models and zone models are solved by similar techniques. These matters are dealt with elsewhere in this handbook. This chapter concentrates on the variety of procedural simulation models that may be applied to interdisciplinary systems, specifically those involving human agents and objectives.

Simulation models describe the system under study in terms of individual events of the individual components of the system.¹ In a gross sense, the simulation model of interest to fire protection practitioners can be di-

vided into human (i.e., evacuation or egress) and physics (i.e., fire effects) components. The simulation model then combines these parts in their natural order and allows the computer to present the effect of their interaction on each other.¹ After the model is constructed, it is provided with data and run to simulate the actual operation of the system. Advances in computer software and hardware have greatly reduced the cost and simplified the use of simulation models. Recent developments in virtual reality are expected to facilitate more realistic interaction between the model and its user.

Uncertainty can be handled by introducing stochastic elements into the model. Estimates of risk can be derived from simulation models by the use of Monte Carlo techniques. Regression analysis can be applied to obtain compact expressions that can be used to measure the sensitivity of the output variables to variations in the inputs.

Types of Models

A model can represent a system as a unified and precisely definable whole, all of whose aspects are simultaneously and unambiguously accessible for assessment. Models include pictures, diagrams, and "scale models," as well as mathematical structures.

Models can be classified as descriptive, physical, and symbolic.² The *descriptive model* is expressed in ordinary language and is the most common tool for decision making in science, engineering, and everyday life. Descriptive models function like metaphors. For example, the flow of smoke through a vent might be compared to the flow of water in a channel, implying that buoyancy and gravity play a similar role albeit with a reversal of sign.

Physical models include scale models, and examples can range from basic hydraulic models of harbors and estuaries to transparent plastic models to demonstrate the flow of smoke in buildings. They make it possible to try out alternative arrangements in the search for an optimum design or strategy. Analogue models are a special

William G.B. Phillips, BSc (Eng), BSc (Econ), ARSM, MIMM, is a member of the Fire Risk Unit at the Fire Research Station of the Building Research Establishment at Borehamwood, Hertfordshire. His recent research has been mainly concerned with the development of new methods of fire risk assessment based on simulation models.

Douglas K. Beller is a fire modeling specialist.

Rita F. Fahy, PhD, is the manager of fire databases and systems at NFPA.

type of physical model that exploits the isomorphisms that exist between different physical processes. The behavior of voltages, currents, resistance, capacitance, and inductance in an electrical circuit has many analogies with processes in heat and fluid flow and acoustic, electromagnetic, and mechanical systems.

Science and engineering depend heavily on *symbolic models* in which algebraic symbols represent the values of variables and the relationships between them. Once a model has been cast in symbolic form, the whole mathematical apparatus can be deployed to deduce additional relationships and solve equations to find optimal solutions. Symbolic models may be static or dynamic; in the latter case they specifically include a variable representing time. A very important type of dynamic model is formulated in terms of ordinary or partial differential equations. Many problems in fire science lead to models that can be expressed in the form of one or more simultaneous differential equations. Some of these have simple analytic solutions, but many interesting cases do not, for example, the partial differential equations that arise in fluid dynamics (Navier-Stokes equations). Such equations are normally solved on computers by standard numerical methods.

A *simulation model* treats the dynamic relationships that are assumed to exist in the real situation as a series of elementary operations on the appropriate variables. A simulation model is made to predict outcomes by actually executing the procedural steps with appropriate initial data and parameters. All of the components comprising a simulation model need not be contained in a single piece of software. Furthermore, as long as each procedural step is represented in the model, the model need not be entirely computer-based. This is to say that the procedural steps associated with some components of the model may be determined using simple hand calculations. The model user then ensures that the components are constructed in the proper manner to provide the intended output. Running the model creates the prediction. The variables in a simulation may change continuously in value or take on only certain discrete values. These changes may take place at any time or only at certain times, or both. For example, a simulation of a fire incident might handle the flow of hot gases by a differential equation expressed in continuous terms, while the people would be treated as discrete individuals moving at prescribed moments in time. However, since such a model would almost certainly be implemented on a computer, the differential equations would be approximated by a difference equation for the purposes of numerical integration (a computer cannot handle "real" numbers). Therefore, the distinction between continuous simulation models and the dynamic symbolic models discussed in the previous paragraph tends to blur.

Simulation Models

A procedural simulation model is a representation of a dynamic system in which the processes or interactions bear a close resemblance or relationship to those of the specific system being simulated or studied. These models are concrete rather than abstract and may contain approx-

imations and subjective elements. They are amenable to manipulations that would be impossible, too expensive, or impractical to perform on the entity portrayed. The operation of the model can be studied, and properties concerning the behavior of the actual system or its subsystems can be inferred. Manipulation of a procedural model requires the acceptance of inputs and the generation of outputs that are similar or analogous to those of the system represented.

Procedural simulation is essentially a technique that involves setting up a model of a real situation and then performing experiments on the model. The idea that a computer model might partly replace experimentation is both dangerous and attractive. It is, therefore, appropriate to remember a warning given by Ackoff and Beer:³

Often when an operations researcher does not understand a phenomenon which he can nevertheless describe well, he can simulate it on a computer and thus conduct experiments. These are experiments on the model on which the simulation is based, not on the system involved. The fact that a simulation may reproduce history with some accuracy does not by itself establish a correspondence of structure between the model and reality. This is true for the same reason that a straight line may have been generated by a sine function, not one that is linear.

Procedural simulation modeling has been widely applied; examples are Link (aircraft pilot) trainers, military war games, business management games, space exploration, physical models of river basins and estuaries, econometric models, electrical analog devices, and wind-tunnel tests for aircraft. It has proved particularly useful in situations involving human intervention of one kind or another. There are great opportunities for improving the interface between the model and operator, making use of virtual reality techniques. In this way, "realistic experience" of rare events can be acquired without danger and at low cost.

Types of Simulation Models

Simulation models can be classified as either discrete or continuous. In the real world there is no such distinction, yet it is possible to model some real-world systems either discretely or continuously. In both types of simulation what is of concern are the changes in the state of the model. Continuous simulations are analogous to a stream of fluid passing through a pipe. The volume may increase or decrease, but the flow is continuous. Using the pipe analogy for discrete event simulation, the pipe could either be empty or have something traveling through it. Whether anything came out of the pipe would depend on some event occurring at the other end.

Both types of simulation can be applied to fire. As time progresses the state of a building changes continuously as the once small fire becomes larger, overwhelms the building, and eventually dies out as it runs out of fuel. The chemical processes in the fire and the physical processes that mediate the flow of heat and hot gases naturally lend themselves to the continuous type of model.

On the other hand, discrete simulations are more appropriate to the strategies used to fight the fire and evacuate the building. For example, the fire is ignited and detected, fire fighters and equipment arrive, hoses are deployed, water is applied, more equipment may be called in, and so on. Similarly the occupants respond to the alarm, collect their belongings, locate their household members, and go toward the exits in a sequence of clear-cut stages.

In continuous models, changes in the variables are directly based on changes in time. The values of the variables reflect the state of the model at any particular time, and simulated time advances from one step to the next usually in equal increments. In discrete event models, events occur as items move through the simulation. The state of the model changes only when those events occur. Simulated time advances from one event to the next (generally in unequal increments), and the mere passing of time has no direct effect.

Discrete Event Simulation Models

Discrete event simulation models are built up from several different elements. These are given different names in different programming languages. A terminology based on *blocks*, *items*, and *events* will be used in this discussion. *Items* are characterized by *attributes*, *priorities*, and *values*.

A *block* is used to represent an action, operation, resource, or process. It is like a block in a block diagram. These blocks are connected in an activity or data flow diagram that represents the system. Information comes into the block and is processed by the program that is in the block. The block then transmits information out of the block to the next block in the simulation. Some blocks may simply represent a source of information that is passed on to other blocks. Other blocks may modify information as it passes through them. Output blocks take information from the simulation and present it to the user in graphic form.

The basic unit passed between the blocks is called an *item*. An item is a data set that carries information about the item's attributes, priorities, and values. In a manufacturing model, an item might be a part on an assembly line; in a network model, an item would be a packet of information; in an evacuation model, an item would be an occupant. Items are generated by special blocks, either according to a fixed schedule or a random distribution.

The model moves items from block to block only when an *event* occurs. Events only occur when specific blocks specify that they should. For example:

1. Blocks that depend on time cause events to happen at an appropriate time. For example, a block representing an activity, for example, the journey from the fire station to the fire location, might introduce a delay of t min into the system representing the duration of the journey. If the alarm was received by the fire station at T min, the block would post an event in the event queue at $T + t$ min.
2. Blocks that have an accumulated demand for inputs cause an event immediately after they receive items. For example, a block representing a parent searching for a child, following a fire alarm, would cause an event when the child is located.

3. Blocks that do not generate events allow the blocks after them to pull items during a single event. Thus, an item can pass through many blocks after a single event if those blocks do not stop it.

Note that every event has the potential to cause every block in a model to move items. Thus, one event may cause many unrelated items to progress in the simulation.

In order to provide true discrete event simulation, the time clock that controls the simulation must move to the exact time of each event. The most common way of doing this is to have an event queue. Each block places the time of its next event in a slot in the event queue. In each cycle the event queue is checked to find the next closest time point; the current time is set to that value, and a "simulate" message is sent to every block. Most blocks ignore these messages unless the message occurs at the event time that was previously posted by the block, or there are items waiting in the block's inputs that can be pulled in. For example, a block representing a queue should pull in an available item whenever it gets a "simulate" message, no matter which block posted the event.

Attributes are an important aspect of discrete event simulation. Attributes are characteristic properties of an item that stay with it as it moves through the simulation. For example, an occupant making an escape from a building might have attributes representing mobility and the amount of carbon monoxide absorbed. *Priorities* specify the relative importance of an item. *Values* allow the model to deal with items that represent groups of identical entities.

Continuous Simulation Models

There is a close similarity between continuous simulation models and the solution of ordinary differential equations by numerical methods. Almost any phenomenon that can be represented by differential equations may be modeled by continuous simulation. This classification includes virtually the whole of classical physics, and the method can easily be extended to chemistry and biology and more speculatively to economics, ecology, and human behavior. The fundamental principle is that the rate of change of certain variables can be expressed as a function of a set of variables (the state variables) that describe the state of the system at a given time. Therefore,

$$\frac{dx_i}{dt} = f(x_1 \dots x_i \dots x_n), \quad i = 1 \dots n$$

The solution to this set of equations is found by integration and yields a function that depends on time, which characterizes the dynamic behavior of the system. For example, suppose the rate at which a chemical reagent is consumed is proportional to the concentration of the reagent. This relationship could be expressed in the form of a differential equation, with the following solution:

$$\frac{dx}{dt} = -kx$$

and, therefore,

$$x = Ae^{-kt}$$

This result can be interpreted to mean that the concentration declines exponentially and tends toward zero as the reaction proceeds. Note that the result is a function of time and not concentration. This example leads to a first order linear differential equation that has an analytic solution. Many systems of interest, however, give rise to higher order nonlinear differential equations, which, in general, do not have analytic solutions or only have solutions if drastic simplifications are imposed. Their solution is normally carried out on computers using one of the standard numerical methods (e.g., Euler, Runge-Kutta). Higher order differential equations can lead to very complex dynamic behavior, for example, various types of oscillation. (It is useful to note that differential equations of an order above the first can always be replaced by one or more first order simultaneous differential equations.)

For a computer to handle a differential equation expressed in continuous terms, the equation has to be replaced by an equivalent difference equation. Consider the following differential equation that shows the rate of change in volume is equal to flow.

$$\frac{d(\text{volume})}{dt} = \text{flow}$$

This equation has an analytic solution that can be found by integration; that is,

$$\text{volume} = \int_{t=\text{start}}^{t=\text{stop}} \text{flow} \cdot dt$$

The original differential equation can be written as a difference equation:

$$\frac{\text{volume}_t - \text{volume}_{t-\Delta t}}{\Delta t} = \text{flow}$$

which can be rearranged to show that

$$\text{volume}_t = \text{volume}_{t-\Delta t} + \Delta t \cdot \text{flow}$$

This equation implies that the value of volume at time t is simply the sum of the value of volume at time $t - \Delta t$ plus the time interval Δt multiplied by flow. This solution (which amounts to Euler's method) can be implemented directly on a computer. Note that the analytic integral solution and the finite difference method will only give the same result if flow is constant. If flow is changing rapidly, the finite difference method will require a large number of iterations (i.e., $\Delta t \rightarrow 0$) to converge to the analytic integral solution.

Continuous simulation models are particularly suited to the analysis of dynamic processes. Frequently the system under examination will display a particular behavior pattern that may be interesting in itself or may be causing a problem. The objective of the model designer is then to construct a model based on differential equations that will reproduce this reference pattern. Decisions need to be made as to which state variables and rates of change are significant. If the model is being used to address some well-understood phenomena, it may be possible to use established relationships that have been tested by experiment. Otherwise, it may be necessary to introduce parameters into the model that lack theoretical back-

ing but enable the model to exhibit the reference behavior either qualitatively or quantitatively.

The overall behavior of the model often depends not as much on the precise value of the parameters and the detailed algebra as on the structure of the model itself. Systems of simultaneous differential equations can usually be shown to be linked together in longer or shorter loops that can be of either positive or negative sign. Positive feedback loops tend to reinforce change and often give rise to exponential growth. Negative feedback loops tend to negate change and are usually associated with goal-seeking activity.

Model building can be thought of as passing through a sequence of iterations in which the model becomes more and more realistic. At each iteration the model designer makes observations, forms hypotheses, carries out tests, modifies the model, and tests the model again. The advantage of working within this framework is that simulation models are objective and explicit rather than subjective and implicit. These characteristics make them particularly valuable for (1) communicating results and (2) acting as a workbench on which alternative solutions to problems can be tested.

Monte Carlo Procedures

Monte Carlo analysis is a simulation technique applicable to problems having a stochastic or probabilistic basis. Two different types of problems give rise to the use of this technique. Firstly, there are those problems that involve some kind of stochastic process. The rate of flame spread and fire growth and the response of individuals to fire alarms are examples of variables that may be considered to be stochastic in nature. In this case, the stochastic element may be introduced at any point in the model run so that the value of a variable at any time depends in some way on its previous value and a random component. Secondly, there are problems in which the process is treated as deterministic, but the starting conditions and model parameters are randomly selected from probability distributions.

The model may be used simply to estimate the value of the endogenous variables at a given location and time. The estimate will, of course, depend on the values of the parameters supplied to the model. However, the exact value of a parameter may not be known, but it might be possible to estimate its mean and variance and the form of its distribution. This information can be encoded as a probability density. A sequence of runs of the model can then be carried out using samples drawn from this distribution. Methods have been developed for generating values from most of the well-known probability distributions as well as any empirical distribution. (For details see Appendix A of this chapter.) It is then possible to estimate probability densities representing, for example, the fire conditions or the number of casualties from the model output. If sensitivity analysis shows that the uncertainty in the input has little effect on the uncertainty in the output, it would not be necessary to go to great expense to refine the value of the input parameter.

Everything said so far about Monte Carlo methods has been on the assumption that there is only one input

variable and one output variable. This assumption can now be relaxed so that all the uncertain input parameters can be treated as random samples from probability densities. The probability density of the output variables is now generated by the probability densities of all the input variables. This function is important because it allows analysis of synergistic effects in which certain combinations of symmetrically distributed input variables can give rise to strongly skewed distributions of the output variables. Distributions of this type are typical of multiplicative stochastic processes. Probability distributions of fire damage are frequently skewed and can often be described by a density of the log-normal variety with a pronounced right-hand tail.⁴ This result may be due to the simultaneous occurrence of several adverse factors which tend to reinforce each other due to nonlinearities in the system.

The input parameters can be interpreted as exogenous variables and the model outputs as endogenous variables. This approach suggests that it would be possible to regress the outputs on the inputs using a standard multiple linear regression routine. This method is equivalent to creating a linear model of the nonlinear simulation model. The relationships between the actual fire, the simulation model, and the linear approximation to the simulation model are shown in Figure 5-9.1.⁵

It can be shown⁶ that the resulting regression coefficients correspond to the partial differential coefficients (i.e., the rate of change of an endogenous variable, y , with respect to each of the exogenous variables, x).

Applications

There are not many fully developed applications of procedural simulation models to fire protection engineering. For example, CRISP II would certainly qualify, while FIRE STATION is not a complete system model because it ignores the interactions between the fire and the oc-

cupants. FIRE STATION might be better described as an OR simulation model. Suites or collections of applications are also available.

CRISP II (Computation of Risk Indices by Simulation Procedures)⁷

Simulation models can be used to compensate for lack of information about "real" fires and to work out the fire risk implications of new materials, building designs, and protection systems. A fire risk assessment model called CRISP II was developed at the Fire Research Station of the United Kingdom to decide priorities for remedial action and to test the validity of new guidelines for building control officers. CRISP II is a Monte Carlo simulation of an entire fire scenario. The model consists essentially of a two-zone model of smoke flow for multiple rooms and a detailed model of human behavior and movement, supervised by a Monte Carlo controller. Its component submodels, which include rooms, doors, windows, detectors and alarms, items of furniture, hot smoke layers and people, run simultaneously so they can continually interact with each other. The model is capable of generating a rich variety of fully interactive behavior patterns. It calculates the fractional effective dose (FED) for occupants as they move through the building and are exposed to smoke. When an occupant's FED reaches 100 percent, that person is considered dead. CRISP II expresses the fire risk of a building design in terms of the number of deaths predicted over a large number of simulations.

FIRE STATION,⁸ Optimum Fire Station Location for Minimum Loss of Life and Property

The FIRE STATION model determines the optimum location, among five alternate sites, for an urban fire station in a community of 25 wards. Optimization is the min-

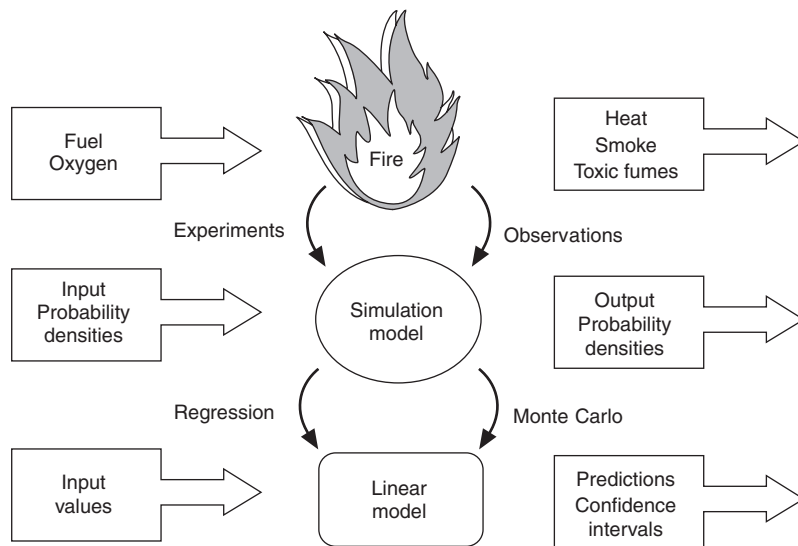

Figure 5-9.1. Relationships between observations and models.⁵

imization of lives lost, building damage, and capital outlay. The model generates a sample population from an observed distribution by ward, structure value, and relative population density. The travel time from the station to the fire is also chosen from an observed distribution. The amount of damage and the number of lives lost is then calculated with reference to the delay in reaching the fire, which depends on the travel time.

Suites or Collections of Fire Protection Computer-Simulated Procedures

Computer models can also be packaged in an integrated set or suite of models that are linked but do not interact as directly as do the modules of CRISP II. Independent models can also be used sequentially, as will be described below. Two examples of integrated suites of computer models are HAZARD I⁹ and FiRECAM.¹⁰

HAZARD I is a fire hazard assessment method that is comprised of four distinct computer models: (1) FAST,¹¹ a multicompartment energy and mass transport model; (2) DETACT,¹² a detector/sprinkler activation model; (3) EXITT,¹³ a human decision/behavior evacuation model; and (4) TENAB,⁹ a tenability model which considers incapacitation and lethality from temperature and toxicity. Figure 5-9.2 illustrates how these, and other, software modules are organized. Figure 5-9.2 follows the progress of a hypothetical scenario entitled "CASE" and shows why HAZARD I is a semiautomatic simulation model.

HAZARD I can model up to six rooms on multiple floors of a building, but data against which its results have been compared are only available for structures of the general dimensions of single-family homes. The method guides the user to identify the fire problems of concern and then to specify representative fire scenarios. The user then employs a computer software package to predict the outcome of each of the identified scenarios in considerable detail. The software predicts over time the temperature, smoke, and fire-gas concentrations in each room of the building; the behavior and movement of the building occupants as they interact with the fire, the building, and each other; and the impact of exposure of each occupant to the fire-generated environment. The occupant exposures are presented as a prediction of successful escape, physical incapacitation, or death along with time, location, and cause. By accounting for the interactions of a large array of factors on the result of a given fire scenario, the method enables the user to analyze the impact of changes in the fire performance of products, building design, and arrangement, or of the inherent capabilities of occupants in the likely outcome of fires. With such information it should be possible to provide better, more cost-effective strategies for reducing fire losses. An overview of the process used by HAZARD I is shown in Figure 5-9.3.

FiRECAM (Fire Risk Evaluation and Cost Assessment Model) consists of submodels that are run in sequence to assess the fire safety performance of a building design in terms of expected risk to life and expected cost of fire. These submodels include a building and risk evaluation model, a fire department response model, a boundary element failure model, an economic model, a design fire model, a fire growth model, a smoke movement model, an occupant response model, a fire department effectiveness model, an evacuation model, a smoke hazard model, a fire spread model, a life loss probability model, a property loss model, an expected number of deaths model, an expected risk to life model, and a fire cost expectation model. FiRECAM can assess whether a proposed design meets the requirements of a performance-based code and can determine if the design is cost effective.

HAZARD I and FiRECAM are examples of methods that link a variety of computer models in such a way that the output from one model can be used directly as the input for the next. It is also possible for the fire protection engineer to use independent models in sequence. There are available collections of programs which cover different aspects of fire technology and science that are components of fire protection simulation models. For example, these collections contain individual programs that predict gas temperatures, heat fluxes on objects, activation of devices, and some aspects of human behavior or evacuation.

These collections do not tend to be comprehensive in nature in that the individual programs are independent of other programs in the collection. Therefore, these programs must be run sequentially and data manually transferred between programs. While less sophisticated and more cumbersome than the integrated simulation models, these models have their uses and may be adequate in some cases. Two advantages of these collections of programs are that they offer the user a significant amount of control over the input to any given component, and they

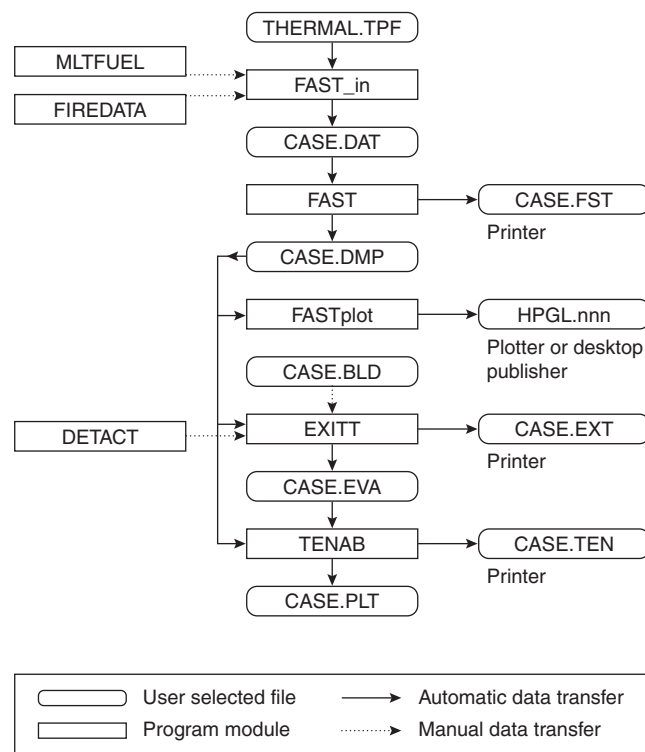

Figure 5-9.2. HAZARD I software.

Figure 5-9.3. Interrelationships of major components of a fire hazard model.

lend themselves to being run many times. This latter point is important when the user wishes to characterize a single component. By running the component program many times the user can adequately define the probabilistic nature of the component in question. Examples of these collections include FPEtool,¹⁴ FASTLite,¹⁵ and FireCalc.¹⁶

The fire protection engineer can also evaluate a design by combining more specialized standalone models of the individual components of interest, for example, a human behavior or egress model with a fire effects model. This approach to simulation modeling, while more cumbersome (since it requires more user intervention), may also be more effective since it allows the user greater con-

trol over the process as well as the use of more sophisticated models.

In this approach, the fire effects model would be run independently of the human behavior or egress model. This approach would facilitate analyzing a number of fire scenarios and choosing the ones that most closely reflect the expected conditions. The human behavior or egress model could also be run for a number of conditions and assumptions. The user would then go through the exercise of comparing the predicted output from the two component models and arriving at the final answer.

A number of human behavior or egress models and fire effects models are available that can be used in tan-

dem to perform fire protection simulation modeling. (Space does not permit an attempt to list all models known to the authors, but compendia have been developed^{17,18} and are expected to be updated continually to reflect the state of the art.) Given the predicted fire effects obtained from a fire model and the predicted locations of occupants from an evacuation model, the designer or engineer could then use a toxicity model, either a computer model or one of the available calculation methods, to predict the cumulative exposure of the occupants as they move through the modeled fire environment.

Model Validation

Simulation models can never be validated over the whole range of their behavior. However, confidence in the reliability of a model is enhanced if the relationships built into it are based on accepted scientific theory supported by experimental evidence. The model must also stand up to tests designed to show it behaves reasonably in response to exogenous disturbance. The calibrated model should also be able to simulate time-series data from instrumented experimental fires. Finally, the model should be able to mimic the sequence of events recorded by observers at real fires.

Like other models, the validity of simulation models depends on goodness of fit and predictive power. In the fire situation, deterministic predictions are not feasible except in very simple cases. In a typical case, a simulation model would be calibrated to produce an output distribution whose mean and variance were in agreement with an observed distribution. Changes in fire protection strategy would be reflected in the model, which would then be used to generate a new output distribution with a different mean and variance. Comparisons between the output distributions before and after implementing the strategy can be used to calculate confidence intervals for statements such as "if strategy B is preferred to A, casualties will be reduced in x percent of cases." Statistical predictions of this kind are quite sufficient for the purposes of fire protection engineering.

Models undergo limited validation; that is, they are applicable to the experimental results they are based upon and/or the limited set of scenarios to which the model developers compared the model's output. The Society of Fire Protection Engineers has formed a task group to independently evaluate computer models. As of March 2001, they were preparing to finish their first evaluation and had chosen a second model to evaluate. Until more models can be independently evaluated, the model user must rely on the available documentation and previous experience for guidance regarding the appropriate use of a given model. By choosing a specific model, the user is tacitly assuming that the model is valid for the scenario under consideration.

Sensitivity Analysis

Sensitivity analysis can be used to draw useful conclusions to guide decisions on fire safety design and

priorities for research. In its simplest form, sensitivity analysis is carried out by varying one of the input parameters in steps over a prescribed range and observing the effect on chosen output parameters, either at the end of the model run or at a set time after the run commences. (Advanced methods of sensitivity analysis are available that allow more than one variable to be varied at a time.) The results of this exercise can then be presented as a table or, more usefully, the output parameter can be regressed against the input parameters to give a simple linear or nonlinear expression that summarizes the results and permits interpolation and extrapolation.

The rate of change of the output parameter, with respect to the input parameter, is defined as the *sensitivity*. In fire safety terms sensitivity might indicate how much the risk is reduced as fire protection measures are improved. If the cost of improved protection is also known, it is possible to estimate the cost of saving a life.

Figure 5-9.4 shows five runs of an evacuation model in which the delay in giving the fire alarm has been increased in steps of 1 min, from 6 min to 10 min. The number of people trapped in a building at, for example, 18 min is represented by the distances between the curves and the horizontal axis. If the number of casualties is regressed against the delay, the results shown in Figure 5-9.5 are obtained. The number of casualties that would occur if the alarm were delayed by t min can be calculated directly from the formula. Conversely, the formula can be used to predict the number of lives that might be saved if the delay were reduced by, for example, an improved alarm system. Note that, in this case, the sensitivity is not a constant, but an exponential function of time.

A similar exercise can be undertaken for fire effects models. Ideally, every input parameter which is based upon an assumption should be the subject of a sensitivity analysis. After establishing a base case, the user should vary the "assumed" input parameter values by ± 10 percent and observe what effect this change has on the output variable of interest. If the predicted output varies by

Figure 5-9.4. Occupants remaining in a place of assembly if the alarm is delayed for the periods shown.

Figure 5-9.5. *The number of casualties rises exponentially as the delay in giving the signal to evacuate is increased.*

less than ± 10 percent, then the output is insensitive to that input variable. Conversely, if the predicted output varies by more than ± 10 percent, then the output is sensitive to the input variable in question. The more sensitive input parameters may require further investigation depending on their degree of sensitivity.

The significance of calculations like these is that they enable designers to select those areas where expenditure on fire protection measures would earn the greatest return in terms of lives saved. It also makes it possible to identify those areas where additional expenditure might have little or no effect. This approach is also helpful for making decisions on research priorities. If preliminary calculations indicate that the fire risk can be substantially reduced by a small change in a parameter, it would make sense to put research effort into investigations designed to refine the measurement of that parameter and reduce the level of uncertainty associated with it.

Sensitivity analysis makes it possible to place the tools of fire protection engineering in the hands of designers and other users who might not have the time or the inclination to work directly with a simulation model. The results of the analysis could be published as tables or graphs in manuals for the guidance of draftspersons who would not need to know in detail how the figures were derived. It is vital to ensure that figures are not applied outside their range of application. This criterion implies that the work must be verified by a fully qualified professional who would check that the guidance was appropriate to the circumstances. Similar problems of professional self-regulation have been successfully resolved in other disciplines.

Conclusion

Overall, progress in fire protection engineering is handicapped by data limitations and the difficulty of conducting realistic experiments on complete fire systems involving human behavior, although efforts in the collection of the data on human behavior have intensified over the past several years, particularly in the areas of occupant

characteristics and pre-movement delay times.¹⁹⁻²⁸ These problems may be overcome by applying a variety of procedural simulation models originally developed in operations research. These models make efficient use of the available data and can be used to test fire protection strategies. They can be complemented by Monte Carlo methods to take account of uncertainty in the data, measure the sensitivity of the casualty rate to fire protection measures, and estimate fire risk.

Appendix A: Handling Uncertainty

Generating Random Numbers

In order to introduce a stochastic element into simulation modeling, a source of random numbers is required. Virtually every computer is equipped with a subroutine that can generate a pseudo-random number in the interval $[0, 1]$ on demand. These are not truly random numbers because they are generated by a deterministic algorithm that will repeat itself cyclically after an interval. The algorithm is designed to make this interval as long as possible given the capacity of the computer. A variety of methods, most of which are based on congruence relationships, are discussed by Naylor et al.²⁹

Generating Probability Distributions for Monte Carlo Studies

The generation of simulated statistics is entirely of a numerical nature and is carried out by supplying pseudo-random numbers into the process or system under study and obtaining probability distributions from it as the result. As a rule, statistical simulation involves replacing an actual sample population by some assumed theoretical distribution and then sampling from this theoretical population by means of some type of random number generator. In some cases it may not be possible to find a standard theoretical distribution that describes a particular stochastic process. In these cases the process can be simulated by sampling from an empirical distribution rather than a theoretical one. Naylor et al.²⁹ provide specific techniques for generating variates from several of the widely used probability distributions as well as general methods for generating variates from empirical distributions.

Inverse transformation method: This method depends on the relationship between the probability density function (pdf) and the cumulative distribution function (cdf). The pdf gives the probability that the variate x lies between x and $x + dx$. The cdf gives the probability that $x \leq x$. The cdf $F(x)$ is obtained from the pdf $f(x)$, by integrating $f(x) dx$ over the interval from $-\infty$ to x .

To generate variates x_i from some particular statistical population whose pdf is given by $f(x)$, one must first obtain the cdf $F(x)$. Since $F(x)$ is defined over the range $[0, 1]$, one can generate uniformly distributed random numbers and set $F(x) = r$. It is clear that x is uniquely determined by $r = F(x)$. It follows that for any particular value of r , say r_0 , that is generated, it is possible to find the value of

x , in this case x_0 corresponding to r_0 by the inverse function, if it is known. That is,

$$x_0 = F^{-1}(r_0)$$

where $F^{-1}(r)$ is the inverse transformation or mapping of r on the unit interval into the domain of x .

EXAMPLE 1:

Generate variates x with pdf $f(x) = 2x, 0 \leq x \leq 1$.

SOLUTION:

$$\begin{aligned} r F(x) &= \int_{-\infty}^x f(t) dt \\ &= \int_0^x 2t dt \quad 0 \leq x \leq 1 \\ &= x^2 \end{aligned}$$

Then taking the inverse transformation, $F^{-1}(r)$, that is, solving this equation for x , one obtains

$$x = F^{-1}(r) = \sqrt{r} \quad 0 \leq r \leq 1$$

Therefore, values of x with pdf $f(x) = 2x$ can be generated by taking the square root of random numbers r .

EXAMPLE 2:

Generate a variate x with density function

$$\begin{aligned} f(x) &= \frac{1}{4} \quad 0 \leq x \leq 1 \\ &= \frac{3}{4} \quad 1 \leq x \leq 2 \end{aligned}$$

SOLUTION:

The pdf and cdf are illustrated graphically in Figure 5-9.A1. Using the previous results

$$\begin{aligned} r = F(x) &= \int_0^x \frac{1}{4} dt \quad 0 \leq x \leq 1 \\ &= \frac{x}{4} \\ f = F(x) &= \frac{1}{4} + \int_1^x \frac{3}{4} dt \quad 1 \leq x \leq 2 \\ &= \frac{3}{4}x - \frac{1}{2} \end{aligned}$$

Taking the inverse transformation, that is, solving the above equations for x , one obtains

$$\begin{aligned} x &= 4r \quad 0 \leq r \leq \frac{1}{4} \\ x &= \frac{4}{3}r + \frac{2}{3} \quad \frac{1}{4} \leq r \leq 1 \end{aligned}$$

The rejection method: In many cases it is either impossible or very difficult to express x in terms of the inverse transformation of the probability distribution, $F^{-1}(r)$. In these cases it is necessary to obtain a numerical approxi-

Figure 5-9.A1. Probability density function (top) and cumulative distribution (bottom) for empirical data.

mation to the inverse function, F^{-1} , or make use of the rejection method. The application of the rejection method requires the following steps:

1. Normalize the range of f by a scale factor, c , such that

$$cf(x) \leq 1 \quad a \leq x \leq b$$

2. Define x as a linear function of r

$$x = a + (b - a)r$$

3. Generate pairs of random numbers (r_1, r_2)
4. Whenever one encounters a pair of random numbers that satisfy the relationship

$$r_2 \leq cf[a + (b - a)r_1]$$

then “accept” the pair and use $x = a + (b - a)r_1$ as the variate generated.

The theory behind this method is based on the realization that the probability of r being less than or equal to $cf(x)$ is

$$P[r \leq cf(x)] = cf(x)$$

Consequently if x is chosen at random from the range $[a, b]$ according to Step 2 above and then rejected if $r > cf(x)$, the probability density function of accepted x will be exactly $f(x)$. It can be shown³⁰ that the expected number of trials before a successful pair is found is equal to $1/c$. This result implies that the method may be quite inefficient for certain probability density functions. The rejection method can also be used as a Monte Carlo technique to evaluate definite integrals. This application may be particularly useful for the evaluation of multivariate functions.

EXAMPLE 3:

Use the rejection method to generate variates x with density function $f(x) = 6(x - x^2)$, where $0 \leq x \leq 1$.

SOLUTION:

Since x was defined over the unit interval, $x = r$. But $f(r) = 6(r - r^2)$ is defined over the interval $0 \leq f(r) \leq 1.5$. Scaling will transform $f(r)$ to the unit interval if $g(r) = 2/3f(r)$, in which case $g(r) = 4(r - r^2)$. The rejection method then consists of the following four steps:

1. Generate r_1 and calculate $g(r_1)$.
2. Generate r_2 and compare with $g(r_1)$.
3. If $r_2 \leq g(r_1)$, accept r_1 as x from $f(x)$. If $r_2 > g(r_1)$, then reject r_1 and repeat Step 1.
4. Repeat this procedure until n values of x have been generated.

A comparison between the theoretical distribution and the distribution obtained by using the rejection method is shown in Figure 5-9.A2.

EXAMPLE 4:

Generate a variate with a normal distribution.

SOLUTION:

If a random variable x has a pdf $f(x)$ given as

$$f(x) = \frac{1}{\sigma\sqrt{2\pi}} e^{-\frac{1}{2}\left(\frac{x-\mu}{\sigma}\right)^2}, \quad -\infty < x < \infty$$

it is said to have a normal or Gaussian distribution with parameters μ and σ . The graph of this function is the familiar bell-shaped curve. The cdf $F(x)$ does not exist in explicit form and, therefore, the inverse transformation method cannot be applied. There are several ways to avoid this difficulty, which are fully described in the literature. However, it is useful to include here a method for generating variates from a normal distribution, because data with this type of distribution is so widely encountered in practice.

Let r_1 and r_2 be two uniformly distributed random variables defined on the interval $[0, 1]$. Then

$$x_1 = (-2 \log_e r_1)^{1/2} \cos 2\pi r_2$$

$$x_2 = (-2 \log_e r_1)^{1/2} \sin 2\pi r_2$$

are two variates from a standard normal distribution. This method produces exact results and is quite fast, subject to the efficiency of the special function subroutines.³¹

Figure 5-9.A2. Generating a sample from a quadratic pdf using the rejection method.

Appendix B: Analysis of Model Output

Local Linearization

Suppose that at a given time, t , the output variables are dependent on the input variables of the model, according to a set of functions:

$$y_i = f_i(x_1, x_2, \dots, x_n); \quad i = 1, \dots, n$$

Then, in the neighborhood of x_1, x_2, \dots, x_n , one can make a local linear approximation to y_i by expanding $f_i(x_1 + \Delta x_1, x_2 + \Delta x_2, \dots, x_n + \Delta x_n)$ as a Taylor series about $f_i(x_1, x_2, \dots, x_n)$, and then truncating all terms after the second. The Taylor series expansion of the i th variable is

$$y_i = f_i(x_1 + \Delta x_1, x_2 + \Delta x_2, \dots, x_n + \Delta x_n)$$

$$\therefore y_i = f_i(x_1, x_2, \dots, x_n) + \sum_j \Delta x_j \frac{\partial y_i}{\partial x_j}$$

$$+ \frac{1}{2!} \left(\sum_j \Delta x_j^2 \frac{\partial^2 y_i}{\partial x_j^2} + 2 \sum_{j \neq k} \Delta x_j \Delta x_k \frac{\partial^2 y_i}{\partial x_j \partial x_k} \right) + \dots$$

$$\therefore \Delta y_i \cong \sum_j \Delta x_j \frac{\partial y_i}{\partial x_j}; \quad i = 1, \dots, n$$

provided that Δx_j is small. It is more convenient to express this in matrix notation:

$$\Delta y = A \Delta x$$

where A is the Jacobian for the y s, that is,

$$a_{ij} = \frac{\partial y_i}{\partial x_j}$$

Note that, if S is the variance-covariance matrix for the x s, then V is the variance-covariance matrix for the y s and is given by

$$V = A'SA$$

Additivity of Variances

It can often be shown that a model is stable, with respect to variations in any one of its input variables taken one at a time. However, it is possible that, if more than one variable were allowed to change simultaneously, the variance of the sum would be greater than the sum of the variances. This result would imply that the interaction or covariance term could not be ignored. However, if the regression procedure establishes that the linear hypothesis is valid, then the variance of the output is equal to the sum of the variances of the inputs weighted by the squares of the coefficients. Note, however, that the linear hypothesis will probably hold only over a limited range, and can be estimated by examining a plot of the residuals.

If it is established that the linear hypothesis holds over a certain range, that is,

$$y = a_0 + a_1x_1 + a_2x_2 + \dots + a_nx_n$$

and if x_1, \dots, x_n are random variables, then

$$\begin{aligned} \text{var}(a_0 + a_1x_1 + a_2x_2 + \dots + a_nx_n) \\ = \sum_i a_i^2 \text{var}(x_i) + \sum_i \sum_j a_i a_j \text{cov}(x_i, x_j) \end{aligned}$$

The variables x_1, \dots, x_n have been generated so as to be independent, which implies that the covariance term vanishes, and, therefore,

$$\text{var}(y) = \sum_i a_i^2 \text{var}(x_i)$$

The regression model can, therefore, be used to predict the variance of a dependent variable on any assumptions that are chosen about the variances of the independent variables.

If it turned out that the contribution of one variable to the total variance was large, it would be desirable to undertake further studies to establish more exact values for this parameter. A smaller variance could then be assigned to this variable, and one could immediately deduce how much effect this would have on the uncertainty in the dependent variable, without having to carry out any further Monte Carlo runs. Within limits there is no need to be too particular about the variances ascribed to the independent variables in the preliminary studies, since these can be revised at a later date. It is necessary to make a distinction between (1) parameters that have a large variance due to measurement uncertainties (which can be improved), and (2) parameters drawn from populations having a large variance (where further measurement may

reduce the uncertainty of the variance but not the variance itself).

CHAPTER 10

Fire Risk Indexing

John M. Watts, Jr.

Introduction

Fire risk indexing is a link between fire science and fire safety. As we learn more about the behavior of fire, it is important that we implement new knowledge to meet fire safety goals and objectives. One of the barriers to implementing new technology is the lack of structured fire safety decision making. Fire risk indexing is evolving as a method of evaluating fire safety that is valuable in assimilating research results.

Fire safety decisions often have to be made under conditions where the data are sparse and uncertain. The technical attributes of fire risk are very complex and normally involve a network of interacting components. These interactions are generally nonlinear and multidimensional. However, complexity and sparseness of data do not preclude useful and valid approaches. Such circumstances are not unusual in decision making in business or other risk venues. (The space program illustrates how success can be achieved when there are few relevant data.) However, detailed risk assessment can be an expensive and labor-intensive process, and there is considerable room for improving the presentation of results. Indexing can provide a cost-effective means of risk evaluation that is both useful and valid.

Fire risk indexing systems are heuristic models of fire safety. They constitute various processes of analyzing and scoring hazard and other system attributes to produce a rapid and simple estimate of relative fire risk. They are also known as rating schedules, point schemes, ranking, numerical grading, and scoring. Using professional judgment and past experience, fire risk indexing assigns values to selected variables representing both positive and

negative fire safety features. The selected variables and assigned values are then operated on by some combination of arithmetic functions to arrive at a single value, which is then compared to other similar assessments or to a standard.

There are numerous approaches to fire safety evaluation that can be construed as risk indexing. A more general description of this area is presented in Reference 1, while greater detail on the more rigorous application is given in Reference 2.

Fire Risk Indexing

Quantitative fire risk assessment originated with the insurance rating schedule. The approach has broadened to include a wide variety of applications.^{3,4} In general, fire risk rating schedules assign values to selected variables based on professional judgment and past experience. The selected variables represent both positive and negative fire safety features, and the assigned values are then operated on by some combination of arithmetic functions to arrive at a single value. This single value can be compared to other similar assessments or to a standard to rank the fire risk.

A risk index is defined as a single number measure of the risk associated with a facility.⁵ Thus, insurance rates are fire risk indices, as are the outputs of other similar schedules or scoring methods. Fire risk indexing, then, is the process of modeling and scoring hazard and exposure attributes to produce a rapid and simple estimate of relative risk. The concept has gained widespread acceptance as a cost-effective prioritization and screening tool for fire risk assessment programs. It is a useful and powerful approach that can provide valuable information on the risks associated with fire.

Figure 5-10.16 provides a graphic view of the relative power and limitations of three broad levels of risk quantification. Curves A, B, and C do not represent actual data points but are demonstrative of a continuum of fire risk analysis possibilities.

Dr. John M. Watts, Jr., holds degrees in fire protection engineering, industrial engineering, and operations research. He is director of the Fire Safety Institute, a not-for-profit information, research, and educational corporation located in Middlebury, Vermont. Dr. Watts also serves as editor of NFPA's *Fire Technology*.

Figure 5-10.1. Risk index systems and relative sensitivity for defining actual risk.⁶

Curve A is representative of a rigorous probabilistic risk analysis where hazard and exposure are analyzed through full quantitative analysis of the hazard and the statistics of exposure. It is clear that this analysis is the most accurate approach to defining risks, especially where the risk is low. However, it is also clear that a large resource investment is necessary to accomplish this task.

Curve C is a simple fire risk indexing that provides the ability to screen for high-risk catastrophic-type situations where the analysis can be consequence oriented. However, for small differences in risk, the ability of the more simplistic screening system to differentiate between two more subtle risks diminishes.

A more complex and accurate assessment model will provide greater differentiation between lesser risks and an improved overall accuracy. The trade-off for this approach is increased time and resources expended for model development, implementation, and data collection.

Applications

Choosing the depth of the risk analysis is a critical decision that depends on such factors as time, resource commitment, and the intended use of the results. Each approach may have certain advantages or trade-offs for specific tasks. A fire risk indexing approach may be appropriate in several situations:

1. Where greater sophistication is not required
2. Where risk screening will be cost-effective
3. Where there is a need for risk communication

The level of accuracy demanded for a fire risk analysis is not typically the same as for other engineering purposes. Often, establishing an order of magnitude will suffice. Time and resource expenditure will increase as the depth of analysis is increased. Where resources are scarce and efficiency is prized, maximizing the utility of the fire risk indexing is clearly desirable.

The principles of fire risk indexing have been applied to a variety of hazard and risk assessment projects to set priorities and help manage resources. Risk assessment

can be an expensive and labor-intensive process. Much time and money can be wasted if the products or facilities with the greatest potential for risk and associated liability are not identified and assessed first. Without a prioritization plan, it will not be known whether a risk was worth assessing until after the time and money has been spent.

Fire risk indexing also has appeal to staff charged with risk management decision-making responsibilities and those who may be unfamiliar with the details and mechanics of the risk assessment process. Because fire risk indexing simplifies basic fire risk assessment principles, it can be an effective way to acquire a global grasp of the issues.

Significance

The importance of fire risk indexing has been widely recognized. A working group of educators and researchers addressed the issue of fire risk indexing at the National Academy of Sciences 1987 "Workshop on Analytical Methods for Designing Buildings for Fire Safety."⁷ They concluded there is a need for a three-part system of fire safety comprised of (1) codes; (2) the methods of fire risk indexing, referred to as numerical grading systems; and (3) the means of supplying inputs to that system derived, as far as feasible, from basic principles of decision science. The working group went on to state the rationale for its conclusion:

The advantage of keeping numerical grading systems in the trio is that they provide a coherent structure that still allows some qualitative analysis of fire safety. These systems also readily accept change associated with aspects of operations research, management science, risk analysis, and quantitative analytical solutions or models to the fire safety problem or parts of it.⁷

The importance of scientific rigor in the development of fire risk indexing methods cannot be overemphasized and will be addressed in more detail in a later section of this chapter.

Examples of Approaches to Fire Risk Indexing

It is difficult to describe a typical fire risk indexing method. The practical necessity of trying to assess dozens or hundreds of risks with limited resources has led to the creation of an array of fire risk indexing systems. Approaches to fire risk indexing are virtually limitless in their possible variations. Representative examples of fire risk indexing were selected from the literature and are summarized in the following sections. They provide some idea of the types of variations involved with modeling and quantifying fire risk. Publicly available computer applications of these and other fire risk indexing methods are described in the final section of this chapter.

Insurance Rating

The purpose of risk analysis is to facilitate the process of risk management. One of the most fundamental tools of risk management is the transference of risk by insur-

ance. To be acceptable to an insurer, the risk is rated by actuarial means, applying principles of mathematics to the particular pricing problems of the insurance industry.

Fire insurance rates are promulgated as *class* rates and *specific* rates. Class rates apply to all properties that fall within a given category or classification. The most common example of class rating is for dwellings or residences. When class rates do not apply, specific rates are determined by the application of a schedule or formula designed to measure the relative quantity of fire hazard present. This process, known as *schedule rating*, is typically used for institutions, manufacturing properties, and business establishments.

The two most widely used schedules in the United States are known as the *mercantile schedule* and the *analytic system*.⁸ At present, the analytic system is predominantly used throughout the country. It is more generally referred to as the Dean Schedule, named for A.F. Dean, author of the plan.⁹ The schedules differ basically in their fundamental analysis of the factors affecting insurance rates, but they are alike in that they establish an arbitrary point from which to build up the rate, based on various physical hazards. A schedule of additions and reductions is computed, and the difference is applied to the arbitrary point of departure.

Schedule rating, then, is a plan by which fire hazards to any particular property are measured. A schedule has been defined as "an empirical standard for the measurement of relative quantity of fire hazard."¹⁰ Schedule rating takes into consideration the various factors contributing to the peril of fire, such as construction and occupancy, and helps determine which features either enhance or minimize the probability of loss. Credits and charges representing departures from standard conditions are incorporated in the schedules. Thus, the schedule rate is typically the sum of all charges less the sum of its credits and constitutes a standard for the measurement of the fire risk.

Specific Commercial Property Evaluation Schedule

The most commonly used insurance rating schedule in the United States is the Insurance Services Office's Specific Commercial Property Evaluation Schedule.¹¹ For each building, a percentage occupancy charge is determined from tabulated charges for classes of occupancy modified by factors such as the specific hazards of a particular occupancy. The basic building grade is a function of the resistance to fire of structural walls and floor and roof assemblies. The building fire insurance rate is the product of occupancy charges and building grade modified by factors such as the exposure to fire in nearby buildings and protection provided by portable extinguishers, fire alarm systems, and so forth.

An important concept of insurance rating is the use of loss experience. In general, tabulated values and conversion factors are based on actuarial analysis of fire losses paid by insurers and reported to the insurance industry.

Gretener Method

In 1960, Max Gretener of the Swiss Fire Protection Association began to study the possibility of an arithmetic evaluation of fire risk in buildings. His premise was

that determining fire risk by statistical methods based on loss experience was no longer adequate for the following reasons:¹²

1. Lack of exchange of loss experience
2. Inadequate analysis with respect to causes and factors determining the size of loss, resulting in distortion of statistical data
3. Rapid technological change altering the credibility of previous experience
4. Different criteria, according to country and company, for data collection and evaluation

As a result of this new approach to schedule rating, the Gretener method has developed into a widely used fire risk index in Switzerland¹³ and other European countries.^{14,15} The basic idea of the process consists of expressing, in relative, empirically derived numerical values, factors for fire initiation and spread and factors for fire protection. The product of the hazard factors is a value for potential hazard, while the product of the fire protection factors expresses a value for protective measures. The ratio of these products is taken as the measure of expected fire severity.

Of immediate appeal is that the approach begins with the explicit concept of risk as the expectation of loss given by the product of hazard probability and hazard severity:

$$R = A \times B$$

where

R = fire risk

A = probability that a fire will start

B = fire hazard, degree of danger, or probable severity

Thus, the Gretener method is based on these two probabilities and combines them in accordance with probability theory.

A further departure from U.S. schedule rating is the calculation of fire hazard as a ratio rather than a sum:

$$\text{Fire Hazard} = \frac{\text{Potential Hazard}}{\text{Protective Measures}}$$

that is,

$$B = \frac{P}{N \times S \times F}$$

where

B = fire hazard

P = potential hazard

N = standard fire safety measures

S = special measures

F = fire resistance of the building

Potential hazard, P , is the product of hazard elements whose magnitudes are influenced on the one hand by the building contents, that is, materials and merchandise present, and on the other hand, by the building itself.

As with most other schedule approaches, the values for these individual factors are not based on statistics but are empirical figures resulting from a comparison of

analyses of fire risks for which fire protection measures are either common or required by law.

Dow's Fire and Explosion Index

A need for systematic identification of areas with significant loss potential motivated Dow Chemical Company to develop the Fire and Explosion Index and risk guide.¹⁶ The original edition issued in 1964 was a modified version of the Chemical Occupancy Classification rating system developed by Factory Mutual prior to 1957. It has been subsequently improved, enhanced, and simplified, and is now in its seventh edition.¹⁷

Today there are many risk assessment methods available that can examine a chemical plant in great detail. The Fire and Explosion Index (FEI) remains a valuable screening tool that serves to quantify the expected damage from potential fire, explosion, and reactivity incidents and to identify equipment that could likely contribute to the creation or escalation of an incident.¹⁸ Risks associated with operations where a flammable, combustible, or reactive material is stored, handled, or processed can be evaluated with this system. The guide is intended to provide a direct and logical approach for determining the probable "risk exposure" of a process plant and to suggest approaches to fire protection and loss prevention design. An important application of the FEI is to help decide when a more detailed quantitative risk analysis is warranted, as well as the appropriate depth of such a study.¹⁹ This section will

provide an overview of the method. The source document¹⁷ should be consulted for specific application.

The concept of the Fire and Explosion Index (FEI) is to divide a process plant into separate operations or units and consider each of these individually. The key aspect of the method is the identification and assessment of thermodynamic properties of the dominant combustible material in the unit being studied. This basic material factor is then built up with a series of individual features concerning operation of the unit. These potential hazards are based on experience and information from incident records. They are intended to cover the majority of likely abnormal situations leading to fires, explosions, and material releases. Features considered are those upon which all hazard and reliability analyses are based. However, the FEI does not purport to be as comprehensive as a detailed hazard and reliability study. The approach identifies most of the potentially hazardous features of a unit. Quantitative measurements used in the analysis are based on historic loss data, the energy potential of the key material, and the extent to which loss prevention practices are applied.

Index Calculation

The basic procedure for calculation of the Fire and Explosion Index is shown in Figure 5-10.2. The first step is to identify those process units considered pertinent to the process and having the greatest potential impact in the

Figure 5-10.2 Dow procedure for calculating the Fire and Explosion Index.

event of loss by fire or explosion. A *unit* is considered to be a part of the plant that can be readily and logically characterized as a separate entity. Generally a unit consists of a segment of the process, such as reactors, blenders, furnaces, storage tanks, and so forth. In some instances, units may be portions of a plant separated from the remainder by distance, fire walls, or other barriers. In other cases, the unit may be an area where a particular hazard exists.

The next step is the determination of the *material factor* for the dominant combustible component of the process unit. The material factor is a measure of intensity of energy release from a chemical compound, mixture of compounds, or substance. It is determined by considering the flammability and reactivity of a material as described in NFPA 704, *Standard System for the Identification of the Fire Hazards of Materials*, 1990 edition;²⁰ NFPA 49, *Hazardous Chemicals Data*, 1991 edition;²¹ and NFPA 325, *Guide to Fire Hazard Properties of Flammable Liquids, Gases, and Volatile Solids*, 1991 edition.²² Based on these values the material factor is denoted by a number from 1 to 40. This arrangement is an arbitrary ordinal ranking.

Subsequent to selecting the appropriate material factor, penalties for contributing hazards are assessed as indicated by the schedule shown in Figure 5-10.3. Items listed in the schedule are considered contributing factors to an incident that may result in fire or explosion. Not every hazard is applicable to a given process unit; however, all applicable items should be evaluated and an appropriate penalty applied. The list is divided into two parts, "General Process Hazards" and "Special Process Hazards." General process hazards relate to a type of process and represent conditions that may increase the magnitude or severity of an incident. Special process hazards are items that increase the probability of a fire or explosion.

Penalties are summed separately for each class of process hazard. These sums are then multiplied (severity \times probability) to yield a process unit hazards factor. This factor has a numerical range from 1 to 8 and is considered a measure of the probable relative damage exposure magnitude. The Fire and Explosion Index (FEI) is the product of the material factor and the process unit hazards factor.

Risk Analysis

The process unit hazards factor and material factor are also used to derive a damage factor. The damage factor represents the overall effect of fire, plus blast damage resulting from a fire or reactive energy release, caused by the various contributing factors associated with the process unit. It is estimated graphically.

A radius of exposure in feet is estimated as 84 percent of the FEI. The dollar value exposed is the estimated value of all equipment within the circle prescribed by the exposure radius. That is, the defined circular area of exposure indicates those assets that may be exposed to a fire or explosion generated by the process unit being evaluated. The replacement value of equipment in this area multiplied by the damage factor provides the base maximum probable property damage (MPPD), that is, the value at risk times the relative damage potential.

Three categories of loss control features have been assigned credits that can potentially reduce the base MPPD to an actual MPPD: (1) process control, (2) material isolation, and (3) fire protection. Twenty-two potential credit factors are shown in Table 5-10.1. The base MPPD reduced by the loss control credit factor gives the actual MPPD. This value represents the probable resulting loss from an incident of a reasonable magnitude given the proper functioning of protective equipment. Failure of the protective equipment could revert the probable loss to the base MPPD. Final steps include determination of the maximum probable days outage and the business interruption cost. The risk analysis procedure is summarized in Figure 5-10.4.

The most important goal of the FEI analysis is to make the engineer aware of the loss potential of each process area and to help identify ways to lessen the severity and resultant loss of potential incidents. The Dow Chemical Company requires an FEI analysis for existing plants.¹⁸ The requirement for use of the FEI has been adopted into law in the Netherlands.²³ The FEI has been found to be a valuable screening tool that can be used in conjunction with other analyses to help determine the relative risk of process units and to provide valuable guidance to both engineering and management staffs.

Mond Fire, Explosion, and Toxicity Index

The Mond division of Imperial Chemical Industries (ICI), Ltd., identified that the Dow Fire and Explosion Index method had considerable scope for the evaluation of plant hazard potential at the earliest design stages. Following trials with the published Dow method, it was clear that there was a need to extend the method in a number of directions to develop its potential for new project design. The resulting Mond Fire, Explosion, and Toxicity Index^{24,25} was developed and has been applied to a range of new projects within ICI.

The main contribution of the Mond method is the inclusion of *offsetting features*, which allow the effect of good design concepts, good management attitudes, and other preventative measures to reduce the overall hazard. An important outcome of using the technique is to raise questions concerning hazard potential at an early enough stage in planning to allow for adequate investigations to be made before the process is in operation. Achieving some measure of hazard early in the planning process provides information that can be used to select appropriate protection features as the planning proceeds. Early assessment of hazards has value in dealing with possible problems in obtaining approval for proposals and in predicting possible delays and problems that are likely to be encountered.

Fire Safety Evaluation System

The Fire Safety Evaluation System (FSES)^{26,27} is a risk indexing approach to determining equivalencies to the NFPA 101[®] *Life Safety Code*[®], 2000 edition,²⁸ for certain institutional occupancies. The technique was developed at

the Center for Fire Research, National Bureau of Standards in cooperation with the U.S. Department of Health and Human Services (formerly Health, Education, and Welfare) in the late 1970s. It was adapted to new editions of the *Life Safety Code* and is presently published in NFPA 101A, *Alternate Approaches to Life Safety*, 2001 edition.²⁹ (The tables in this section are taken from the worksheets for health care occupancies in Chapter 4 of NFPA 101A.)

Equivalency Concept

In an effort to promote economical upgrading of fire safety, U.S. codes include an equivalency option. This provision allows alternative designs to satisfy regulations if they provide a level of fire safety equivalent to that called for by the regulations. The difficult decision as to what constitutes equivalency has been left to local jurisdictions.

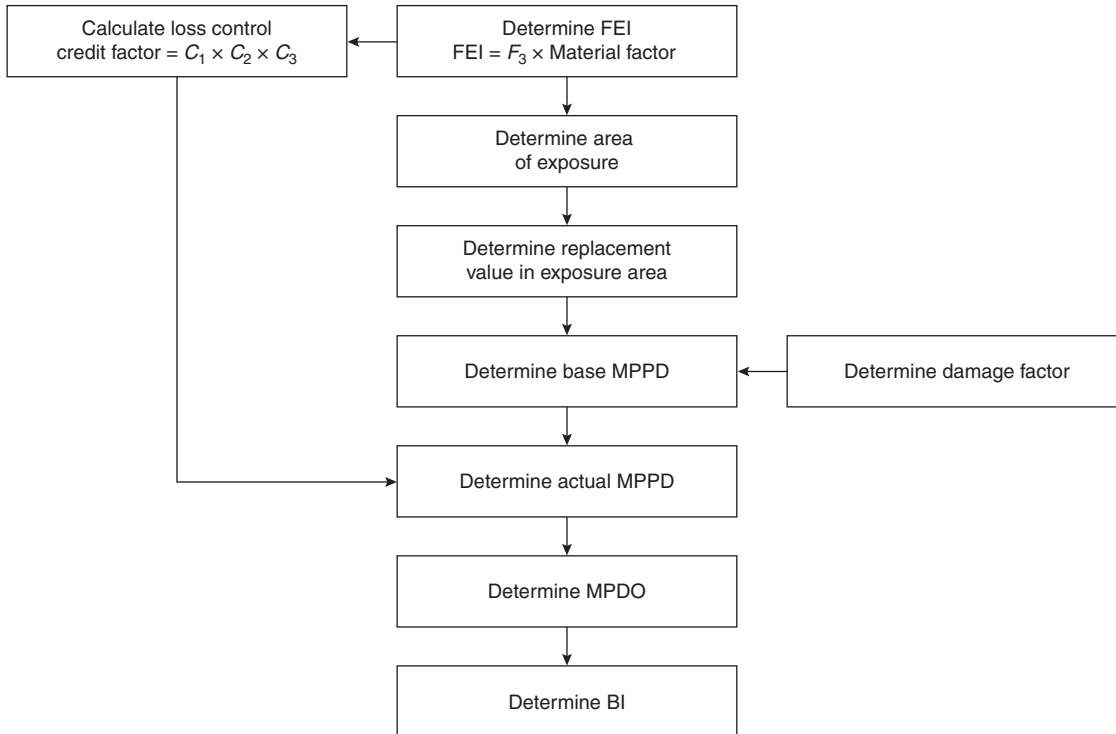

Figure 5-10.4. Dow procedure for calculating other risk analysis information.

Local interpretations lead to a lack of uniformity across the country in terms of what may be waived and what constitutes an adequate alternative to provide the required level of safety. The FSES was developed to provide a uniform method of evaluating health care facilities to determine what fire safety measures would provide a level of fire safety equivalent to that provided by the *Life Safety Code*. The objective was to compile an evaluation system that would be easily workable, presenting useful information for the amount of effort expended.

Fire Zone Concept

Unlike the *Life Safety Code*, the FSES subdivides a building into fire zones for evaluation. A fire zone is defined as a space separated from other parts of the building by floors, fire barriers, or smoke barriers. When fire or smoke barriers do not partition a floor, the entire floor is the fire zone. In application, every zone in the facility should be evaluated. Repetitive arrangements may be evaluated by selection of a typical zone.

Risk

Also unlike the *Life Safety Code*, the FSES begins with a determination of relative risk deriving from characteristics of a health care occupancy. Five occupancy risk parameters are used: (1) patient mobility, (2) patient density, (3) fire zone location, (4) ratio of patients to attendants, and (5) average patient age. Variations of these parameters have been assigned relative weights as indicated in Table 5-10.2.

These values were determined from the experienced judgment of a group of fire safety professionals and represent the opinions of that panel of experts. There is no documented process for validating or revising these values.

Occupancy risk factor for a zone is calculated as the product of the assigned values for the five risk parameters. Multiplication implicitly suggests these factors are interdependent. A hardship adjustment for existing buildings is applied to the occupancy risk factor. This adjustment modifies the risk in existing buildings to 60 percent of that for an equivalent new building.

Fire Safety Parameters

Safety features must offset the calculated occupancy risk. Thirteen fire safety parameters were selected. These parameters and their respective ranges of values (shown in Table 5-10.3) were also developed by the same panel of experts. Table 5-10.3 is designed to be used as a survey instrument whereby appropriate values for each safety parameter can be selected by inspection of the fire zone. There is no attempt made to directly correlate these fire safety parameters to the previously defined risk parameters.

Fire Safety Redundancies

An important concept of the FSES is redundancy through simultaneous use of alternative safety strategies. The purpose is to ensure that failure of a single protection device or system will not result in a major fire loss. Three fire safety strategies are identified: (1) containment, (2) ex-

Table 5-10.2 FSES Occupancy Risk Parameter Factors

Risk Parameters	Risk Factor Values					
1. Patient Mobility (M)	Mobility Status	Mobile	Limited Mobility	Not Mobile	Not Movable	
	Risk Factor	1.0	1.6	3.2	4.5	
2. Patient Density (D)	No. Patients	1-5	6-10	11-30	> 30	
	Risk Factor	1.0	1.2	1.5	2.0	
3. Zone Location (L)	Floor	1st	2nd or 3rd	4th to 6th	7th and Above	Basements
	Risk Factor	1.1	1.2	1.4	1.6	1.6
4. Ratio of Patients to Attendants (T)	Patients	1-2	3-5	6-10	> 10	One or More ^a
	Attendant	1	1	1	1	None
	Risk Factor	1.0	1.1	1.2	1.5	4.0
5. Patient Average Age (A)	Age	Under 65 Years and over 1 Year		65 Years and over, 1 Year and Younger		
	Risk Factor	1.0		1.2		

^aRisk factor of 4.0 is charged to any zone that houses patients without any staff in immediate attendance.

tinguishment, and (3) people movement. Table 5-10.4 indicates the expert panel's opinion of which fire safety parameters apply to each fire safety strategy. Values from Table 5-10.3 are entered in the appropriate places on Table 5-10.4 and summed for each column. The implication of addition is that there is no interaction among the fire safety parameters. The limited value of automatic sprinklers for people movement safety is adjusted for by using one-half of the parameter value in this column. The resulting sums are considered to be the available level of each fire safety strategy.

Equivalency Evaluations

The FSES determines if the fire zone in question possesses a level of fire safety equivalent to that of the *Life Safety Code*. This conclusion is made by comparing the calculated level for each fire safety strategy to stated minimum values. These values for existing buildings range from 100 percent down to 12 percent of those for new buildings. For the column of Table 5-10.4 labeled "General Safety," the sum of all available safety parameter values is compared to the occupancy risk factor calculated from the parameters in Table 5-10.2.

Supplemental Requirements

Because the thirteen selected fire safety parameters were found not to cover all requirements of the *Life Safety Code*, an addendum to the FSES was created. The adden-

dum consists of twelve additional parameters that may be required by the *Life Safety Code*. It should not be implied that these parameters are extraneous to the risk and safety factors of Tables 5-10.2 and 5-10.3 or to the identified fire safety strategies.

Optimization

A distinct advantage of index approaches to fire risk assessment is that they lend themselves to optimization techniques. This characteristic has been exploited for the FSES through incorporation of a linear programming optimization algorithm.³⁰⁻³⁵ Linear programming refers to a mathematical model for allocating limited resources among competing activities subject to a set of constraints. The procedure finds the distribution of values that optimizes an objective function.

For a fire risk index, the objective is to minimize cost of fire protection that will meet a prescribed acceptable level. In the FSES, the acceptable levels are given and the variables are the safety parameters that can take on the values indicated in Table 5-10.3. By assigning a cost to each value in Table 5-10.3, an economic optimum can be calculated. A personal computer version of this model is described in the last section of this chapter.

Derivative Applications

NFPA 101A now includes FSESs for health care occupancies, correctional facilities, board and care homes, and

Table 5-10.3 FSES Safety Parameter Values

Parameters	Parameter Values

business occupancies. One of the most widely used of these is Chapter 8, "Fire Safety Evaluation System for Business Occupancies." NFPA 101A classifies the transaction of business other than mercantile, the keeping of accounts and records, and similar purposes, as a business occupancy. Typical examples are professional, financial,

and governmental offices. The FSES for business occupancies was derived from a project to appraise the relative level of life safety from fire in existing office buildings and combination office-laboratory buildings of a U.S. government agency.³⁶ It was based on the approach developed for health care occupancies and was subsequently

incorporated into NFPA 101A. An analysis of the FSES for business occupancies, using the attribute value spread as a measure of importance to rank the fire safety attributes, found a difference between criteria for new and existing buildings of 6 to 10 percent.³⁷ A PC-based computer program, Enhanced Fire Safety Evaluation System for Business Occupancies (EFSES), is described later in this chapter.

Also derived from the original FSES is Section 3408, "Compliance Alternatives," of the BOCA *National Building Code*³⁸, an indexing system for fire safety in existing buildings. As stated in paragraph 3408.1, the purpose of this section is to maintain or increase safety in existing buildings without full compliance of other chapters of the code. This system allows for older designs to be judged on their performance capabilities rather than forcing the buildings to comply with modern standards for new construction. Originally adopted in the 1985 code, significant changes were effected between the 1993 and 1996 editions. Section 3408 is applicable to all occupancy use groups. For each use group there are separate point values for each safety attribute and separate mandatory values to be considered as criteria for equivalency. This procedure for compliance alternatives has also been adopted as an appendix to Chapter 34 in the International Building Code.³⁹ A detailed comparison of both qualitative and quantitative aspects of Section 3408 of the BOCA *National Building Code* and Chapter 8 of NFPA 101A shows some significant differences.⁴⁰

Chapter ILHR 70 of the Wisconsin Administrative Code is a building code for historic structures.⁴¹ Its purpose is to provide alternative building standards for preserving or restoring buildings or structures designated as historic. Subchapter IV of the code is a risk indexing system, called the Building Evaluation Method. It assesses life safety for a qualified historic building by comparing seventeen building safety attributes with the requirements of the prevailing code. If a historic building has less of a safety attribute than is required by the prevailing code, a negative number is assigned. If a historic building has more of a safety attribute than is required by the prevailing code, a positive number is assigned. Thus, evaluation is directly related to the prevailing code. If the sum of all the attributes is greater than or equal to zero, the building is compliant. The same trade-offs previously would have been allowed under the variance petition process but are now codified. This system adds a degree of certainty of approval that did not previously exist, often impeding development of historic buildings. Unlike the FSES and BOCA Chapter 34, the Building Evaluation Method has no mandatory scores. If the total safety score is equal to or greater than zero, the building is considered code compliant. Also unlike the FSES and BOCA, Wisconsin Subchapter IV does not vary by occupancy. A table for each attribute gives a set of numerical values, one of which is selected for each evaluation. Criteria for these values refer directly to the prevailing code. The same set of values applies for all nonexcluded building uses and occupancies. This code can be accessed through the State of Wisconsin, Department of Commerce web site <http://www.commerce.state.wi.us>.

Hierarchical Approach

Development of a hierarchical approach to fire risk ranking was initially undertaken at the University of Edinburgh, sponsored by the U.K. Department of Health and Social Services.⁴²⁻⁴⁴ The objective of this study was to improve the evaluation of fire safety in U.K. hospitals through a systematic method of appraisal. This approach was further developed at the University of Ulster for application to dwelling occupancies.^{45,46} It has been refined and implemented for the assessment of fire risk in telecommunications facilities.^{47,48}

Defining fire safety is difficult and often results in a listing of factors that together comprise the intent. These factors tend to be of different sorts. For example, fire safety may be defined in terms of goals and aims, such as fire prevention, fire control, occupant protection, and so forth. These broad concepts are usually found in the introductory section of building codes and other fire safety legislation. Or, fire safety may be defined in terms of more specific hardware items, such as combustibility of materials, heat sources, detectors, sprinklers, and so forth. These topics are more akin to items listed in the table of contents of building codes. A meaningful exercise is to construct a matrix of fire safety goals versus more specific fire safety features. This matrix helps to identify the roles of these two concepts, in theory and in practice.

Decision-Making Levels

As a logical extension of a single fire safety matrix, consider that there are more than two categories of fire safety factors. This idea suggests a hierarchy of decision-making levels, or lists denoting things that comprise fire safety. A hierarchy of fire safety decision-making levels is presented in Table 5-10.5.

These represent common levels of fire safety decision making, but there may be more or fewer in a particular

Table 5-10.5 Hierarchy of Fire Safety Decision-Making Levels

Level	Name	Description
1	Policy	Course or general plan of action adopted by an organization to achieve security against fire and its effects
2	Objectives	Specific fire safety goals to be achieved
3	Strategies	Independent fire safety alternatives, each of which contributes wholly or partly to the fulfillment of fire safety objectives
4	Attributes	Components of fire risk that are determinable by direct or indirect measure or estimate
5	Survey items	Measurable feature that serves as a constituent part of a fire safety attribute

application. For example, an even lower level dealing with individual physical items could be added or intermediate levels could be used to better define certain relationships.

This hierarchy of levels of detail of fire safety suggests that a series of matrices is appropriate to model the relationships among various fire safety factors; that is, a matrix of policy versus objectives would define a fire safety policy by identifying the specific objectives that are held most desirable. In turn, a matrix of objectives versus strategies would identify the relationship of these factors, and a matrix of strategies versus attributes would suggest where to use what. Thus, a matrix may be constructed to examine the association of any two adjacent levels in a hierarchy of fire safety factors.

An even more appealing aspect of this approach is that two or more matrices may be combined (multiplied) to produce information on the importance of specific detail of building elements to an overall fire safety policy—information not previously available. This approach is the only such grading of fire safety with an explicitly defined relationship to fire safety goals and objectives.

Generalized Procedure

A generalized procedure for ranking fire safety attributes to determine their relative importance is summarized in the following five steps:

1. Identify hierarchical levels of fire safety specification.
2. Specify items comprising each level.
3. Construct and assign values to matrices of each sequential pair of levels.
4. Combine (multiply) matrices to yield importance ranking of items.
5. Verify the results.

Table 5-10.5 represents an example of Step 1. Step 2 requires that lists of objectives, strategies, attributes, and survey items be developed. A list of fire safety objectives might include statements about life safety, property protection, continuity of operations, environmental protection, and heritage preservation.

No significant work has been done to identify just what it is that fire safety is trying to achieve (i.e., allocation of resources for fire safety is not generally directly associated with a specific corporate objective), so these objectives are a very subjective list. (One benefit of the hierarchical approach is facilitating the incorporation of fire safety into more global organizational objectives.)

In most applications a Delphi process is used to define fire safety policy in terms of the specified list of objectives. That is, a group of experts is asked to rank fire safety objectives with respect to their importance to policy. Each member of the Delphi group receives feedback in the form of response averages, and the process repeats until an acceptable level of consensus is reached. The Delphi exercise yields a vector representing the relative importance of each objective to organizational policy. In some work the more formal Analytical Hierarchy Process (AHP) is used.^{49,50} However, this process is unstable when there are more than six or seven factors to be ranked.²

The next decision-making level involves fire safety strategies. A list of strategies can be derived by taking a cut set of the NFPA Fire Safety Concepts Tree.⁵¹ Example fire safety strategies are ignition prevention, limitation of combustibles, compartmentation, fire detection and alarm, fire suppression, and protection of exposed people or things.

Now, a matrix of objectives versus strategies can be constructed. Values of the cells are again supplied by Delphi or some other subjective decision-making process. In this case the question to be answered is, how important is each strategy to the achievement of each objective?

In order to facilitate mathematical manipulation, the values of the matrices can be normalized. Then, multiplying the objectives/strategies matrix by the policy vector yields a new vector that shows the relative contribution of each strategy to overall fire safety policy. While this vector is not essential to the fire safety evaluation, it illustrates the matrix manipulation process that is the essence of the hierarchical approach.

Continuing this procedure, the next level of fire safety attributes is considered. The following is a typical list of these attributes:

construction	equipment	fixed suppression
height	special hazards	fire department
compartmentation	detection	egress system
building services	alarm	personnel
furnishings	smoke control	management

A matrix of strategies versus fire safety attributes is then constructed and evaluated. Multiplying this matrix by the previously derived vector yields a new vector that weighs each fire safety attribute according to its relative contribution to organizational fire safety policy. The significance of this vector is that it is the only such weighing of fire safety factors that has an explicit link to fire safety goals and objectives. The matrix manipulation process is summarized in Figure 5-10.5.

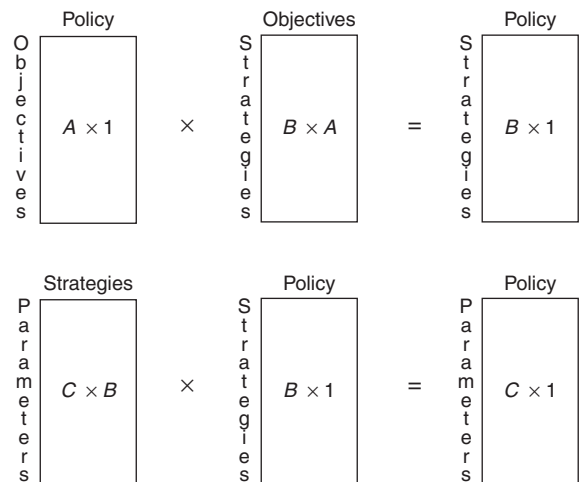

Figure 5-10.5. Schematic summary of hierarchical approach.

Evaluating Attributes

In order to use the resulting vector of attribute weights to develop a fire risk ranking of a building or facility space, the extent to which each attribute is present must be evaluated. That is, a level of functional value of each fire safety attribute must be assessed. These attribute grades may be directly observable or, more often, they are derived from various functions of a lower level of features that includes specific hardware components, for example, fire safety survey items.

Attributes are defined as components of fire risk that are quantitatively determinable by direct or indirect measurement or estimation. They are intended to represent factors that account for an acceptably large portion of the total fire risk. In most cases they are not directly measurable. This case is especially true for existing buildings for which only limited information is readily available.

Each attribute has a specific relative importance that is universal for all facilities within the scope of the assessment method. Individual buildings will vary in the degree to which attributes exist or occur in a space. Attribute grades are a measure of the intensity level or degree of danger or security afforded by the attribute. Partitioning them into measurable constituent parts facilitates grading of attributes. Usually these parts are directly assessable survey items, the next lower level in the decision hierarchy. The determination of attribute grades is dependent on those features of a space identified as survey items.

A survey item is a measurable feature of a space that serves as a constituent part of one or more attributes. In developing means to grade attributes in a given building, each attribute is associated with one or more survey items. These specific features evolve from analysis of the attributes. Items are chosen for contributing significantly to the effectiveness of the irrespective attributes and for being directly measurable. It is, therefore, necessary that survey items be defined in sufficient detail to support these traits. Detailed descriptions of the survey items are required to frame questions that provide input into the decision logic that produces the attribute grades.

In one application, grades were established for each fire risk attribute by associating readily measurable survey items, using logic described by decision tables.⁵² Input to these tables included fire test results, fire hazard modeling, field experience from previous fire events, logic diagrams, and professional judgment.

The scalar product of the resulting attribute weights and grades yields a relative measure of fire risk. The result may be used to rank facilities, or it can be compared to a standard value.

Areas of Application

As indicated in the beginning of this section, the hierarchical approach has evolved from applications in the areas of health care facilities, dwellings, and telecommunications central office facilities. Recent applications of this approach to fire risk indexing have developed in many forms and for many uses. In the United States, a Historic Fire Risk Index has been developed that includes

an assessment of the cultural significance as a parameter of fire risk.^{53,54} In Hong Kong, aspects of fuzzy systems theory have been incorporated into a fire risk indexing technique to evaluate existing high-rise buildings.⁵⁵

While most fire risk indexing methods focus on life safety issues, FireSEPC (fire safety evaluation procedure for the property of parish churches) is insurance motivated and deals with building worth.⁵⁶ Using the hierarchical framework, the procedure rates the contribution of eighteen fire safety components and compares the score to a "collated norm" developed from guidance documents.

In Sweden there is a significant program for the development and verification of a fire risk index method for timber-frame, multistory apartment buildings.^{57,58} This work is of particular importance due to its comprehensive documentation and validation procedures.

Criteria for Development and Evaluation of Fire Risk Ranking

The fire protection engineering community appears to be largely unconcerned with the proliferation of fire risk ranking and how it is being used. The available literature deals only with development and application of a specific method or general descriptions of several selected approaches. Like any analytical technique, risk ranking methods have their limitations and should not be used uncritically.

The purpose of fire risk ranking is to provide a useful aid to decision making. It must be easy to apply but sophisticated enough to provide a minimum of technical validity. Credibility can also be improved through consistency and transparency. The approach should be systematic, and it should be clear to all interested parties that the relevant technical issues have been appropriately covered. Based on the review of numerous fire risk ranking systems, 10 criteria have been proposed to aid in the development and evaluation of other such systems.⁵⁹

Criterion 1: *Development and implementation of the method should be thoroughly documented according to standard procedures.* One of the hallmarks of professionalism is that, as a study proceeds, a record is made of assumptions, data, attribute estimates and why they were chosen, model structure and details, steps in the analysis, relevant constraints, results, sensitivity tests, validation, and so on. Little of this information is available for most fire risk ranking methods.

In addition to facilitating review, there are three other practical reasons not to slight the documentation: (1) if external validation is to be conducted, adequate documentation will be a prerequisite; (2) during the life cycle of a fire risk ranking system the inescapable changes and adjustments will require appropriate documentation; and (3) clear and complete documentation enhances confidence in the method, while its absence inevitably carries with it the opposite effect.

The value of the documentation will be improved if it follows established guidelines. Standard formats for doc-

umentation are primarily directed at large-scale computer models^{60,61} but can be readily adapted in principle to more general applications.

Criterion 2: *Partition the universe rather than select from it.* One of the least well-established procedures in fire risk ranking is the choice of attributes. In following a systemic approach it is best to be comprehensive. Using an exhaustive model of fire safety such as the NFPA Fire Safety Concepts Tree³⁸ is helpful in being inclusive. This logic tree branches out from the holistic concept of fire safety objectives. A cut set on the tree will then identify a group of attributes that encompasses all possible fire safety features.

Criterion 3: *Attributes should represent the most frequent fire scenarios.* In determining the level of detail of the attributes, it is necessary to look at those factors that are most significant, statistically or by experienced judgment. This criterion may also be used as an alternative to Criterion 2, providing the need for systemic comprehensiveness is satisfied.

Criterion 4: *Provide operational definitions of attributes.* If the methodology is to be used by more than a single individual, it is necessary to ensure precise communication of the intent of key terms. Many fire risk attributes are ambiguous concepts that have a wide variety of interpretation even within the fire community.

Criterion 5: *Elicit subjective values systematically.* Most fire risk ranking methods rely heavily on experienced judgment. The use of formalized, documented procedures, such as the multiattribute utility theory, analytical hierarchy process, and Delphi process, significantly increases credibility of the system. Similarly, use of recognizable scaling techniques will enhance credibility.

Criterion 6: *Attribute values should be maintainable.* One variable that is not explicitly included in fire risk ranking, but which is very important, is time. It influences the fire risk both internally (e.g., deterioration) and externally (e.g., technological developments). In order for a method to have a reasonable useful lifetime, it must be amenable to updating. This requirement implies that the procedure for generating attribute values must be repeatable. Changes over time and new information dictate that the system facilitate revisions.

Criterion 7: *Treat attribute interaction consistently.* In the majority of cases treating attribute interaction consistently will consist of an explicitly stated assumption of no interaction among attributes. Where interactions are considered, it is important that they be dealt with systematically to avoid bias.

Criterion 8: *State the linearity assumption.* While the linearity assumption is universal in fire risk ranking, it is also well known that fire risk variables do not necessarily behave in a linear fashion. It is important to the acceptance of ranking methods and their limitations that such assumptions are understood.

Criterion 9: *Describe fire risk by a single indicator.* The objective of most fire risk ranking methods is to sacrifice details and individual features for the sake of making the assessment easier. Information should be reduced to a single score even in the most complex applications. The results should be presented in a manner that makes their significance clear in a simple and unambiguous way. Unless all those involved can understand and discuss the meaning of the ranking, there will not be general confidence in its adequacy.

Criterion 10: *Evaluate predictive capability.* Some attempt should be made to verify that the method does in fact differentiate between lesser and greater fire risks with sufficient precision. It is not feasible to validate a model per se, but some testing should be documented. Reference 62 gives some guidance on this subject. The level of accuracy demanded here is not the same as for other engineering purposes, and establishing an order of magnitude will generally suffice.

Computer Models for Fire Risk Indexing

In most cases, a fire risk index can be readily implemented on a typical computer spreadsheet. However, several software packages or programs have been developed to facilitate optimization, file management, and extensions of fire risk indexing methods. The following programs are presented as illustrative examples and do not constitute an exhaustive list.

ALARM 1.0 (Alternative Life Safety Analysis for Retrofit Cost Minimization) is a PC software tool that helps decision makers in health care facilities to achieve cost-effective compliance with the *Life Safety Code*.^{63,64} The program is based on earlier work by Chapman and Hall.³⁰⁻³⁵ It uses a mathematical optimization algorithm called linear programming to quickly evaluate all possible code compliance solutions and identify the least-cost means of achieving compliance. ALARM 1.0 generates a set of options from which the most appropriate code compliance strategy based on cost and design considerations can be selected. Also listed—for both individual zones and the entire building—are up to 20 alternative, low-cost compliance plans and the prescriptive solution for benchmarking purposes. The software includes the integrated code compliance optimizer, full-screen data editor, and file manager. ALARM 1.0 is available from the National Fire Protection Association (www.nfpa.org) through the One-Stop-Data Shop.

COFRA (Central Office Fire Risk Assessment) is a proprietary computer program that assesses risk in telephone central office facilities.⁶⁵ Two incidents in the last decade have shown the potential severity of a fire that causes interruption of a telecommunications network. Conformance with fire safety code requirements does not adequately address the susceptibility of critical equipment or service continuity. Initial evaluation of this issue revealed that significant conflicts existed among demands for technical accuracy, ease of use, and implementation cost. This evaluation led to the development of a

fire risk indexing method for the assessment of telecommunications network integrity. The approach uses a multiattribute evaluation model to determine the potential contributions to fire risk from individual fire safety attributes of a facility space.^{47,48} Weights for the identified attributes were developed systematically from fire safety policy, objectives, and strategies. Methods were constructed to grade the attributes from onsite survey information. Principles of the Delphi process, decision tables, analytic hierarchy process (AHP), and other techniques of decision analysis were used in the development of attribute weights and grading methods. The scalar product of the attribute weights and grades produces a relative measure of the fire risk to integrity of a communications network. This program is presently an unsupported product of Telcordia Technologies.

EFSES (Enhanced Fire Safety Evaluation System for Business Occupancies)^{66,67} is a PC-based computer implementation of Chapter 8 in NFPA 101A and has been adopted as Chapter 9 of NFPA 101A. The PC-based software automates the calculation process and forms generation. Also, it provides the user with guidance and on-line help in making the decisions involved in completing the EFSES. The help screens provide background information and reference material to assist the user in choosing attribute values. Another enhancement allows the user to interpolate between attribute values in the worksheet table. The program also allows "refinement calculations" that consider attributes in more depth. For example, the construction refinement calculation uses Law's fire severity calculation to estimate the fire duration in the worst-case space in the building. If this result is less than the fire resistance of the building's structural elements then the attribute value can be increased. The program is distributed through NFPA and can be downloaded and installed from <ftp://209.21.183.33/efsesinstall.exe>, where the EFSES user manual is on-line in PDF format.

FREM (Fire Risk Evaluation Model) is Windows-based software that calculates a simplified assessment of fire risk associated with a given building.^{68,69} FREM follows the general approach of the Gretener method.¹³ Developed by National Risk Control Services in Australia, the program was sold to Gallagher Basset Services, Inc., in Itasca, Illinois, in 1996.

RiskPro is another model based on the Gretener method¹³ that was also developed in Australia.⁷⁰ It incorporates a database of input values for more than 400 typical occupancies.

The software tool **Dow Indices**⁷¹ uses the Dow Fire and Explosion Index¹⁷ in an interactive, computer-based environment to identify hazards associated with the storage and use of flammable and explosive materials in a chemical plant. The program includes a library of chemicals, on-line help, and a variety of visual tools to determine the dominant contributors to the overall hazard. The Dow Indices tool can be linked to existing chemical process simulators through the Visual Basic programming platform. In addition, the software can be coupled with economic evaluators, such as a cash flow analysis, using the maximum probable property damage and business interruptions

loss predicted by the index. The American Institute of Chemical Engineers (AIChE) is currently reviewing the program for marketing opportunities.

CHAPTER 11

Product Fire Risk

John R. Hall, Jr.

Introduction

In the big picture of fire safety, there are only two ways to make changes—change things or change behavior. Every *thing* you can change could be seen as a product, in that it is a physical object that people buy, for example, from the raw materials that are used to make furniture to the finished furniture, from the components of fire detection and suppression systems to the complete systems, from wood and steel and concrete to whole buildings. That definition of product is too broad for one chapter.

For purposes of this chapter, a product will be a finished product, not raw materials or components in an assembly, but objects in an end-use form. And a product will be something that starts or feeds a fire as either a heat source or a fuel source. Computationally, fuel-source products involve much more elaborate calculations and effects, because the risk of heat-source products is measured solely in terms of whether or not ignition occurs. The treatment in this chapter will reflect that.

The fire risk of a product captures the range of severities of fires associated with the product and the probabilities that fires will occur having those severities. Fire risk is usually measured as expected loss, that is, the sum over all fires of probability times severity, or as the probability of having a fire more severe than a stated threshold. Either way, fire risk analysis relies heavily on fire scenarios, which are used to set up calculations of both probabilities and severities. This is *not* the same as choosing a handful of specific fires and calculating their severities and probabilities. A valid calculation must demonstrate that each specific fire analyzed is representative of a

larger class of fires, that probabilities are calculated for the larger classes of fires rather than the specific fires, and that collectively the larger classes include every type of fire there can be.

For additional guidance, examine the sections on fire risk analysis in the two Society of Fire Protection Engineers references on performance-based design.^{1,2}

Steps in a Product Fire Risk Analysis

The steps and sub-steps briefly described below parallel current thinking at U.S. standards-writing organizations, notably the American Society for Testing and Materials (ASTM), and previous global reviews of approaches to this subject, particularly as synthesized by Bukowski and Tanaka.³ Later sections expand on techniques to be used in executing these steps.

- 1. Define the Scope of Products to Be Analyzed, Including Context of Use.**
 - a. Define the product or, more typically, the product class to be evaluated.
 - b. Specify where and how the product is used. For example, the product class of floor coverings would not include all uses of carpeting, because carpeting is sometimes used as a wall covering. The specification of application will not only limit the range of product characteristics, but also specify or limit the input parameters used to identify fire scenarios in which the product may play a role.
- 2. Specify the Class of Properties in Which the Product Will Be Used.** Part of identifying the scope is categorizing and specifying the property in which the product is used. The end-use or principal activity in a property defines it as an *occupancy*, which will imply a variety of characteristics and conditions in the environment of the product. For example, a risk analysis of upholstered furniture in homes will be different from a risk analysis of upholstered furniture in offices, and

Dr. John R. Hall, Jr., is assistant vice president for Fire Analysis and Research at the National Fire Protection Association. He has been involved in studies of fire experience patterns and trends, models of fire risk, and fire department management experiences since 1974 at NFPA, the National Bureau of Standards, the U.S. Fire Administration, and the Urban Institute.

both will be different from a risk analysis of upholstered furniture in hotels. The types of pieces used are different, the applicable standards are different, the mix of fires they could be exposed to are different, and the mix of people likely to be present (and their capabilities) are different.

3. Specify Goals, Objectives, and Measures.

- a. Specify goals in terms of acceptable target outcomes, usually in terms of types of harm to be prevented, minimized, or otherwise reduced. Life safety, defined in terms of fatal injury or other health effects, is usually the principal goal. Property protection, avoidance of indirect loss, and protection of heritage and the environment are other typical goals.
- b. Specify objectives, which are more specific means to the end, that is, the goals. If objectives are stated in terms of the systems and features that engineers design, they are called *functional* objectives. Alternatively, objectives may be stated in terms of events (e.g., flashover) or other physical conditions of fire.
- c. Specify or quantify goals and objectives in the form of performance criteria or other measures of loss or harm. Some measures, called *end* measures, are meaningful in and of themselves but are very difficult to predict in models or measure in tests (e.g., monetary damages, injuries). Some measures are easily predicted in models or measured in tests, but are not meaningful in themselves (e.g., temperature or toxic gas concentrations or obscuration for particular areas or volumes). Typically, models must be used to convert readily measurable quantities to end measures of loss.

4. Set Assumptions. Set assumptions covering all aspects of the building, occupant, system, feature, fuel load, modeling, or other elements affecting the outcomes that are not defined either by the product specifications (for the product being assessed) or by the scenarios, which address factors that vary. Set assumptions in terms of *average* conditions (or, if necessary, *typical* conditions), in order to predict overall risk-severity weighted by probability.

5. Identify and Specify the Relevant Scenarios. A scenario is a set of details about the initiating conditions and early growth of a fire that are needed as input conditions to a test method, fire model, or probability or other calculation. This may include

- a. Location and characteristics of the initial fuel and initial heat source. (The product will have the potential to be one or the other, depending on which type of product it is.)
- b. Proximities and characteristics of other fuel packages near the first ignited item. (The product may also belong here, if it is a fuel-source-type product.)
- c. If fire growth or effects beyond the first affected room or area are important to the estimation of the chosen measures of loss, then complete descriptions of those other areas will be needed, including spatial dimensions; fuel load; thermal properties of room linings, barriers, and openings connecting areas; occupants; and damageable property.

d. Fire protection systems must be specified for any areas to be modeled.

6. Identify Test Methods, Models, and Other Data Sources and Calculation Procedures. The models needed will depend, in part, on the scenarios to be addressed, but the models listed below include the major modeling components included in most of the major modeling packages now in use. Each model has implications for data needs, including fire tests and statistical databases. (See Reference 4 for a more detailed review of available models.)

- a. Fire growth model
 - i. Model of rate of growth in terms of heat release rate, for example, as a function of fuel load and distances between items
 - ii. Horizontal flame spread model
 - iii. Barrier failure (e.g., door, ceiling, window)
 - iv. Exterior vertical flame spread model
 - v. Flame spread model in concealed spaces
 - vi. Building-to-building flame spread
- b. Smoke spread model
 - i. Model of room filling
 - ii. Model of spread between rooms
 - iii. Flashover models, including timing of flashover and post-flashover smoke spread
 - iv. Model of spread via heating, ventilation, or air conditioning system
- c. Occupant behavior model
 - i. Model of automatic detection equipment performance
 - ii. Model of how fire is discovered in the absence of automatic detection
 - iii. Model of decision-making activities leading to decisions to egress or attempt rescue
 - iv. Model of egress and rescue activities
- d. Intervention models
 - i. Automatic suppression models, including timing of activation and effects on fire growth
 - ii. Model of other suppression or extinguishment efforts and their effects (e.g., whether fire extinguishers will be used and to what effect)
 - iii. Fire fighter response models
- e. Fire effects or outcome models
 - i. Predicted deaths and injuries due to fire effects in affected areas as a function of time
 - ii. Structural damage or failure models
 - iii. Predicted extent or monetary value of property damage
- f. Ignition probability models
 - i. Fault tree, success tree, or event tree
 - ii. Bayesian analysis of test results, historic fire probabilities, and other data

In practice, many of these component models are rarely used. For example, a fire risk assessment of a burnable product may not need an elaborate analysis of intervention strategies, because the dominant scenarios may be those in which no prompt, effective intervention occurs. On the other hand, the modeling components used may identify a need for data for which no standardized source exists (e.g., burning properties of products in post-

flashover environments). It is not unusual, therefore, for the full calculation to require judgments by analysts, which must be checked through sensitivity analyses.

Bukowski and Tanaka³ have proposed a conceptual scheme for standardizing the role of these expert judgments in fire hazard and risk assessment. Their scheme involves identifying groups of parameters and variables in the models and defining the acceptable sources of data for them, among which could be expert judgments.

Specifying and standardizing needed data sources is an essential part of the process of using fire hazard or risk assessment in a standard. The expectation is that, instead of stating a standard in terms of specifications, the standards-setting process would specify outcome measures, models and other calculation methods, modeling assumptions and input parameters, test methods and other data sources, and possibly the type of expertise required by those who run the models.

Define the Scope of Products to Be Analyzed

The scope definition should define a class of interchangeable items having a common function or application in a specified occupancy and with a range of allowable choices for composition. Specification of the product should be done in a way that facilitates use of existing data, from fire incident data to product test data.

For heat-source products, this means that initial specification of the product by function and construction should be based on the categories defined by NFPA 901, *Uniform Coding for Fire Protection*,⁵ 1976 edition, Chapter F, "Equipment Involved in Ignition," and Chapter G, "Form of Heat of Ignition," or directly to categories defined in the National Fire Incident Reporting System (NFIRS) (see Section 5, Chapter 5).

For fuel-source products, this means that initial specification of the product by function should be based on the categories defined by NFPA 901,⁵ Chapter I, "Form of Material First Ignited." Initial specification of the product by material composition should be based on the categories defined by NFPA 901,⁵ Chapter H, "Type of Material First Ignited" (see Section 5, Chapter 5). A product (e.g., carpet) is defined as a floor covering made of certain materials, chosen to distinguish it from vinyl flooring, wood flooring, concrete slabs, and so forth.

Further specification of the product by function may be needed (e.g., selecting bookcases from the cabinetry group). In such cases, the nationally representative fire incident databases will not be sufficient to estimate probabilities. Other, special fire incident databases and expert judgment will be needed.

When calculating probabilities, be sure to include appropriate shares of fires involving products that were partially or wholly undefined (e.g., upholstered furniture fires should include shares of fires involving unknown-type furniture or unknown-type form of material first ignited, and might include shares of fires involving unclassified furniture or unclassified form of material first ignited).

The range of items defined as examples of the product—which may be referred to as members of the

product class—must, for analysis purposes, be reduced to a manageable number of subgroups. Each subgroup will be *defined* by a range of characteristics (e.g., all cellulosic versions of the product) but will be *represented* by one specific set of product fire characteristics. Ordinarily, these product fire characteristics will be identified from review of results of actual fire tests on one or more representatives of the product class.

Specify the Class of Properties

For reasons similar to those already cited for product scope definitions, property classes (i.e., occupancies) should have their primary definitions stated in terms of the categories defined in NFPA 901,³ Chapter B, "Fixed or Specific Property Use" or in NFIRS. Whenever occupancy scenarios can be defined using nationally representative, valid fire incident data, the analyst will have the strongest possible basis for estimating probabilities. The principal weakness of this data source involves the level of detail of readily available fire incident data, which often falls well short of the detail needed to run the fire hazard analysis portion of the method.

Specify Goals, Objectives, and Measures

Overall goals for fire safety tend to fall into one of the following categories:

- Prevent adverse health effects, particularly fatal injury, to people exposed to fire. Emergency responders are normally addressed separately and may be excluded from consideration.
- Prevent monetary losses due to direct property damage.
- Prevent indirect losses due to fire, such as business interruption, missed work, and temporary housing. The types of indirect losses will differ for residential versus nonresidential occupancies, as will the relative importance of direct damage versus indirect loss.
- Prevent environmental damage. This may be damage due to fire, damage incidental to firefighting or other suppression activities, or damage associated with fire prevention or protection strategies. The negative impact of some fire retardants on recyclability of plastics could be addressed under the latter type of goal.
- Prevent harm to cultural heritage. This refers to historic buildings and similar structures for which fire damage may be more expensive or impossible to repair if historical authenticity is an objective.

The most natural context for fire risk assessment is a whole building, vehicle, or other built environment, because all fire prevention and fire mitigation strategies are available. A fire risk assessment of products can be conducted using the overall goals. It is also possible to use the overall goals for a building or vehicle fire risk or hazard assessment, then to set objectives supporting those goals as functional objectives, defined in terms of the various functions in the building. With such an approach, a product class can be defined as a function having its own objective(s).

The advantage of the functional objective approach is that it does not require the analyst to define scenarios, set assumptions, and model phenomena far away from the product of interest. Instead, it is possible to construct the outcome measures using measurement scales closer to the ones traditionally derived from product fire tests. The disadvantage of the functional objective approach is that it tends to be difficult to execute unless you can specify characteristics at the level of an individual building. If one attempts to use this approach as a basis for qualifying products for an entire class of occupancies, then one is forced to develop all the same information for overall goals, assumptions, scenarios, and models that would have been needed for an assessment at the building level, in order to derive generic functional objectives.

For measures of loss in fire hazard assessment, the measure will be a predicted severity value, such as predicted deaths. For fire risk assessment, both severity and probability are important. Two common summary measures are expected loss (i.e., a sum over all scenarios of scenario probability times predicted scenario hazard) and probability of loss exceeding a certain threshold. Both measures can be calculated directly from nationally representative fire incident databases, without the need for modeling or testing, provided that the product class definition matches the categories used in those databases. For example, a fire risk analysis comparison of the major types of home heating equipment is possible, because each can be identified within the fire incident databases. However, a comparison of different designs for, say, portable electric heaters could not be easily done from statistics alone, because different designs cannot be so distinguished. And for fuel-source products, their role in fire can be identified in statistics only when they are the first item ignited.

For a variety of reasons, therefore, one is usually forced to use test methods and models to develop probability estimates and fire severity estimates more appropriate to the product class and product alternatives of interest. In such cases, much calculation effort can be saved if the problem lends itself to restatement in terms of measures of loss that can be measured in the laboratory and at the fire scene. Three examples are

1. Probability of flashover and/or of flame spread beyond the room of origin
2. Probability of fire ignition
3. Probability that time to flashover exceeds x minutes (where x is chosen to reflect the expected arrival of suppression and rescue forces)

One approach that should usually be avoided is to try to measure loss in terms of the product's share of responsibility for overall fire severity. Such measures tend to be far too subjective and require answers to inherently unanswerable questions. For example, suppose a small trash can fire leads to a large couch fire. If *either* factors in the initial trash ignition or the burning properties of the couch are changed, no large fire would have resulted. How much loss should be assigned to the couch? There is no good answer to that question.

Instead, fire risk analysis should proceed through calculations of differences, that is, fire risk with the prod-

uct of interest versus fire risk with something else substituted for the product of interest.

From this perspective, one can see how fire risk analyses can be constructed as extensions of past successful applications of fire modeling. For example, one of the earliest practical applications of the Harvard code was to the reconstruction of the 1980 MGM Grand Hotel fire. As suggested above, flashover was used as a well-defined event to focus the analysis, after it was shown that most of the fatal fire victims would have survived if flashover had been prevented. Professor Howard Emmons then used the model to rerun the fire with changes, considered individually, in the room of origin's ceiling covering; its benches and chairs; and the area's heating, ventilating, and air-conditioning (HVAC) arrangements.

If one wished to do a fire risk analysis on, say, benches and chairs for dining areas of hotels, one could define a range of possible fire scenarios, do a similar Harvard code analysis of each, weight the consequences by the scenario probabilities, and thereby calculate an overall probability of flashover with two different choices of benches and chairs. The difference between the two probabilities would be a valid product fire risk measure.

A recent fire hazard analysis of rigid non-metallic conduit in hospital emergency systems, done by Benjamin/Clarke Associates, provides a rare example of circumstances where the product's share of fire loss can be validly used for analysis. Dr. Fred Clarke devised a realistic scenario designed to maximize the likelihood of significant product involvement in fire, by placing the initiating fire directly under the product, which was assumed to be exposed due to missing ceiling tile. From a fire risk analysis perspective, this scenario was designed to put an upper bound on the product's share of fire loss in scenarios with significant loss.

If this upper bound were applied to all scenarios and if it were assumed that a substitute product could eliminate the product's role as a fuel source for the fire, then one would have all the requisite parameters for an upper bound estimate on the fire risk consequences of using that product. This is a one-sided analysis. That is, if the product's fire risk proves to be negligible under these conditions, one knows that the true fire risk is also negligible; but if the product looks bad in this analysis, one does not know whether it would still look bad in a fairer, more representative analysis.

Set Assumptions

Fire risk assessment requires the analyst to make assumptions. Some of the assumptions are embedded in elements of the analysis, such as the zone model's assumption that fire conditions in a room can be reasonably approximated by dividing the room into an upper and a lower layer. Some assumptions set boundaries to the analysis, such as an assumption that an effective local public fire department will respond within five minutes, which permits the designer to track fire development and effects for a limited period of time.

Many assumptions address the building, occupant, fuel load, or system characteristics that do not vary from one scenario to another. These assumptions may be treated

as scenario characteristics in one assessment and as assumptions in the next assessment. Therefore, the more detailed discussion of elements of scenarios, in the next section, also applies to most of the candidate assumptions.

There is a critical difference in the handling of assumptions in fire risk assessment versus fire hazard assessment. In fire risk assessment, the purpose of the calculation is to predict what *will* happen. Challenging, high-severity scenarios must be addressed but given only as much or as little weight as the probabilities of those scenarios would justify. In fire hazard assessment, the purpose of the calculation is to predict what *might* happen for which the designer is responsible. This is where concepts like *probable worst-case scenario* become relevant. Fire hazard assessment needs to address only challenging, high-severity scenarios, and does not discount the scenarios it addresses by their probabilities. But some high-severity scenarios will be declared too challenging for a fire hazard assessment. Thus, fire hazard assessment takes an all-or-nothing approach to scenarios.

Fire risk assessment, for these reasons, will assign more variables to scenarios and fewer to assumptions than will hazard assessment. Fire risk assessment needs to address all possible scenarios. But fire risk assessment will tend to set assumptions in terms of typical or average conditions. This approach better serves the purpose of fire risk assessment, which is to predict what will happen.

Specify Fire Scenarios—Initiating Fire

For every scenario, each aspect of fire initiation and growth must be specified in such a way that (1) one can model, test, or otherwise calculate the fire severity consequences of a fire with those specifications; and (2) one can calculate or estimate the probability of having a fire with those specifications. This process of specification usually requires the analyst to address three stages of fire:

1. *What are the initial heat source, the initial fuel source, and the circumstances that bring them together?* These are the basics of the initiating fire, and they need to be specified so that fire incident databases can be used as a major source for estimating probabilities.
2. *What are the factors that will determine whether, and how quickly, fire will spread from the first item to the product, if they are not the same?*
3. *What are the characteristics of the room or area of origin and its fuel packages and surfaces that will determine how large the fire will grow and whether, and how quickly, it will reach flashover and leave the room?*

These three questions reflect the three stages at which a burnable product may become involved in a fire—as the first item ignited; as a secondary item ignited by exposure to other items ignited earlier; or as part of a room that has gone to flashover, when everything that can burn will burn. (If the product is a heat-source product, the latter two stages are not concerns and the analyst need not address them in as much detail.)

For each scenario characteristic, consider the possibility that the characteristic may need to be handled as a variable. That is, one may need to define a set of scenar-

ios, each having a different value of the scenario characteristic (e.g., a different rate of growth in the rate of heat release for the initial fire growth). Theoretically, of course, one might need to vary this scenario characteristic for every combination of the other scenario characteristics. (For example, varying the rate of growth in the initial rate of heat release would not mean four scenarios instead of one but would mean four times as many total scenarios.) This multiplication of scenarios would quickly become unmanageable.

Two general approaches can be used to set up the model of these stages. One is to use surveys of typical fuel loads, room configurations, and the like. Then, one can run a fire growth model with these specifications. The drawbacks of this approach are that the magnitude of the data requirements is extremely large; that such survey data are very scarce, and, when they exist, almost never capture the variations in practice that produce different probabilities and different fire outcomes; and that the probability of ignition is probably not constant from one configuration to another nor is it susceptible to estimation from any existing fire incident databases. If this approach is used, it will tend to force the analyst away from some of the essentials of fire risk analysis, that is, a suitably diverse set of scenarios and an adequate attention to the role of probabilities.

The other general approach is to infer patterns of fuel loads and room configurations from fire loss experience. The logic used here is as follows: Recent fires were produced by recent fuel load and room layout practices. What would those practices have to be in order to produce the observed fires? A critical element in this approach is data on final extent of flame damage, which are captured in the major fire incident databases, as follows:

- Confined to object of origin
- Confined to area of origin
- Confined to room of origin
- Confined to fire-rated compartment of origin
- Confined to floor of origin
- Confined to building of origin
- Extended beyond building of origin

One can assume that a fire confined to object of origin involved only the first item ignited and that a fire extending beyond the room of origin reached flashover in the room of origin.

If the product was not the first item ignited but the fire spread beyond the object of origin, then the fire could have ignited the product through radiant exposure. What is the best way to estimate the probability that this will occur? The fire risk analysis method FRAMEworks,⁶ developed under the auspices of the National Fire Protection Research Foundation, uses the following four elements:

1. For each type of item first ignited (e.g., trash), a set of estimated typical values for mass and burning properties, sufficient to estimate a rate of heat release curve for the product burning alone
2. Ignitability characteristics of the product (i.e., critical radiant flux)
3. For each type of item first ignited, a probability distribution on the distance from the item to the product, as

a function of the type of room, with distributions based on survey data and expert judgment

4. Established mathematical relationships showing the minimum distance at which ignition of a second item will occur, given the first item's burning characteristics and the second item's ignitability characteristics

This second approach still needs the kind of property survey data required by the first approach, but far less of such data because the only geometric information sought is distances between the product and other items. Even so, this is still a data-hungry approach that requires either (1) survey data that may not exist or may be very expensive to collect, or (2) expert judgment that may be especially difficult to make.

As in so many other areas, the temptation will be to reshape the analysis to bypass elements that cannot now be modeled with confidence. However, the analysis must somehow provide a valid basis for combining different product burning properties, and the phenomenon of secondary ignition is central to any evaluation of the product's relative ignitability.

Still other phenomena must be reduced to assumptions for modeling purposes. The following are examples: for a fire that does not reach flashover, what is the physical measure (e.g., temperature) of its peak size? What stops the fire, and what characteristics of fire development (e.g., burning time, detector activation, fire size) triggered fire suppression? (Identifying these characteristics is important in order to know when to stop the fire if the product is changed.) What is the fire's profile after it reaches its peak? Is there an initial smoldering phase, and, if so, how long is it and what is the fire profile during this period? Each of these questions needs to be answered through a crosswalk between the physical parameters measured in tests and used in models and the parameters recorded in fire incident databases, because the latter is always needed to calibrate probability estimation.

Specify Fire Scenarios—The Building Beyond the First Room

The dimensions used to define the different occupancy scenarios need to be dimensions that are relevant to fire development. Most of these dimensions will be one of three types:

1. *Building Dimensions and Geometry.* Dimensions of rooms and other areas in which fire may grow or smoke may spread.
2. *Openings.* Dimensions of openings between rooms and areas relating to paths of flame or smoke spread and sources of air to feed the fire.
3. *Room Linings.* Thermal properties of rooms that may bear on burning at and after flashover.

Building dimensions and geometry: The overall building size and geometry can be structured into a series of questions on which data must be sought and decisions made. The first is the range of variation in the number of floors. After determining this point, the user must specify a number of floors for each occupancy scenario and assign a probability to each.

The second is a room layout for each floor. Room heights and the sizes of openings connecting rooms tend to be standardized by common industry practices, so there may be no need to consider variations. For other factors, (e.g., the number and sizes of rooms) there usually is too much variation in practice and too little data on the relative likelihood of these variations to do much more than (1) estimate one or two values for the number of rooms or the total square feet per floor, and (2) use expert panels to develop detailed layouts for the purposes of modeling and analysis of the rooms or spaces specified in (1).

However, panels of people who are experts on buildings of a certain type are likely to think in terms of the characteristics of the particular buildings they know best. They may therefore give estimates biased toward characteristics of new construction or characteristics of the buildings they live in or frequent. Fires are more likely to occur in smaller, less prestigious units in any property class. The expert panel needs to be continually reminded to adjust their perspective to think in terms of those kinds of buildings.

Openings: There usually will be some information on the sizes of doors and windows, because construction practices are highly standardized even beyond code requirements. However, in a fire, the openings will depend critically on whether and how much key doors and windows are open. There are little or no data on this point for any occupancy. It may be possible to ignore windows, because there are studies indicating that windows affect most fires only after the point in time where fire severity has been determined. (However, the few exceptions will tend to be very large fires, so the reasonableness of an assumption excluding windows will need to be rechecked for any analysis.) How does one set the assumptions for doors, short of large-scale property surveys or special fire data collection projects?

For most fire protection engineering studies, the answer would be to make conservative assumptions, that is, those that present the greatest fire challenge. It is important to understand that this is usually not the right answer for fire risk analysis. If conservative assumptions lead to an overestimate of fire risk, then they may also lead to a gross overestimate or underestimate of the fire risk consequences of particular product choices. There is no substitute for a best estimate, without conservatism, in fire risk analysis.

However, an assumption that might be made in fire hazard analysis because it is conservative may also turn out to be a reasonable best estimate for fire risk analysis, if it reflects a pattern in actual fire experience. If a certain arrangement *could* produce more serious fires, it qualifies as a conservative assumption for fire hazard analysis. If that same arrangement *is producing* more serious fires, then it is more likely that that arrangement is present when a reported fire occurs than that it is present in buildings in general, and one could be justified in assuming that that arrangement is likely, in a fire risk analysis.

However, this line of reasoning has limits. Suppose that open doors is the conservative assumption, but that we know that doors tend to be open only 5 percent of the

time. In that case, the fire risk analysis could reasonably assume that doors are open 10 to 20 percent of the time, reflecting the likelihood that open doors will be more likely in reported fires than in buildings, in general. But the typical situation would still be closed doors.

The analysis would need to have scenarios with open doors and scenarios with closed doors, because neither condition is dominant enough to justify omitting the other condition for a variable (i.e., whether doors are open) that is so influential on final fire size. Or, it might be possible to use one condition, consisting of doors open slightly, trying to seek a single physical condition that will reproduce the appropriate average between fully open and fully closed. Either way, considerable judgment would be needed.

Remember that, if an *average* value is used, the analyst is implicitly assuming that the fire severity associated with that average value is equal to the average of the fire severities associated with all the individual values that occur. In mathematics, this is sometimes called assuming that the average of the function equals the function of the average, and it is not usually the case. The analyst has to make the case that the assumption is reasonable in the situation being analyzed.

Room linings: Linings of rooms and other areas need to be addressed in terms of the thermal properties required for calculations of time to flashover, speed of vertical flame spread, and the like.

Room and area linings for most occupancies are tightly regulated by codes. However, some of the most important occupancies (e.g., dwellings) are not so covered, and even for those that are, one must allow for a significant probability that the codes will not have been in force when fire occurs. Unfortunately, there is little or no data on the probabilities of different combinations of fuels in particular occupancies; and there is only very limited, dated information on typical or average fuel loads and only for some occupancies.

Specifying Fire Scenarios—Exposure of People or Property

In order to translate model or test outputs on the physical characteristics of fire, as a function of location and time, into end-measures of human or property loss, one must address (1) the locations of people or property as a function of time, and (2) the damage or loss consequences to people or property of the different possible physical characteristics of fire, for example, temperature, quantities of toxic gases by type, corrosive properties, and quantities of smoke. The methods for doing this are not extensively developed, except for deaths. Therefore, this section will focus on that outcome.

Occupant exposure depends upon (1) initial locations of the occupants relative to the fire, and (2) their escape behavior. A complete specification of the number of occupants with their initial locations and other characteristics is called an *occupant set*. The user must first define a group of occupant sets that can validly represent all possible combinations of people and their characteristics and locations, and then must estimate probabilities for each. These

must then be joined to a model of occupant behavior. (See Reference 2 for a list of evacuation models.)

Occupant behavior models consist of a set of rules for calculating the locations of occupants at a time, t , as a function of their locations, other occupant characteristics, and fire characteristics at the time stage just prior to t . Some such models track occupants individually; others give only the number of people at each location. Some, but not all, models include interactions among occupants, such as congestion or queuing effects or behavioral rules based on relationships between occupants (e.g., parents who seek to rescue babies). The more comprehensive the model may be in capturing potentially important phenomena, the more computationally demanding it will be and the more data it will demand, possibly including data that are not readily available. As in all other aspects of fire risk analysis, tradeoffs must be made in the modeling.

A brief summary of the steps required is as follows:

- Develop a probability distribution for the number of people present in the building.
- Expand the basic distribution to address relevant characteristics, including ages and relationships of occupants, time of day, and occupant conditions.
- Develop probability distributions for occupant activity as a function of time of day and of occupant characteristics, specified in the previous step.
- Develop probability distributions for occupant location given occupant activity and other occupant characteristics. (If every activity implies a unique location, this will reduce to a crosswalk.)
- Combine all probability distributions to produce a probability distribution for all occupant sets. Merge very similar occupant sets, if needed, for computational simplicity.

Specifying Fire Scenarios—Fire Protection Systems and Features

All significant fires seem to involve a series of failures that set the stage for the event. Thus, it is important to examine the consequences of things not going according to plan. Consider a scenario where automatic systems fail and the fire department does not respond. In a fire hazard assessment, one must ask whether this scenario is so unlikely—or can be made so unlikely through inspection, maintenance, or backups—that the scenario need not be considered. In a fire risk assessment, one must ask whether the scenario's huge severity will be offset by a sufficiently low probability. If nothing else, such scenarios can help to identify the factors that mean the difference between an incidental fire and a major disaster.

The following requirements are straightforward, in principle, but necessary models or data are often sketchy:

- For each type of fire protection system (e.g., detectors, sprinklers, smoke control systems) or feature (e.g., fire doors), identify a range of alternatives. These alternatives must address not only variations in the type and coverage of system or feature used (e.g., quick-response versus conventional sprinkler), but also variations in operational status (e.g., fully operational versus water turned off).

- For each alternative, probabilities will be needed. As in the other parts of the analysis, start with representative national fire incident databases for best estimates, then add needed detail using other databases and expert judgment.
- For each alternative, it will be necessary to specify rules for how the system or feature, under that alternative, will affect the fire development, the evacuation, or other conditions being tracked. Often, this will be fairly simple. One could assume that a fully operational sprinkler system will activate once a specified set of fire conditions are reached and, once activated, will totally and immediately stop the fire, except for certain specified fire scenarios (e.g., fire origin in concealed spaces), when its effect will be only to block fire entry into sprinklered areas. One could assume that a full-coverage automatic detection system will activate once a specified set of smoke or heat conditions is reached and, once activated, will alert everyone in the building to the fire, leading anyone not already in motion in the occupant evacuation model to begin evacuating. In fact, both these examples are oversimplified and possibly dangerously so. A sprinkler's full effect on fire and a detection/alarm system's full effect on occupant behavior will not be instantaneous. The delay may be critical to outcomes and needs to be addressed in the analysis, if only to make explicit what simplifying assumptions have been made.

Identify Test Methods and Models

Analyzing ignition probability: While historic fire data may suffice to estimate ignition probabilities for the mix of existing products, they may not suffice to estimate ignition probabilities for specific existing products, and they will not suffice for new products. The basic approach involves converting laboratory test results to ignition probabilities.

Probabilities of ignition must be estimated from frequencies of ignition in laboratory tests of existing and new products. In essence, it is assumed that, if the new product produces more or fewer ignitions in laboratory tests than the existing products did, then the new product will have a higher or lower probability of ignition, increased or decreased by the same proportion as the ratio of the laboratory ignition frequencies. For fuel-source products, this estimation should be done separately for each of the major classes of heat sources (e.g., flaming versus smoldering), because product ignitability may vary across different heat sources. For heat-source products, it should be done for suitably chosen classes of initial fuel sources.

To prepare a set of laboratory test data for use in these calculations on a fuel-source product, organize the data according to the following terminology:

- Distinguish different versions of the product ($i = 1, 2, \dots$)
- Distinguish different heat sources ($j = 1, 2, \dots$)
- Estimate the share of all the product now in use that is version i ; call this q_i where $\sum_i q_i = 1$
- Let N_{ij} be the number of times that version i of the product has been tested in the laboratory against heat

source j ; let n_{ij} be the number of times that ignition occurred; and let $f_{ij} = n_{ij}/N_{ij}$.

- Let p_j be the probability of ignition of the mix of existing product by heat source j , calculated from fire experience data on the occupancy being studied.

Then assume that p_j (the product's overall probability of ignition) is proportional to $\sum_i q_i f_{ij}$ (the weighted frequency of laboratory ignitions). For a more sophisticated approach, one may wish to use Bayesian analysis, which requires estimating prior probability distributions to which one can apply the lab tests.

- Let f_{ij} be corresponding values summarizing laboratory tests on new product I against heat source j . Note that every heat source must have its own body of test results.
- Let p_{Ij} refer to the quantities to be estimated, which are the probabilities of ignition of product I by each heat source j . Estimate as follows:

$$p_{Ij} = p_j \left[\frac{f_{Ij}}{\left(\sum_i q_i f_{ij} \right)} \right]$$

In general, the p values will be much smaller than the f values, which is assumed to reflect the fact that the p values incorporate all the probabilities involved in bringing the heat source and the product in contact with one another. This estimation procedure is not so reliable if the f values are equal to, or very near, 0 or 1. Bayesian analysis is definitely required in such cases.

Calibration, sensitivity, and uncertainty analysis: Any fire risk analysis will involve complex calculations, with many unavoidable assumptions. While you should not use a more complex method than necessary, you also should not use a less complex method than is valid. A fire risk analysis model without a long list of stated assumptions is bound to be a model with many hidden assumptions, which are almost certain to be less well-founded, if examined, than a list of shaky but explicit assumptions.

For these reasons, running the calculations in a product fire risk analysis is easier to do well than the blend of science and art required to set up the analysis correctly (e.g., appropriate models, reasonable assumptions, best data) and to interpret the results, which includes calibration and sensitivity analysis.

Every step, starting with framing the problem and choosing the models, tests, and data, is subject to error and uncertainty, and that uncertainty must be examined in any interpretation or evaluation of the analytical conclusions. A design analyzed as having an acceptably low risk may also have enough uncertainty in the analysis to create a significant probability of unacceptably high risk.

The principal rule to remember is that the model is calibrated by assessing how well it reproduces recent fire experience from data on recent product use patterns and other practices. If the model captures the principal aspects of fire risk, then it will predict rates of loss that are very close to those actually experienced in the properties being analyzed. Results should be close not only from an overall perspective, but also for major groups of scenar-

ios. Use the specifics of the scenarios that need better calibration as guides to which assumptions need to be modified. For example, if predictions are poor for fires with long smoldering periods, but good for all other fires, then one might want to adjust the assumptions on length of smoldering period or on fire profiles (e.g., rate of heat release curve) during smoldering periods.

Some options involve changes not just to the parameter values, but to the model structure. Examples include changes that would further multiply scenarios by allowing for multiple values (and associated probabilities) of walking speeds, evacuation decision rules, rules for waking people without detectors, and so forth.

Another approach to calibration is to use the model not to directly predict losses, but to predict percentage changes in losses due to product choices, by major scenario group. The advantage of this approach is that it allows the analyst to use the fire experience statistics to do a great deal of automatic recalibration. The disadvantage is that it does not directly address, or correct, the flawed assumptions and estimates that are preventing the model from producing accurate results without such recalibration.

Most analysts will need to both (1) adjust the structure of the analysis, and (2) use fire statistics to recalibrate.

Identify Data Sources

Product and property survey data: There are many good sources of national data on the characteristics of occupancies or products in general. For occupancies, this kind of data may be obtained from ongoing federal government data collection activities (typified by publications of the U.S. Census Bureau; the General Services Administration, e.g., fuel load per room, by type of room; and the U.S. Departments of Defense and Energy), from major one-time studies, or from industry association surveys (e.g., Building Owners and Managers Association, American Hotel and Motel Association, and American Restaurant Association).

For products, there may exist market surveys on patterns of composition or use. The U.S. Census Bureau and, for certain types of products, the U.S. Departments of Commerce, Energy, Housing and Urban Development, and Health and Human Services are all likely sources of information. Much of the data gathered by the U.S. government can be found in summary form in the *Statistical Abstract of the United States*, with reference to primary sources. Another source of information is the U.S. Consumer Product Safety Commission, which carries out some field surveys of product performance and usage.

Section 5, Chapter 5, gives specific references for these data sources if they are readily accessible. Industry association data are available through the association's periodicals or by special request to the association.

For products, however, often the only source of such information is trade associations of manufacturers and sellers of the product. It is important to recall, however, that some products have a lifetime longer than that of a trade association, which means the association's knowledge of current industry practice, however accurate, may not describe use patterns as a whole. Upholstered furni-

ture, for example, is typically cushioned today with synthetics, with previously used natural materials, such as cotton batting and horsehair, now a rarity. Nevertheless, the lifetime of a piece of furniture can be 30 years or more, during which time it may be re-covered several times and pass through several owners, often of continually diminishing economic station. Therefore, it is reasonable to expect that a substantial fraction of the current furniture inventory retains the burning characteristics of products of a bygone era.

In general, people knowledgeable of today's product will tend to have statistics on, and think in terms of, what is currently being *sold*, not what is currently being *used*. Translating sales data into usage statistics is far from straightforward. Moreover, one might suspect that such products would be found disproportionately where fires are likely to be more common, that is, among people and places at the lower end of the economic spectrum.

For the method to operate, all of these qualitative observations must take a quantitative form, and it is the analyst who must decide how this is to be accomplished.

Always remember that, although data on national practices are more representative of the nation than fire incident data, they are less desirable for that very reason for fire risk analysis, because they do not provide probabilities implicitly weighted by the likelihood of having a fire. For example, if you walked into a randomly selected U.S. home in 1989, the chances were better than 85 percent that you would find a smoke detector present; but if you focused on homes that had fires, the chances would drop below 50 percent. It is the latter probability that is more relevant in determining how risk will develop in home fires. Therefore, when data on national practices are used, it is necessary to review the data for any adjustments that may be needed to better estimate probabilities relevant to fires.

Code requirements: Many relevant building characteristics are covered by provisions of building and fire codes. Some product fire characteristics also are covered by regulations. In the absence of direct data from the field, one may assume that all buildings and products have the characteristics implied by compliance with these codes and regulations. This assumption bypasses the need for probability estimation and usually provides enough detail to permit calculation of the input needs of the fire hazard analysis method.

When this approach is followed, the analyst needs to check a number of points that may undercut the central assumption of the approach, namely, that all buildings and products are as the codes and regulations would have them. In practice, many code provisions are of fairly recent vintage so that they were not in place when many or even most of the buildings and products now in use were put into place. Some jurisdictions do not follow national consensus codes, and many more lack the enforcement apparatus to ensure a high rate of compliance. Buildings and products can be altered or may deteriorate after being built, manufactured, or sold. And some building and product features may be better than code requirements because of marketplace demands.

Putting all this together, it is important that the user verify, through the expertise of people with broad familiarity with the state of old and new buildings and products around the country, that the particular characteristics of interest are ones where the code provisions are good indicators of actual practice in nearly all buildings and products in recent use.

Expert judgment: When all else fails and numbers are needed, there is no alternative but to make the best estimates possible. In some cases, it will be a judgment made by the user alone, but especially in areas where the user is least experienced, one or more true experts should be sought. For example, if the user is a maker or seller of the product, it would be wise to make use of fire scientists for assistance in assigning values to the product's fire properties.

One of the persistent potential pitfalls in the method is the danger that the typical product in use is not the typical product involved in fires. There is no foolproof way to avoid this situation, but one way to address it is to include fire service personnel in drawing up the profile of product characteristics. Fire fighters and fire marshals see the products involved in fires, whether or not they make up a substantial fraction of the statistical profile of the product.

Another pitfall is that, no matter what the expert's area of expertise, he or she may tend to underestimate the (typically) enormous variation in every characteristic of interest. Manufacturers may focus on a few best-selling versions of the product; surveys may focus on a few most widely used versions; and fire officials may focus on a few of the worst, most obsolete versions, seen in the worst (but not necessarily the most) fires. This illustrates the value of (1) a panel of experts, where biases can be balanced, and (2) a facilitator sensitive to the variation in

practice, who can steer the group away from premature or overly narrow consensus.

It also suggests that, even when data are available, expert judgment is needed to interpret the data and apply them correctly. Knowledge of common versus uncommon practices, relevant codes and standards, and the length of time they have been in place, are among the kinds of information essential to spot areas of likely bias or critical uncertainty.

For all these reasons, the user can expect to make extensive use of expert judgment and should make sure that the expertise available to the project is both broad and deep.

CHAPTER 12

Building Fire Risk Analysis

Brian J. Meacham

Introduction

The aim of building fire risk analysis is to comprehensively understand and characterize fire-related risks to better inform the wide range of decisions that must be made as part of building design, construction, and operation. As used in this chapter, risk is defined as the possibility of an unwanted outcome in an uncertain situation, where the possibility of the unwanted outcome is a function of three factors: loss of or harm to something that is valued, the event or hazard that may occasion the loss or harm, and a judgment about the likelihood that the loss or harm will occur.¹ Specifically, fire risk is the possibility of an unwanted outcome in an uncertain situation, where fire is the hazard that may induce the loss or harm to that which is valued (e.g., life, property, business continuity, heritage, the environment, or some combination of these). Building fire risk analysis, then, is the process of understanding and characterizing the fire hazard(s) in a building, the unwanted outcomes (relevant losses or harm) that may result from a fire, and the likelihood of fire and unwanted outcomes occurring.

Building fire risk analysis must consider several factors. Some of these factors are familiar to fire protection engineers and some perhaps are not. For example, building fire risk analysis should consider (1) what the fire hazards are and how fires might occur; (2) how the unwanted outcomes (consequences) are valued and by whom (including offsetting benefits); (3) what differences in risk perception and valuation exist and how they should be treated (i.e., should high-consequence events be disregarded if the probability of occurrence is very low); (4) if

there are any social or cultural issues that may be relevant; (5) if there are different stakeholder views on the likelihood of fire occurrence and of the resulting consequences; and (6) whether uncertainty, variability, and unknowns have been identified and appropriately addressed.

Evaluation of fire hazards is something that fire protection engineers do well, and for which numerous tools and methods exist (e.g., this handbook). The valuation of consequences, however, may not be so familiar to engineers and is typically quite challenging, as it should consider physical, economic, health, environmental, social, cultural, and psychological factors. In valuing life safety consequences, for example, many engineers consider only injury and loss of life to an individual. However, there are also such factors as reduced quality of life, the inability to continue to work, and the impact on family relationships. On property protection, factors such as smoke and water damage should be considered, in addition to thermal damage. On business continuity, there are long-term issues, such as loss of image and market share, in addition to the short-term monetary losses associated with downtime.

Much like the difficulties in valuing consequences, the issue of determining the likelihood of fire occurrence and of resulting consequences is unfamiliar to many fire protection engineers, and is not without its challenges. One issue concerns the differing views on the concept of probability (likelihood): the frequentist view versus the subjectivist view.^{1,2} In brief, the frequentist view is held by classical statisticians, who consider probability to be a property of a process that can be determined from an infinite population of data. They believe probability to be a precise value, and that information needed to estimate it can come only from observing the process. (For example, one can only determine the probability of a coin landing with “heads” up or “tails” up by flipping the coin an “infinite” number of times.) The subjectivist view, however, holds that probability has a value at any time that represents the total available knowledge about the process at that particular time. (For example, one can look at a coin

Based in Massachusetts, Brian J. Meacham is a principal risk consultant for Arup and a principal fire engineering consultant for Arup Fire. Brian has over 15 years of professional experience in the United States and in Europe, is a licensed professional engineer (U.S.) and a chartered engineer (U.K.), and holds the degrees of M.S. in fire protection engineering and Ph.D. in risk and public policy. Brian is a fellow of the Society of Fire Protection Engineers.

having a “head” and a “tail,” assess whether it is well-balanced, observe a single coin toss, and estimate the probability of getting a “head” or a “tail” if one flips the coin again.)

Regardless of whether one holds the frequentist or subjectivist viewpoint, the availability of information to determine probabilities is critical, as is the applicability of the probability information to the problem at hand. For example, (1) what data are available (e.g., how many fire ignitions have there been in office buildings in the past ten years that did not result in significant fire damage?); (2) how applicable are historical data as an indicator of future events (e.g., were fire loss data from cellulosic materials prior to 1960 an appropriate indicator of fire losses involving synthetic materials after 1960?); and (3) how might changes to the building or its contents in the future impact the likelihood of fire occurrence and/or magnitude and type of consequences?

The above points to a critical factor in building fire risk analysis: there will be uncertainty, variability, and unknowns in any risk problem. How uncertainty, variability, and unknowns are identified and addressed will be critical to the risk analysis, especially with respect to the stakeholders involved in passing judgment on the “acceptability” of the risk. Should point values be used or should distributions? How is the variability in building occupant health and ability addressed in the analysis? These are just a few items that must be addressed.

Building fire risk analysis requires judgments about the likelihood of fires occurring and the consequences that may result. Developing these judgments requires significant information from numerous sources, including objective data (e.g., historical fire loss data), subjective judgment, and input from interested and affected stakeholders. As part of the building fire risk analysis process uncertainty, variability, and unknowns must be identified and appropriately addressed. To help the diversity of stakeholders involved in building fire risk analysis better understand how each view each building fire risk problem, and to address the above issues, an understanding of risk characterization is needed.

Building Fire Risk Characterization

Risk characterization requires a well-defined problem that those involved agree with, a sound scientific base, the proper use of analytical techniques with proper consideration of uncertainties and unknowns, and sufficient discussion and deliberation so that everyone understands all of the issues.³ The risk characterization process will likely require several iterations, as new information and data become available, and as participants gain better understanding and raise more issues. It needs to be an interactive process, and not one where one group dominates the deliberations and/or analysis and forces a solution.

To help characterize building fire risks, a number of questions need to be asked:^{1,3-6}

1. Who or what is exposed?
2. If it is people, what groups are exposed?
3. What is posing the risk?
4. What is the nature of the harm or loss?

5. What qualities of the hazard might affect judgments about the risk?
6. Where is the hazard experience?
7. Where and how do hazards overlap?
8. How adequate are the databases on the risks?
9. How much scientific consensus exists about how to analyze the risks?
10. How much scientific consensus is there likely to be about risk estimates? How much consensus is there among the affected parties about the nature of the risk?
11. Are there omissions from the analysis that are important for decisions?

Various tools and methods exist to help obtain needed information for building fire risk characterization. Several of these are outlined in the following section. Detailed discussion on the above questions can be found in the references.^{1,4,5,6}

Methods for Gathering Building Fire Risk Information

To help obtain necessary information regarding what is valued and how, how it may be impacted by fire and fire effects, how particular fire hazard conditions may occur, and the likelihood of losses occurring; several tools, methods, and approaches are available. This section provides a brief overview of various tools, methods, and approaches available to fire protection engineers for the purpose of gathering needed information. This section does not constitute a comprehensive review, and readers are urged to consult the fire and risk literature for more tools, methods, and approaches and for more details on the approaches discussed herein.

As part of a risk analysis effort, one needs to identify what is of value, assess the hazards that may result in harm or loss to that which is valued, and make a judgment regarding the likelihood of the loss occurring. In building fire risk analysis, life safety, property protection, business continuity, the environment, and heritage are the value foci. To determine how they are valued and the associated levels of unacceptable impact (damage, injury, or failure), consequence analysis is used. To determine the extent of exposure from potential hazard situations, fire hazard assessments are undertaken. To complete the risk analysis, judgments concerning the likelihood of hazard events occurring that result in unacceptable or intolerable levels of impact are required.

Consequence Analysis

To determine how a hazard may occasion loss or harm to that which is valued, some form of consequence analysis is required. Consequence analysis, a key component of risk characterization, is concerned with determining the potential impacts of a hazard event without consideration of the likelihood of the consequences occurring. Consequence analysis is more difficult than hazard assessment, in that it may not always be clear in what ways and to what extent something is valued and how the loss should be characterized. Consider life safety. For

some, the line may be drawn simply between life and death. For others, quality of life, pain and suffering, and/or rehabilitation after a fire-induced injury may be critical factors. For property protection, it may not always be clear to the interested and affected parties where, how, and how much damage may occur. Some may not realize that code compliance, for example, can be significantly different than protecting their building, process, contents, or other assets of value. The issues can get even more complex for assessing potential business continuity impacts and damage to historically important buildings or contents. Nonetheless, such differences are important for characterizing risks, determining tolerable impacts, and selecting acceptance (damage, failure) criteria, and are why interested and affected parties must be involved in the process.

The nature of consequence analysis will vary based on the risk problem, with the issues of what is valued and how it is valued being two central foci. Determination of what is valued and how it is valued may require facility surveys, research into the impact of fire effects on that which is valued, an understanding of the state of knowledge for assessing impacts on that which is valued, and discussions with a wide variety of interested and affected parties. Uncertainty, variability, and unknowns will be key factors in many consequence analyses, especially as related to such factors as available data, randomness in affected populations, selection of acceptance criteria, selection of methods for assessing the impacts, and values of the affected and interested parties. (See Section 5, Chapter 4 by Notarianni for discussion on uncertainty, variability, and unknowns.)

In the vernacular of performance-based fire safety design, consequence analysis is often described in terms of establishing fire safety goals, objectives, and criteria; and tools, methods, and approaches to determining fire safety objectives can be found in pertinent references.⁷⁻¹⁰ Although such documents contain some guidance on selecting acceptance (performance) criteria, there is often a need to refer to more specific resources for details on particular physiological thresholds, material failure points and related impact-related criteria (e.g., see pertinent chapters in this handbook). For monetary valuation equivalents, guidance can be found elsewhere in this handbook (see Section 5, Chapter 6 by Ramachandran) as well as in the general risk literature.¹¹⁻¹³ It is worth noting, however, that valuation in terms of monetary worth can be difficult to achieve. This is especially true for life safety, where identifying a value for human life can be difficult (if not impossible) and controversial.¹⁴⁻²⁰ Discussions on monetary valuation for the purpose of insurance/no-insurance tradeoffs can also be found in the literature.^{21,22}

Hazard Assessment

The purpose of a fire hazard assessment is to identify possible sources of fire ignition and various conditions that may result from the fire without consideration of the likelihood of occurrence. Fire hazard assessments typically involve surveys of facilities or processes to obtain such information as potential ignition sources, potential fuel sources, arrangement of fuel packages, building and

compartment configurations, and presence of fire safety features. Armed with this information, one either assumes ignition or established burning and estimates or predicts the fire growth, spread, and impact under a variety of fuel, compartment, and fire protection systems configurations. Identification of ignition sources requires knowledge of how ignition can occur (see Section 2, Chapter 8 in this handbook) and often involves simply a visual survey. However, visual inspections may be supplemented by general or facility-specific loss data, material hazard data sheets, and other sources of information as appropriate. This latter point is important, as a review of historical loss data can help minimize the chance of focusing too closely on unique hazards, while overlooking more common, but equally important hazards.

There are a number of tools and methods available to the fire protection engineer for the purpose of fire hazard assessment. Checklists are often used as a quick method to verify compliance with codes, standards, or recommended practices. They can be as simple or as detailed as needed, and can provide a good foundation for inexperienced persons to gain an understanding of potential hazards by making them focus on areas of concern. They can be used during design, as part of an approval process, and/or as part of an inspection and maintenance program. A potential downside may exist if the user focuses too much on the checklist and inadvertently ignores other hazards or potentially hazardous conditions. In addition, the user, if inexperienced, may not understand the relative importance of one item on the checklist over another, or how the hazard condition could manifest itself.

Safety reviews are typically performed for existing facilities and involve regularly scheduled visual inspections.²³ The primary purpose is to identify conditions or procedures that could lead to accidents (initiating events), illness, injury, or damage (consequences). As with a checklist, the scope of the review can be as simple or complex as deemed necessary. It may be simply a walk-through, or may require review of material safety data sheets (MSDSs), testing of systems, or other safety-related functions. Checklists and a routine schedule are often helpful components of a safety review.

A "what if" analysis is primarily a mental process used to help identify areas of concern for use in checklists, safety reviews, and the following tools and methods.²³ It involves people asking "what if" about potential situations or scenarios that could arise, such as "what if the pump fails?" or "what if the operator mistakenly activates switch A instead of switch B?" "What if" analysis is typically informal and is used as a basis for initiating more detailed analyses.

Checklists and "what if" analyses can be combined as part of hazard and operability (HazOp) studies.²³ A HazOp study primarily involves taking a checklist, a MSDS, a system flow or operation chart, or other document about a process or system and systematically asking questions aimed at determining outcomes for specific actions. For example, if a valve on a drawing is labeled "flow," the question might be asked, what happens when there is "no flow"? Where the answer is unknown or unsatisfactory, additional analysis is undertaken. As with "what if" analyses, HazOps tend to be more informal than formal.

More formal approaches include failure modes and effects analysis (FMEA) and failure modes and effects and criticality analysis (FMECA).²³ FMEA and FMECA require a tabulation of equipment, components and systems, their failure modes, the effect of the failure, and the criticality of the failure (in a FMECA). These analyses typically focus on single-mode failures, and usually do not include human failure analysis.

If, after application of one of the above methods, a potential failure mode or hazard condition is deemed to require more detailed analysis, fault tree analysis (FTA) or event tree analysis (ETA) is often used.²³ FTA is essentially a “reverse thinking” deductive technique that focuses on one particular event that could (or did) occur (typically an accident) and provides a structure for evaluating the potential causes of the event (e.g., given failure X, what could have been the cause). It does this by providing a structure, in the form of a graphic model, that an analyst uses to display various events, conditions, actions, and outcomes. The output of a FTA is a sequence of events that could lead to (or could have lead to) a failure, and may include component, equipment, system, operating and/or human actions, failures, or errors. Although FTA is primarily a qualitative tool as used in hazard assessment, it can be used as a quantitative risk assessment tool if probabilities are assigned to the various outcomes.

Whereas FTA begins with a failure and provides a structure to look for potential causes, event tree analysis (ETA) provides a structure for postulating an initiating event and analyzing the potential outcomes. The principle tool is a decision tree (as used in decision analysis) with branches for success or failure (yes or no, or other binomial output). The basic approach is to identify an initiating event, identify systems or strategies intended to mitigate the event, and ask the “success or failure” question for each system or strategy, building the tree in the process. As with FTA, ETA is primarily a qualitative tool as used in hazard assessment, but is often used as a quantitative risk assessment tool by assigning probabilities, much the way probabilities are used in a decision tree. (See Section 5, Chapter 13 and other sources.²⁴⁻²⁶)

Cause-consequence analysis combines the forward thinking concept of ETA with the reverse thinking concepts of FTA to provide a more broadly encompassing picture of possible sequences of events.²³ Although primarily a qualitative tool as used in hazard assessment, it can be overlaid with frequencies or probabilities where used as a quantitative risk assessment tool.

Human error analysis describes a group of task-analysis-based qualitative techniques used to better understand the types of errors people might make and under what circumstances. Although helpful in better understanding potential sources of error, it has been noted that some such analyses treat human error and reliability in much the same way as mechanical systems, and it is argued that “desirable systems states” may be a more appropriate model.²⁷ In essence, “desirable systems states” focus on the goals that systems are aiming to achieve; and with why, what, and how questions, focus in on the potential for errors in various states of the system. Where people are part of the system, this approach highlights ar-

reas of concern and uncertainty related to human reliability and error.

In addition to the above methods, a variety of analytical tools, such as models, are used to assist in the hazard assessment. As Britter²⁸ points out, models are useful for a variety of tasks, including

- A means of summarizing extensive analytical and experimental results in order to assist in the transfer of that knowledge and to focus attention on deficiencies in the knowledge base
- A means to provide knowledge in a form accessible to users with varying levels of expertise in the subject area
- A means to highlight the sensitivity of the output to the various input parameters
- Predictive tools for various scenarios of interest that have not, themselves, been tested

As used here, models can be mathematical or physical. Mathematical models include empirical models (based on correlation), models based on fundamental equations, analytical models (exact or approximate solutions to a set of equations in closed form), and numerical models (computational models). Physical models (simulations) rely on actual physical representations, often at a reduced scale (e.g., a wind tunnel), and sometimes with the actual material of concern (e.g., air movement in a wind tunnel), and sometimes with different materials with similar properties. Models are widely used to support fire hazard assessment. Details on fire effects modeling are provided elsewhere in this handbook and can be found throughout the fire literature. It is worth noting here that, regardless of the model one uses for fire hazard assessment or risk analysis, one must understand its uses, applications, and limitations; and appropriately account for the sources of uncertainty and variability that matter. (See Section 5, Chapter 4 by Notarianni for more details.)

Causal Relationship of Initiating Events, Hazards, and Consequences

In addition to being viewed as separate components, consequence analysis and hazard assessment can be thought of as two parts of a process for identifying and evaluating the potential for unwanted consequences (loss or harm of something that is valued) given some initiating event. This definition implies that an event without unwanted consequences does not constitute a hazard and that there is a causal relationship between initiating events and unwanted consequences. One way to assess the potential for some initiating event to result in unwanted consequences is to view the situation in terms of a causal sequence, which looks at the situation as starting with some basic human need and ending in some consequence(s).²⁹ The basic causal structure is illustrated in Figure 5-12.1.

In brief, there are a variety of basic human needs, such as shelter, companionship, and love, which in turn lead to wants or desires. These wants or desires often result in the application of some technology to address the want. Unfortunately, the choice of technology can result in an out-

Figure 5-12.1. Causal sequence.²⁸

come that exposes someone or something to loss or harm, resulting in some potential for unwanted consequences. To change the potential for unwanted consequences, one can modify the causal sequence by initiating one of six alternatives: modify wants, alter technology, block events, block outcomes, block the exposure, or block the consequence. This can be illustrated by example.

One basic human need is protection from the elements. To address this need, humans want shelters that provide protection from things such as rain, snow, and cold temperatures. To address this want, they may choose to live in structures that provide protection from rain and snow and can be heated to a comfortable temperature. Furthermore, they may choose to build these structures out of wood and to use an open fire as a source of heat. Under “normal” circumstances, everything could work fine, and the choice of technologies would provide the desired benefits. However, there could be some event, such as the blocking of a ventilation opening or too much fuel being put on the fire, that could lead to potentially unwanted outcomes. These outcomes, such as the presence

of smoke, CO, or excessive temperatures in the structure, could then lead to exposures to people and property and ultimately result in unwanted consequences. Such a sequence can be illustrated diagrammatically as shown in Figure 5-12.2.

By applying an assessment methodology such as the causal sequence, one is able to visualize events, outcomes, exposures, and consequences in a systematic manner. The application can be as simple or as complex as needed, with the addition of multiple events, outcomes, exposures, and consequences and the addition of feedback loops providing further detail. Furthermore, the approach is compatible with various other hazard assessment techniques, as outlined previously, that may be more focused on specific parts of an overall assessment problem. This is illustrated in Figure 5-12.3.

As can be seen in Figure 5-12.3, numerous methods and approaches can be used for specific hazard assessments. Although some are applicable to a variety of problems, many are intimately associated with specific characteristics of the hazard, the type of risk problem, the

Figure 5-12.2. Illustration of potential unwanted fire-related consequences.

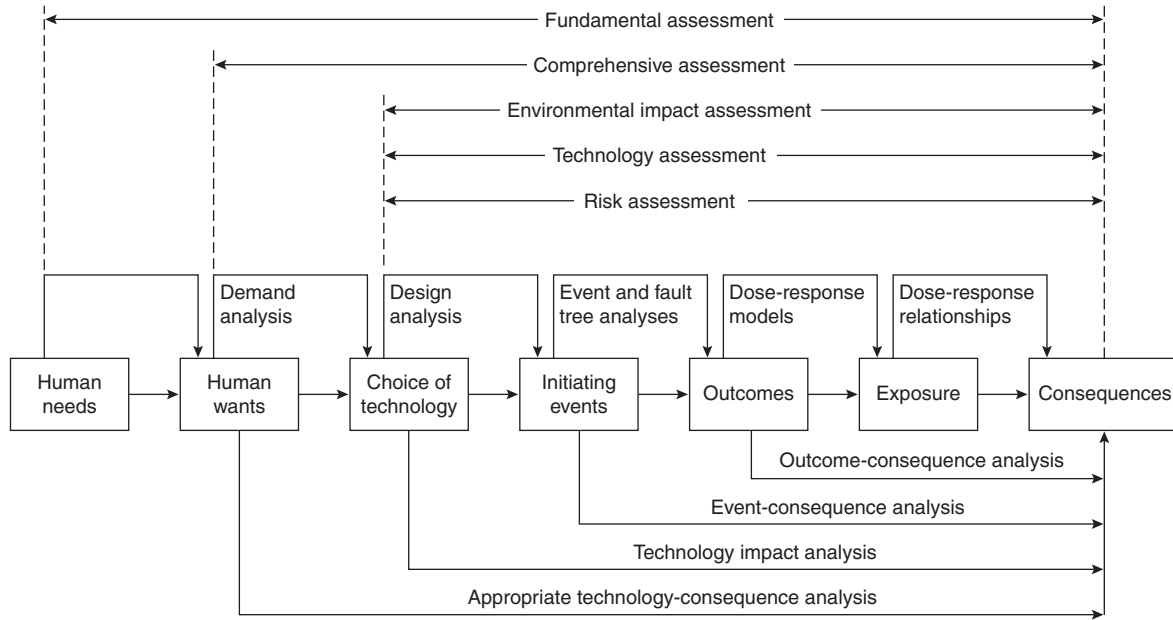

Figure 5-12.3. Modes of analysis compatible with the causal structure.²⁸

current state of knowledge, and the available technology. For example, most health hazard and risk assessments (toxicological, physiological, cancer, disease) rely heavily on epidemiological studies and dose-response relationships and models.³⁰⁻³⁴ In these cases, a causal relationship is often sought between exposure to a substance and unwanted outcomes (e.g., exposure to asbestos and the causation of cancer). Such approaches may be considered if an incapacitation assessment is being undertaken. For technology-related hazard and risk assessments, the focal point is typically the relationship between initiating events and outcomes (through to consequences). For these analyses, methods such as those outlined previously, like failure mode and effects analyses, fault tree analyses, and event tree analyses are often used.^{2,23,35-39}

Fire Safety Concepts Tree

A useful tool for fire hazard and consequence analysis is the *fire safety concepts tree*.⁴⁰ The fire safety concepts tree is a graphical representation of the deliberations and professional judgments of the NFPA Technical Committee on Systems Concepts for Fire Protection in Structures, and represents one way in which building fire safety can be viewed.⁴¹ It is divided into two primary branches, “prevent fire ignition” and “manage fire impact,” with the concept being that one or the other must be accomplished in order to meet one’s fire safety objectives. One can use the tree as a guide to evaluate potential fire impacts in those cases where a building fails to meet the criteria of one or more branches (e.g., if ignition is not prevented, one can evaluate the ability of the building’s systems to manage the fire impact). One can also modify the fire safety concepts tree into the form of an event tree or a decision tree for risk analysis.

A portion of the fire concepts tree is provided in Figure 5-12.4, which shows the top-level choices, “prevent ignition” or “manage fire impact.” A complete version of the event tree can be found in NFPA 550, *Guide to the Fire Safety Concepts Tree*.⁴⁰

Assessing the Likelihood of Occurrence

Thus far, the risk analysis components of determining what is valued and assessing the hazard conditions that may occasion the loss or harm have been discussed. The final component is concerned with obtaining a judgment on the likelihood of specific losses occurring to what is valued. The concepts of frequency, probability,

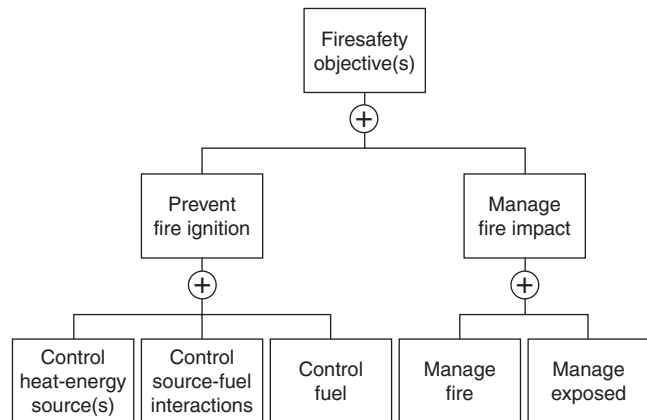

Figure 5-12.4. Top branch of the fire concepts tree.⁴⁰

and the differing views of probability are important to this discussion.

One dictionary defines probability as the likelihood of an occurrence expressed as the ratio of the number of actual occurrences to that of possible occurrences, and frequency as the rate of occurrence.⁴² (Inherent in these definitions is the concept of events per unit time.) Thus, a frequency of fire ignitions during a specific period of time, on its own, is not an indication of the probability of fire ignition. To obtain a probability of fire ignition, an estimate of the number of possible occurrences is required as well. For example, a hypothetical statistic of 20 fires per year occurring in toasters as they are switched on is a *frequency*. To estimate the *probability* of a fire in a toaster when it is switched on, one would also need data on the total number of times toasters are switched on per year. If one had data which indicated that toasters are switched on 20 million times per year, one could then estimate the probability of fires in toasters as they are switched on as 20 fires per 20 million toaster starts per year, or one in a million per year.

Probability theory is a branch of mathematics that deals with the modeling of uncertainty through measures of relative likelihood of alternative occurrences.⁴³ Measuring likelihood is one place where the differing view of frequentists and subjectivists comes into play: the estimation of actual and possible occurrences. As noted earlier in this chapter, frequentist approaches rely heavily on data from observed events whereas subjectivist approaches utilize the current state of knowledge coupled with judgment. This distinction is important to remember because fire is a relatively rare event and thus data are somewhat limited. In addition, people can change the nature of the fire hazard over time (e.g., by reconfiguring buildings, changing contents), and the material composition of building products and contents will likely change, making the ability to predict future hazards or risks, based on past loss experience, challenging at best.

Such conditions provide a strong argument for the use of subjective probability measures over objective measures for building fire risk analysis. Because data are often scarce, and actual occurrences and possible occurrences may not be precisely known, it is often necessary to make estimates. At issue is how one chooses to make the required estimates.⁴⁴ For example, whereas one may have frequency data on fire ignitions in a particular class of buildings, a subjective judgment relative to the number of possible future occurrences may be more appropriate than a judgment based on statistical treatment of limited and potentially highly-uncertain data.

Regardless of the differences in philosophy between frequentists and subjectivists, data are needed. Sources of fire loss data, including fire frequency data, can be found in Section 5, Chapter 5 by Hall and Ahrens, as well as in various other publications, including annual⁴⁵ and periodic^{46,47} journal articles, NFPA reports,⁴⁸ government reports,⁴⁹ and handbook appendices.^{10,50,51} In addition, it should be clear that the concepts of uncertainty, variability, and unknowns, by the nature of the problem, are critical concerns in risk analysis and must be appropriately addressed. (See the following section as well as Section 5, Chapter 4 by Notarianni.)

Uncertainty, Variability, and Unknowns

The amount of literature on the topics of uncertainty, variability, and unknowns indicates that identifying, understanding, and addressing these are clearly critical issues. For example, these issues pervade discussions of acceptable risk,⁵²⁻⁵⁵ risk characterization,³ risk assessment,^{38,56-60} and decision analysis.^{11,13,61-64} However, as one can see from a review of the various reference sources, there seems to be little consensus regarding how to treat these factors. There are several reasons for this, many of which impact building fire risk analysis, including

- The risk problem may not be clearly understood or sufficiently well defined.^{3,54} Any uncertainty in the problem definition will be propagated throughout the risk assessment and management process. If this uncertainty is large (i.e., if the stakeholders do not agree on key issues or parameters of the problem), the uncertainty in any proposed solution will be some factor greater.
- There are many types of uncertainties that go unrecognized or ignored.^{3,54,57,59} These include uncertainties in variables that are built into analytical tools and methods, uncertainties associated with criteria selected for assessing acceptability, and uncertainties in human behavior, attitudes, and values.
- There may be variability that is treated as uncertainty.^{32,59,60} If the risk problem relates to the human population, for example, it should be recognized that both uncertainty and variability exist, and that they need to be addressed differently. It may not be known how many people may be exposed (uncertainty), and for any population postulated to be exposed, there will be differences among the individuals (variability). Uncertainty and variability become important when discussing issues such as using the entire population or some subset of sensitive or vulnerable persons, and if the latter is selected, what defines the subset.
- There may be unknowns that are treated as uncertainties.^{3,65-67} In some cases, it is impossible to accurately predict some event that may happen far into the future, or to control the circumstances upon which certain assumptions are based. If these indeterminate events are treated as events that can be accurately predicted, the uncertainties in any solution could be significant (see Reference 3).
- There may be disagreement regarding how to address uncertainties of different types. First, the differences between uncertainty, variability, and indeterminacy need to be identified.⁶⁰ Then one needs to identify appropriate mechanisms to address the uncertainty, variability, or indeterminacy. For example, Morgan and Henrion⁵⁷ argue that the only type of quantities whose uncertainty may be appropriately represented in probabilistic terms are empirical quantities. However, there are other types of quantities, such as model domain parameters, decision variables, and value parameters. For these, parametric or switchover analysis (or other) may be needed.
- There may be disagreement on a quantitative methodology (or set of quantitative methodologies) for treating uncertainty. Even if it is decided to perform a

probabilistic analysis on an empirical quantity, there may be disagreement as to an appropriate approach to apply. For example, probabilistic approaches range from classical, statistical-based analyses to subjective, Bayesian analyses, with other types of quantitative or qualitative analyses scattered in between.^{3,44,68,69} To complicate the issue, frequentists often reject the Bayesian approach, and vice versa.

- There is concern that the data, mathematical rigor, and expertise needed to conduct a quantitative uncertainty analysis would render such an analysis impracticable in many situations, and as a result, the analysis would not be undertaken or would be performed incorrectly.⁷⁰

To help people better understand the complex issues surrounding uncertainty, variability, and unknowns (hereafter lumped as uncertainty for convenience), various taxonomies and treatments have been suggested.^{3,7,54,57,71,72} Regardless of specific differences, much of the literature identifies the following areas as requiring consideration: scientific uncertainty; human factors uncertainty; uncertainty in risk perceptions, attitudes, and values; and decision-making uncertainty.

Scientific uncertainties result from lack of knowledge (either obtainable through further study or due to random chance and variations) and from necessary approximations. They are often among the most readily recognizable and quantifiable uncertainties, and can be grouped into five subcategories: theory and model uncertainties, data and input uncertainties, calculation limitations, level of detail of the model, and representativeness.^{7,28,71,72}

Theory and model uncertainties may arise when physical processes are not modeled due to a lack of knowledge about them or about how to include them, when processes are modeled based on empirically derived correlation, and/or when simplifying assumptions are made. Data and input uncertainties arise from inaccuracies in data collection and reporting, incomplete knowledge of specific input values and variations in those values as a function of confounding factors, and input errors made by the modeler. Calculation limitations encompass such factors as the control volume selected for modeling, the level of detail of the model, and the model-domain parameters specified. Representativeness relates to how well the modeled situation reflects reality.

In considering human factors, uncertainty and variability are present in several modes. There is uncertainty regarding who might be affected and how. That is, it is not always known who will be impacted (uncertainty or indeterminacy), and within the population affected, there will be physiological uncertainties and variability. There are also uncertainties and unknowns related to how people will react in different situations, especially under stress.

As discussed earlier, there can be significant differences in the way people perceive and value risk, as well as in their attitudes about risk. Differing perceptions give rise to both variability and uncertainty, and capturing these differences is important. There will be situations in which age, family, infirmity, or other factors or conditions will impact perceptions of risk. There may be social, eco-

nomie, philosophical, religious, or cultural differences in people's values systems. In addition, some people are risk tolerant, while others are risk averse. It is important to recognize these differences exist, and thus reduce uncertainty and unknowns, and better understand and address variability where it exists. Also important are the perceptions and issues of equity, efficacy, and fairness—issues of importance in risk characterization and management.⁶⁴ Here again, social, economic, or cultural differences of the interested and affected parties may play a major role.

There is also uncertainty in the decision-making process, including uncertainty about how to best define the decision problem, difficulties in assessing the facts of the matter, difficulties in assessing relevant values, uncertainties about the human element in the decision-making process, and difficulties in assessing the quality of the decisions that are produced.⁵⁴

All of these factors should be considered and appropriately accounted for when undertaking a building fire risk analysis. For more details on uncertainty and its treatment, see Section 5, Chapter 4, "Uncertainty," by Notarianni in this Section.

Building Fire Risk Analysis Approaches, Methods, and Models

This section provides a brief overview of various qualitative and quantitative risk analysis approaches, tools, and methods available to fire protection engineers. This section does not constitute a comprehensive review, and readers are urged to consult the fire and risk literature for more approaches to risk analysis and for more details on the approaches discussed herein.

Magnusson²⁵ suggests that there are two primary approaches to risk analysis: the single scenario, analytic safety index β approach, and the multi-scenario, event-tree approach. In the single scenario, analytic safety index β approach, there is a single-limit state described by an analytical expression developed from physically derived correlation (e.g., mass flow in plumes, smoke-filling times, radiation from flames) or from response surface equations describing output from a computer program. The design problem is formulated in terms of the limit state function, G , as $G(X_1, X_2, \dots, X_n) = 0$. The parameters X_i are stochastic parameters describing the system, such as fire growth rate and response time of occupants. The goal is to find a solution given the constraint that $P(G < 0) < P_{\text{target}}$.

Challenges and limitations to the use of this approach include difficulty in developing appropriate analytical expressions, difficulty in developing uncertainty factors, and the limitation of being a single-scenario application. Nonetheless, this approach is useful for some applications, and details can be found in the literature.²⁴⁻²⁶ Although not developed, it has been suggested that this basic approach can be applied more broadly to the building fire problem as well.^{73,74}

Event tree analysis (ETA) is often used to analyze complex situations with several possible scenarios, where several fire or life safety systems are in place or are being

considered. In brief, event trees are developed for a scenario, and probabilities and frequencies for components are applied (see previous discussion on ETA). In the *SFPE Engineering Guide to Performance-Based Fire Protection Analysis and Design*,¹⁰ the method for quantifying fire risk from multiple fire scenarios is given as

$$\text{Risk} = \text{Risk}_i = (\text{Loss}_i < F_i)$$

where

Risk_{*i*} = risk associated with scenario *i*

Loss_{*i*} = loss associated with scenario *i*

F_i = frequency of scenario *i* occurring

This relationship is similar to the general discussion on engineering risk analysis discussed earlier, but in the case, the term “loss” is used instead of “consequence,” and the summation indicates “total” risk from multiple scenarios. This type of risk analysis, commonly referred to as probabilistic risk assessment (PRA), is widely used in the chemical process industry (see Section 5, Chapter 13) and for fire safety assessments of nuclear facilities,³⁷ and is beginning to see broader application in fire protection engineering applications.^{10,24-26,39}

Although ETA-based risk analyses methods are applicable to multi-scenario situations, it does not mean such approaches are necessarily simple. This can be illustrated using a three-room example. Figure 5-12.5 shows

Figure 5-12.5. Event tree for three-room fire risk analysis.¹⁰

an event tree for a three-room building that is compartmented as shown. For this example, the fire scenario frequency, *F_i*, is assumed to be uniformly distributed across the three rooms, and the consequence of a single room loss is *C/3* (i.e., the consequence of losing all three rooms to a fire would be *C*).¹⁰

If the probability that the fire will be contained in one room is *P_c*, and is prevented from propagating to the third is *P_f*, then the overall risk as shown in Figure 5-12.5 can be estimated as

$$\begin{aligned} R = & \frac{C}{3}[F_i P_1 P_c] + \frac{2C}{3}[F_i P_1 (1 - P_c) P_f] \\ & + C[F_i P_1 (1 - P_c)(1 - P_f)] + \frac{C}{3}[F_i P_2 P_c] \\ & + \frac{2C}{3}[F_i P_2 (1 - P_c) P_f] + C[F_i P_2 (1 - P_c)(1 - P_f)] \\ & + \frac{C}{3}[F_i P_3 P_c] + \frac{2C}{3}[F_i P_3 (1 - P_c) P_f] \\ & + C[F_i P_3 (1 - P_c)(1 - P_f)] \end{aligned}$$

where *P₁*, *P₂*, and *P₃* are the probabilities that a fire will start in room 1, 2, or 3, respectively.

With some mathematical manipulation, the above equation simplifies to the following:

$$R = \frac{CF_i}{3}[3 - 2P_c - P_f + P_c P_f]$$

For this example *P_c* and *P_f* can be interpreted as the success probabilities of the fire barriers. To place these results in context, numeric values will be added. If *P_c* and *P_f* are both equal to 0.1 (i.e., fire propagates 9 in 10 times), then the risk is

$$R = \frac{CF_i}{3}[3 - 2(0.1) - (0.1) + (0.1)(0.1)] = 0.90CF_i$$

If *P_c* and *P_f* are both equal to 0.9 (i.e., fire propagates 1 in 10 times), then the risk is

$$R = \frac{CF_i}{3}[3 - 2(0.9) - (0.9) + (0.9)(0.9)] = 0.37CF_i$$

If *P_c* and *P_f* are set to unity (i.e., fire barriers never fail), then the risk is

$$R = \frac{CF_i}{3}[3 - 2(1) - (1) + (1)(1)] = \frac{CF_i}{3} \cup 0.33CF_i$$

Although this example is very simplified, it suggests how complicated a classical ETA-based engineering risk analysis can be. For each fire protection feature considered, the number of branches (i.e., potential outcomes) in the event tree will increase. Given that this increase is usually geometric, the analysis can become quite complex.

The above example also illustrates an important concept in risk-based calculations. The bounding risk for this problem would be *CF_i* (i.e., complete facility loss). This is the risk if all fire protection features are assumed

to always fail. The risk when the fire protection features are always assumed to work (i.e., the fire barriers never fail, thus P_c and P_f are set to unity) is the lower bound risk. Thus, the potential range for the calculated risk is bounded between $0.33CF_i$ and CF_i . The better the protection, the closer the risk will approach $0.33CF_i$.

The above example can also be used to illustrate the difference between fire scenarios (all possible scenarios that could occur) and design fire scenarios (that subset of fire scenarios selected for design purposes).¹⁰ For example, the total range of fire scenarios for the above example could consider various room-to-room sequences (e.g., starts in room 1, then goes to room 2 and finally to room 3.) If this is done, one finds that there are a total of 15 possible paths of fire propagation:

1. Starts in room 1 and is contained in room 1
2. Starts in room 1 and propagates to room 2, but not to room 3
3. Starts in room 1 and propagates to room 3, but not to room 2
4. Starts in room 1 and propagates to room 2 and then to room 3
5. Starts in room 1 and propagates to room 3 and then to room 2
6. Starts in room 2 and is contained in room 2
7. Starts in room 2 and propagates to room 1, but not to room 3
8. Starts in room 2 and propagates to room 3, but not to room 1
9. Starts in room 2 and propagates to room 1 and then to room 3
10. Starts in room 2 and propagates to room 3 and then to room 1
11. Starts in room 3 and is contained in room 3
12. Starts in room 3 and propagates to room 1, but not to room 2
13. Starts in room 3 and propagates to room 2, but not to room 1
14. Starts in room 3 and propagates to room 1 and then to room 2
15. Starts in room 3 and propagates to room 2 and then to room 1

If simultaneous propagation to the second and third room were considered a significant threat, there would be three additional scenarios. This brings the total scenarios to 18 before considering such details such as doors being open or closed, whether people of various characteristics are in the rooms, and whether they are sleeping.

It is also important to address the fact that fire protection systems may not always be operational. As such, the concepts of availability and reliability should be addressed. A system is considered available when it is ready and able to perform its intended function (e.g., a smoke detection system is installed and working). If a system is taken out of service, even temporarily (e.g., it is undergoing maintenance), it is unavailable. A risk-based approach should consider some probability that a system will be unavailable if it is a possibility. A system that is available but not functional is considered unreliable (e.g., the smoke detection system is installed but the smoke detec-

tor opening is blocked with duct tape). Probabilities can be developed for evaluation of system availability and reliability. Availability and reliability are reported or derived as a composite value. (When the latter is the case, it should be made explicit.)

Risk-Cost Assessment Model

Because of the complexity of ETA-based risk analysis, computers are often used to enable multiple scenarios to be evaluated in relatively short timeframes. Two such models, CESARE-Risk and FIRECAM, are based on a fire risk and cost assessment model developed by Beck⁷⁵⁻⁷⁷ and expanded collaboratively by Beck and Yung.^{77,78}

A brief description of the current risk-cost assessment model and its submodels are given in this section.⁷⁹ More detailed descriptions are given for the design fire submodel, fire growth submodel, and the smoke movement submodel. As for the other submodels, more details can be found in other publications.^{76,78,80-82}

The risk-cost assessment model employs an event-based modeling approach in which events are characterized by discrete times and probability of occurrence. The event-based approach is used to define the outcomes of fire growth and spread scenarios in terms of the times of occurrence of untenable conditions. The consequence of these outcomes is in terms of the number of people exposed to untenable conditions.

The risk-cost assessment model for office and apartment buildings assesses the fire safety performance of a fire protection design in terms of two decision-making parameters: (1) the expected risk-to-life (ERL) and (2) the fire-cost expectation (FCE). The ERL is the expected number of deaths over the lifetime of the building divided by the total population of the building and the design life of the building. The FCE is the total fire cost, which includes the capital cost for the passive and active fire protection systems, the maintenance cost for the active fire protection systems, and the expected losses resulting from fires in the building. The ERL is a quantitative measure of the risk-to-life from all probable fires in the building, whereas the FCE quantifies the fire cost associated with the particular fire safety system design.

To calculate the ERL and FCE values, the risk-cost assessment model considers the dynamic interaction between fire growth, fire spread, smoke movement, human behavior, and the response of fire brigades. These calculations are performed by a number of submodels interacting with each other, as shown in the flowchart in Figure 5-12.6. In Figure 5-12.6, the term "submodel" has been abbreviated as "model."

Design Fire Submodel

The risk-cost assessment model uses six design fires in the room of fire origin, and the subsequent fire and smoke spread, to evaluate life risks and protection costs in office and apartment buildings. The six design fires, representing the wide spectrum of possible fire types, are

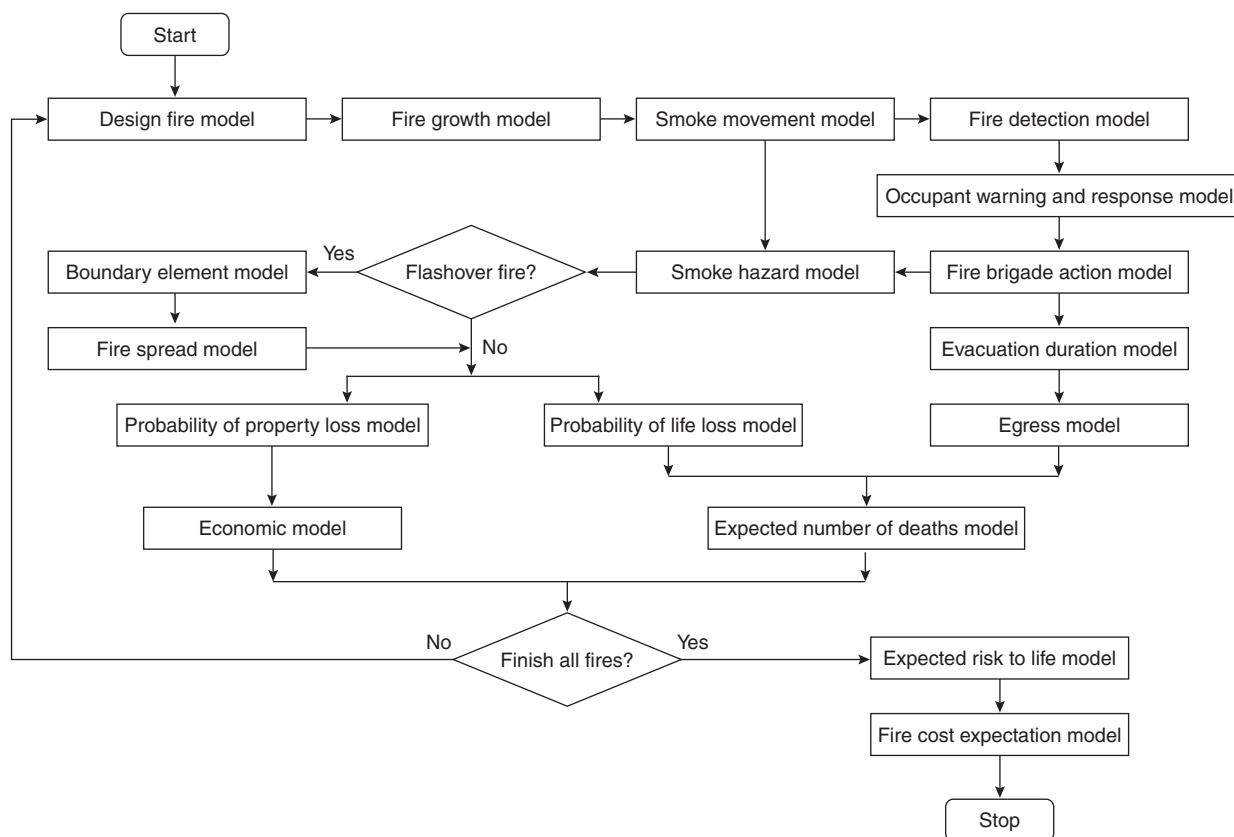

Figure 5-12.6. Risk-cost assessment model.

1. Smoldering fire with room entrance door open
2. Smoldering fire with room entrance door closed
3. Flaming non-flashover fire with room entrance door open
4. Flaming non-flashover fire with room entrance door closed
5. Flashover fire with room entrance door open
6. Flashover fire with room entrance door closed

The probability of occurrence of each design fire, given that a fire has occurred, is based on statistical data. For example, in Canada, statistics show that 18 percent of all apartment fires reach flashover and become fully developed fires, 63 percent are flaming fires that do not reach flashover, and the remaining 19 percent are smoldering fires that do not reach the flaming stage.⁸³ If sprinklers are installed, the model assumes that some of the flashover and non-flashover fires, depending on the reliability and effectiveness of the sprinkler system, are rendered non-lethal.

The risk-cost assessment model evaluates the effects of various fire scenarios that may occur in the building during its life. For example, in an apartment building, one fire scenario is the fire and smoke spread resulting from one design fire in any one of the apartment units in the building and during a time when the occupants are either awake or asleep. The number of fire scenarios, therefore,

is the product of the number of design fires, the number of apartment units, and whether the occupants are awake or asleep.

Fire Growth Submodel

The fire growth submodel⁸⁴ predicts the development of the six design fires in the room of fire origin. The submodel calculates the burning rate, room temperature, and the production and concentration of toxic gases as a function of time. With these calculations, the model determines the time of occurrence of five important events: (1) time of fire cue, (2) time of smoke detector activation, (3) time of sprinkler activation, (4) time of flashover, and (5) time of fire burnout. The first three detection times are used by the evacuation duration submodel to estimate the time available for evacuation; the flashover time is used by the fire brigade action submodel, in combination with the arrival time of the fire brigade, to evaluate the effectiveness of fire fighting; and the burnout time is used by the smoke hazard submodel as part of the calculation for the maximum smoke hazard. The submodel also predicts the mass flow rate, the temperature, and the concentrations of CO and CO₂ in the hot gases leaving the fire room. This latter information is used by the smoke movement submodel to calculate the spread of

smoke to different parts of the building as a function of time.

Smoke Movement Submodel

The smoke movement submodel⁸⁵ calculates the spread of smoke and toxic gases to different parts of the building as a function of time. The submodel also calculates the critical time when the stairs become untenable, which is considered to be the time when the occupants are trapped in the building. This critical time is used later by the evacuation duration submodel to calculate the time available for evacuation.

Fire Detection Submodel

The fire detection submodel calculates the probabilities of detection at the first three detection times mentioned under the fire growth submodel, based on the probabilities of detection by smoke detectors, sprinklers, and occupants. This information is used by the occupant warning and response submodel to calculate the probabilities of response of the occupants.

Occupant Warning and Response Submodel

The occupant warning and response submodel calculates the probabilities of warning and response at the first three detection times mentioned under the fire growth submodel. This information is used by the fire brigade action submodel to calculate the probability of response of the fire brigade, and by the egress submodel to model the evacuation of the occupants.

Fire Brigade Action Submodel

The fire brigade action submodel calculates the probability and time of arrival of the fire brigade. This submodel also evaluates the effectiveness of fire fighting, based on the flashover time from the fire growth submodel and the arrival time of the fire brigade. The information on arrival and effectiveness of the fire brigade is used by the smoke hazard submodel to calculate the maximum smoke hazard to the occupants, and by the fire spread submodel to calculate the probabilities of fire spread.

Smoke Hazard Submodel

The smoke hazard submodel calculates the maximum smoke hazard to the occupants based on the burnout time from the fire growth submodel and the arrival time and effectiveness of the fire brigade from the fire brigade action submodel. This information is used by the life loss submodel to calculate the probabilities of life loss.

Evacuation Duration Submodel

The evacuation duration submodel uses the three fire detection times from the fire growth submodel and the

critical time in the stairs from the smoke movement submodel to calculate three durations available for evacuation. This information is used by the egress submodel to model the evacuation of the occupants.

Egress Submodel

Based on the evacuation time available and the probability of response of the occupants, this submodel calculates the number of occupants who have evacuated the building and the number trapped in the building. This information is used by the expected number of deaths submodel to calculate the expected number of deaths.

Boundary Element Submodel

The boundary element submodel calculates the probabilities of failure of the boundary elements (walls, floors, doors, etc.) when they are subjected to fully developed, realistic fires. The submodel comprises the following probabilistic models: fire severity, temperature distribution, thermo-mechanical material properties, failure performance for each limit state, and overall probability of failure.

Fire Spread Submodel

Based on the probabilities of failure of the boundary elements, this submodel calculates the probabilities of fire spread to each part of the building given a fully developed fire in any enclosure. A probabilistic network of the building is developed where nodes represent building volumes, links represent boundary elements between volumes, and probabilities of failure of the boundary elements are assigned to links. Allowance is made for the effectiveness of the fire brigade. The probability of fire spread information is used by both the property loss submodel and the life loss submodel to estimate fire losses and life loss.

Life Loss Submodel

Based on the probabilities of smoke hazard from the smoke hazard submodel and fire spread from the fire spread submodel, this submodel calculates the probabilities of life loss.

Expected Number of Deaths Submodel

Based on the probabilities of life loss from the life loss submodel and the number of occupants trapped in the building from the egress submodel, this submodel calculates the expected number of deaths in the building.

Property Loss Submodel

Based on the probabilities of fire spread from the fire spread submodel, this submodel calculates the expected property loss.

Economic Submodel

Based on the expected property loss and the capital and maintenance costs of the fire protection systems, this submodel calculates the expected fire costs.

Expected Risk-to-Life Submodel

The expected risk-to-life submodel calculates the overall expected risk to life (ERL) by summing the expected number of deaths in the building for each fire scenario and the probability of each fire scenario.

Fire-Cost Expectation Submodel

The fire-cost expectation submodel calculates the fire-cost expectation (FCE) using the capital and maintenance costs of the fire protection systems, the expected fire loss for each fire scenario, and the probability of each fire scenario.

Assumptions and Limitations

In the risk-cost assessment model, due to the complexity and the lack of sufficient understanding of fire phenomena and human behavior, certain conservative assumptions and approximations were made in the mathematical modeling. In addition, not all aspects of the risk-cost assessment model have been fully verified by full-scale fire experiments or actual fire experience. Only some of the submodels have been verified by experiments or statistical data.

As a result, the predictions made by the model can only be considered as approximate. The model, therefore, should not be used for absolute assessments of life risks and protection costs. For comparative assessments of life risks and protection costs, and for the selection of a cost-effective fire safety system design solution, the model is considered to be reliable.

As in many computer models, the model uses certain input parameters to describe the characteristics of various fire safety designs. These include the fire resistance rating of boundary elements, the reliability of smoke alarms and sprinklers, the probability of doors open or closed, and the response time of fire brigades. The sensitivity of these parameters on the predicted risks have been checked and found to be reasonable.⁸⁶

FRAMEworks

Another computer-based risk assessment model, *FRAMEworks*, was developed through a collaborative effort between the National Institute of Standards and Technology (NIST), the NFPA Fire Analysis & Research Division, and the private consulting firm of Benjamin/Clarke Associates.^{87,88} The goal of this effort was to develop an objective, comprehensive, generally applicable, and widely recognized fire risk assessment methodology for products that go into buildings. The result was a method for quantifying the fire risk associated with a specific class of products in a specified occupancy.

FRAMEworks is similar in many respects to the fire risk and cost assessment model of Beck described above. It combines a quantitative (fire effects modeling) method to evaluate specific products in specific fire scenarios with a statistical method of relating fire deaths to the specific scenarios in order to establish a death rate baseline for the scenarios. The impact of new or replacement products can then be evaluated against the baseline scenarios to determine if the risk is comparatively higher or lower with a change of product(s).

The modeling sequence to compute fire risk in *FRAMEworks* is illustrated in Figure 5-12.7. A more detailed description of the model can be found in the *NFPA Fire Protection Handbook*.⁸⁸

CRISP

A computer-based fire risk assessment model is also under development in the United Kingdom by the Building Research Establishment, Fire Research Station. This model, called CRISP (Computation of Risk Indices by Simulation Procedures), is similar to the Beck model in that it provides a Monte Carlo simulation of entire fire scenarios, but is an object-oriented model as opposed to a state transition model.^{89,90} The basic concept of the CRISP approach is that the building-contents-people system is treated as a collection of objects, represented by a section of the program that defines the objects' behavior in response to stimuli (input data). The objects may interact in a number of ways, depending on the information exchanged between them, but data associated with an object cannot be changed by another object (only by changing that object's code). Thus, for any given scenario, the objects will interact with each other, but not change each other, based on the associated object definition and input parameters.

The types of objects modeled include furniture, hot and cold gas layers, vents, walls, rooms, alarms, occupants, and fire fighters.⁸⁹ The actions of the objects are governed by physical relationships (e.g., fire growth) and tables of rules (e.g., for people). For each run, various conditions, contents, and occupant characteristics are randomly selected and probabilities are assigned. Once the conditions have been defined, the simulation predicts how a scenario develops with time until the fire is out or the occupants are dead or have escaped.

Thus far, the scope of CRISP runs have been limited to two-story residential occupancies, and have been used to evaluate such tradeoffs as fire detection installation versus the need for additional passive fire protection, and caution has been urged relative to the model's use in more complex buildings.⁹⁰

Hazard and Risk Matrices

In addition to the more complicated single-scenario and ETA-based engineering approaches and computer-based risk modeling, various risk analysis alternatives exist that combine hazard analysis, consequence analysis, and judgments about likelihood of events in less quantitatively rigorous manners. This does not imply the methods

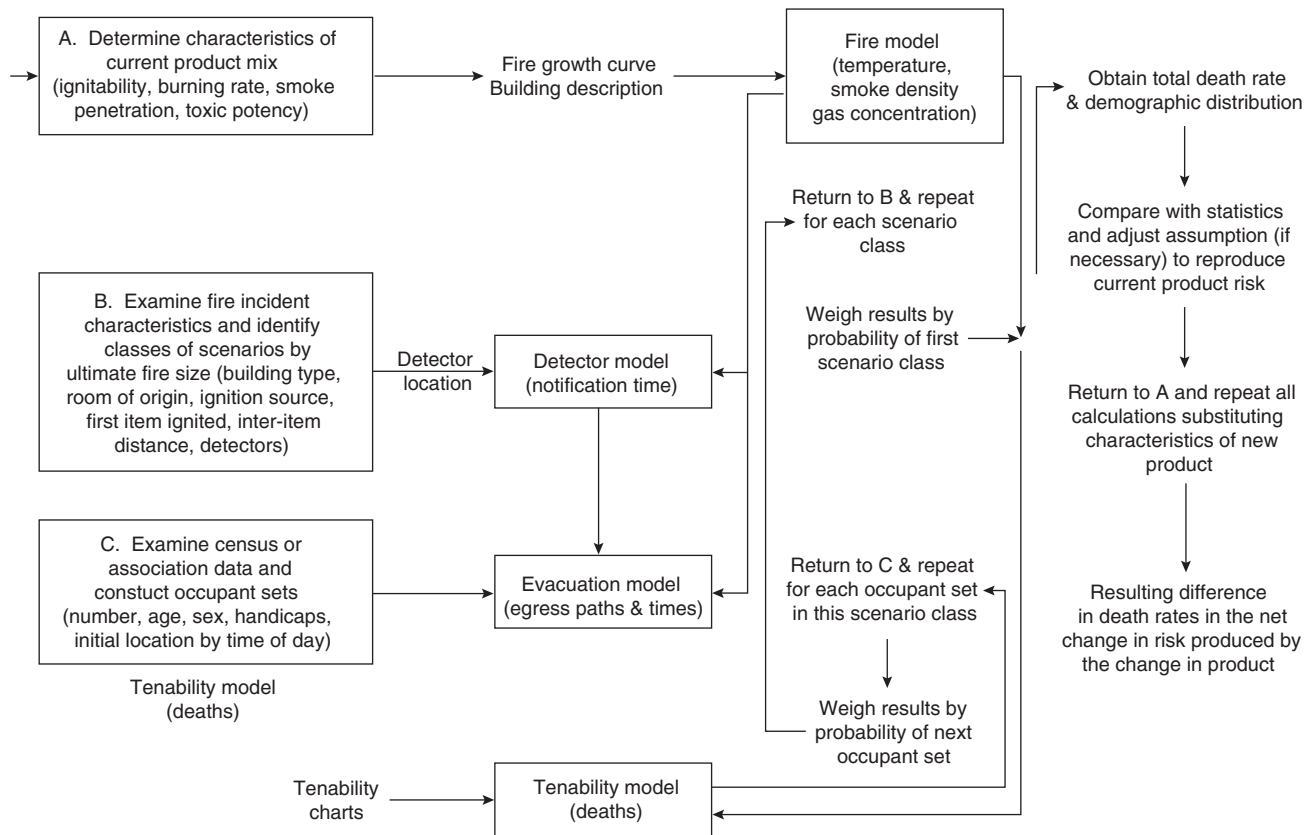

Figure 5-12.7. Modeling sequence to compute fire risk in FRAMEworks.⁸⁷

are less rigorous, or less appropriate, but that they are simply easier to apply. In many cases, such simplified approaches will be more widely accepted by interested and affected parties, as the concepts may be familiar.

One such approach is the hazard matrix,⁹¹ or risk matrix approach.^{10,92} This approach is simpler to apply than a classical engineering risk analysis approach, as the importance of identifying all possible outcomes is less critical. In essence, it works by quantifying the consequences of the most severe events anticipated and coupling these with approximate event frequencies. The result is a quantified approximate risk estimate. In this approach, a maximum consequence for each type of loss is identified (life safety, property, business interruption, environmental damage, etc.) that represents the largest realistic event of each type. Each maximum consequence is then ranked. Table 5-12.1 provides an example of possible consequence ranking thresholds (i.e., negligible, low, medium, and high) that may be selected. For these estimates, the consequence predictions should bound all possible event outcomes at the 95th percentile or better.¹⁰ The 95th percentile value is suggested since it has gained ready acceptance in other engineering fields, and by using such a standard value, it may be possible to compare different analyses. If it is desired to use a different bounding level, all stakeholders must agree. An extensive analysis can often be avoided when selecting the maximum conse-

quence if the total replacement costs are assumed to be the maximum consequence.

The frequencies must also be ranked in this type of analysis. Here, the frequencies should be for exceeding a specific loss (i.e., consequence) rather than for a specific scenario, as frequencies based solely on a specific scenario can be misleading. For example, a scenario may have a frequency of 10^{-7} per year, leading one to the conclusion that fire is not a concern. However, the reported fire risk should actually represent the frequency of multiple fire scenarios, so if 30 specific scenarios are developed, each at 10^{-7} fires per year, the net effect is 3×10^{-6} fires per year. Table 5-12.2 provides a specific example for frequency ranking.^{10,92} As with consequence ranking, alternate frequency rankings (bins) from those presented in Table 5-12.2 can be developed provided that all interested and affected parties agree. It is also possible to add additional layers of ranking where desirable.

Once the bounding consequences and their respective frequencies have been estimated, they must be converted to an estimate of risk. An estimation is accomplished by plotting the consequence-frequency combination in a matrix as shown in Figure 5-12.8 (the numbers in boxes are for identification purposes and do not imply a ranking). The stakeholders assign each consequence-frequency combination, and the resultant risks are considered bounding risks. After this analysis, events that meet a certain risk cri-

Table 5-12.1 Possible Consequence Ranking Criteria¹⁰

Consequence Level	Impact on Populace	Impact on Property/Operations
High (H)	Immediate fatalities, acute injuries—immediately life threatening or permanently disabling	Damage > \$XX million—building destroyed & surrounding property damaged
Moderate (M)	Serious injuries, permanent disabilities, hospitalization required	\$YY < damage < \$XX million—major equipment destroyed, minor impact on surroundings
Low (L)	Minor injuries, no permanent disabilities, no hospitalization	Damage < \$YY—reparable damage to building, significant operational downtime, no impact on surroundings
Negligible (N)	Negligible injuries	Minor repairs to building required, minimal operational downtime

Figure 5-12.8. Example risk ranking matrix.¹⁰

Table 5-12.2 Example Frequency Criteria Used for Probability Ranking¹⁰

Acronym	Description	Frequency Level (median time to event)	Description
A	Anticipated, expected	$> 10^{-2}/\text{yr}$ (<100 years)	Common incidents that may occur several times during the lifetime of the building.
U	Unlikely	$10^{-4} < f < 10^{-2}/\text{yr}$ (100 to 10,000 years)	Events that are not anticipated to occur during the lifetime of the facility. Natural phenomena of this probability class include: UBC-level earthquake, 100-year flood, maximum wind gust, etc.
EU	Extremely unlikely	$10^{-6} < f < 10^{-4}/\text{yr}$ (10,000 to 1 million years)	Events that will probably not occur during the life cycle of the building
BEU	Beyond extremely unlikely	$< 10^{-6}/\text{yr}$ (> 1 million years)	All other accidents

Performance Matrix

A concept similar to that of the hazard and risk matrices approach described above has been developed for use in building and fire safety regulations.^{1,4,5,93-95} This approach establishes a performance matrix that compares performance groups (building types grouped by like performance expectations) by magnitude of design events (probabilistic or deterministic descriptions of hazard event). Within the performance matrix, instead of having risk bins (groups), there are tolerable levels of impact (reflecting the amount of damage expected for buildings within different performance groups given specific magnitudes of design events). As the performance group increases from Group I to Group IV, the level of required performance increases, as do the corresponding levels of tolerable impact. This is illustrated in Figure 5-12.9.

Within the performance matrix, tolerable levels of impacts reflect various limit states of damage, injury, or loss that can be estimated, measured, and/or calculated when subjected to design loads of various magnitudes. As the impacts get larger, it is expected that more damage will occur, unless a higher level of performance is desired. In this manner, the levels of impact are inversely proportional to building performance: less impact means better performance. Establishment of these levels of tolerable impact requires a balance of technical knowledge and ability and societal values. The term *tolerable* is used to reflect the fact that absolute protection is not possible, and

terion may be considered "acceptable" based on the objectives and input from the interested and affected parties (e.g., the interested and affected parties may consider moderate, low, and negligible risk events acceptable).

		Increasing level of building performance			
		Performance groups			
		Performance group I	Performance group II	Performance group III	Performance group IV
Magnitude of design event Increasing magnitude of event	Very large (very rare)	Severe	Severe	High	Moderate
	Large (rare)	Severe	High	Moderate	Mild
	Medium (less frequent)	High	Moderate	Mild	Mild
	Small (frequent)	Moderate	Mild	Mild	Mild

Figure 5-12.9. Performance matrix.^{1,95}

that some damage, injury, or loss is currently tolerated in structures, especially after a hazard event. The term *impact* is used as a broad descriptor of loss.

If one so chooses, one can overlay probabilities and consequences on the performance matrix in a manner similar to the hazard and risk matrices discussed previously. In the performance matrix (Figure 5-12.9), the magnitudes of design event can be overlaid with probabilities (or frequencies) of event occurrence, from high at the bottom to low at the top. For all high-probability events, the allowable magnitude of impact (consequences) is either mild or moderate depending on the performance group. For low-probability events, the allowable magnitude of impact can be moderate, high, or severe depending on the performance group. This approach allows for decisions to be made on the required level of building performance for low-probability, high-consequence events, based on the performance group to which a building is designated.

Performance groups are simply consolidations of use groups with common performance requirements. They are developed as part of the risk characterization process, considering such issues as numbers of people in a building, sensitive or vulnerable populations, the hazards posed by the building, its contents or processes, and essential facilities and services. The number of performance groups that is required should be based on an analytical-deliberative risk characterization process as described previously. The following definitions of performance groups is one example as used in the International Performance Code for Buildings and Facilities:⁹⁵

Performance Group I is intended to cover those buildings or facilities, such as utility sheds, where the failure of such buildings poses a low risk to human life. Performance Group II is intended to be the minimum for most

typical buildings, such as business, mercantile, or storage uses. Performance Group III includes building and facilities with an increased level of societal benefit or importance. These structures and classes of structures require increased levels of performance as they house large numbers of people, vulnerable populations, or occupants with other risk factors; or they fulfill some role of increased importance to the local community or to society in general. Examples include post-disaster command control centers, acute-care hospitals, or a school used as an emergency shelter. Performance Group IV contains building uses or facilities that have an unusually high risk. Such facilities may include nuclear facilities or explosives storage facilities. For specific facilities, for specific jurisdictions, or in countries outside of the United States, other definitions for the performance groups may be appropriate.

Likewise, the number of tolerable levels of impact can be selected based on the level of detail deemed appropriate by interested and affected parties. One possibility is the use of four levels: mild, moderate, high and severe.⁹⁵ The definition of each level would reflect the tolerability limits as developed by a risk characterization effort. For example, a moderate level of impact may be defined as follows (remember that levels of impact are inversely proportional to levels of performance, and that these are design goals):

- There is moderate structural damage which is repairable; some delay in reoccupancy can be expected due to structural rehabilitation.
- Nonstructural systems needed for normal building use are fully operational, although some cleanup and repair may be needed. Emergency systems remain fully operational.
- Injuries to building occupants may be locally significant, but generally moderate in numbers and in nature. There is a low likelihood of single life loss and a very low likelihood of multiple life loss.
- Damage to building contents may be locally significant, but is generally moderate in extent and cost.
- Some hazardous materials are released to the environment, but the risk to the community is minimal. No emergency relocation is necessary.

Associated with the tolerable levels of impact is the actual hazard event. One way to look at the hazard event is in terms of its size, or magnitude. The magnitude of a hazard event can be represented deterministically or as a frequency of occurrence. When characterizing the magnitude of hazard events, it is important to remember that (1) they are on a continuum and are compartmentalized for ease of analysis and design; and (2) they should be considered "design loads," and not as a reflection of the actual magnitude of event that could impact a building.

As with tolerable levels of impact, the number of magnitude of event levels can be established by the interested and affected parties. For example, four categories of event magnitude (design loads) can be selected: small (frequent), medium (occasional), large (rare), and very large (very rare). To understand how the magnitudes can be described, consider earthquake loads and fire loads, where earthquake loads are shown in terms of their mean

return period, and fire loads are shown deterministically in terms of extent of flame spread.

Earthquake Loads (mean return period)

Frequent	72 years
Occasional	225 years
Rare	474 years
Very Rare	2475 years

Fire Loads (deterministic)

Small	Contained to object of origin
Medium	Contained to room
Large	Contained to floor
Very Large	Contained to building

There is often correlation between frequent, occasional, rare, and very rare; and small, medium, large, and very large; in that frequent events tend to be small, whereas very large events tend to be very rare. Also, it is often the very large or very rare events that are of particular concern, as it is these events for which providing high levels of protection against is costly and may not be considered reasonable or cost-effective for all buildings.

The Building Fire Safety Evaluation Method (BFSEM)

Another approach to identifying hazards and consequences, and for obtaining judgments on the likelihood of events occurring, is the *building fire evaluation method* (BFSEM).⁹⁶⁻⁹⁸ The BFSEM is a structured framework for evaluating building fire safety performance that can be used for hazard assessment or risk analysis. With this method, the user can evaluate the likelihood of ignition, fire growth, and fire spread through an existing building or new building for which plans have been developed, focusing on such factors as fuel loading, occupancy characteristics, active fire protection features, and structural features. Using network diagrams, the user evaluates such factors as ignition potential, fire growth potential within the compartment of origin, barrier performance, fire spread beyond the compartment of origin, and occupant safety. The user can assign subjective probabilities, based on experience and engineering judgment, or statistical data when available, to estimate the likelihood of each event occurring (the outcome is the likelihood that any event will or will not occur). Two network diagrams from the BFSEM are shown in Figure 5-12.10.

With the BFSEM, building fire safety performance is evaluated using experience and judgment regarding how fire will develop and spread considering fire-related factors such as fuel load and arrangement, and fire-protection features such as automatic and manual fire detection and suppression, barrier integrity, and emergency systems. When desired or required, experience and judgments can be supported by deterministic calculation methods. In attempting to determine the likelihood of successful control of a fire by sprinkler activation, for example, one must evaluate the ability of the fire to grow to a sufficient size to activate the sprinkler and then evaluate the likelihood that the sprinkler can control the fire. The latter action may involve an evaluation of the sprinkler

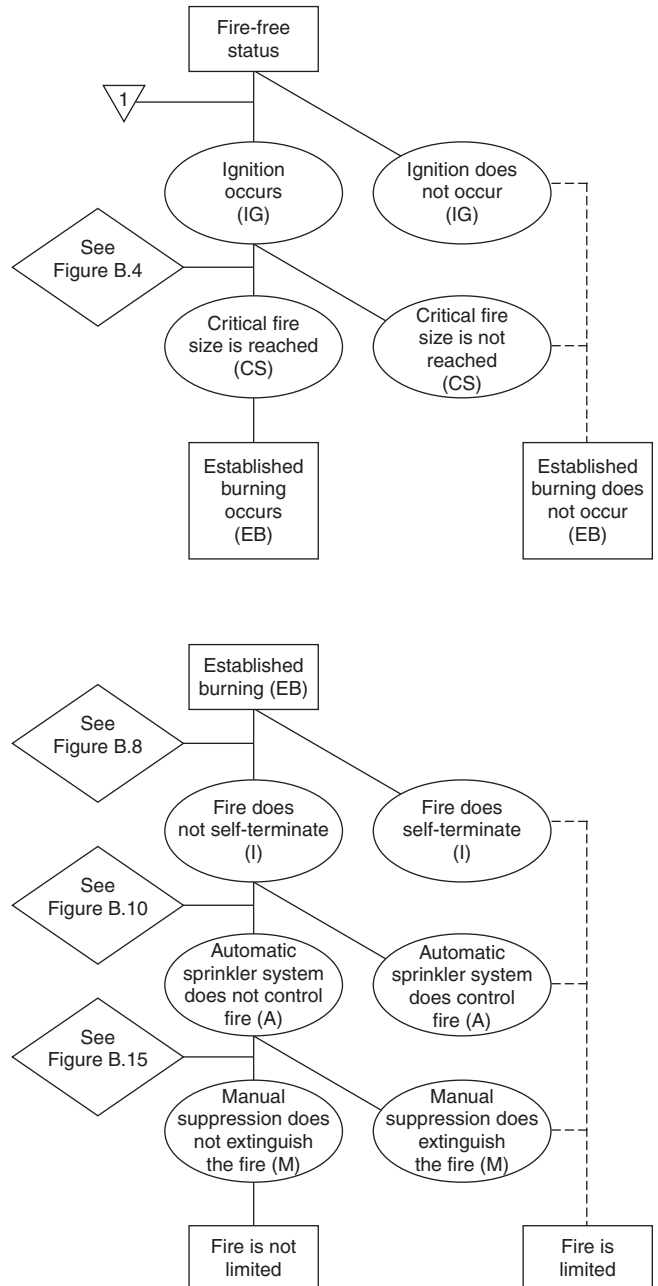

Figure 5-12.10. Examples of BFSEM network diagrams.⁹⁸

system (or design), the water supply, and the reliability of the system operation (statistical data, when available, can be added to support this stage of the evaluation).

In the BFSEM, all buildings are assemblies of spaces and barriers. A clear identification is made for the specific spaces and barriers that are used for a particular building performance analysis. This is defined as *space-barrier organization*. The fire itself is separated into two components: flame/heat and smoke/gas. This is done because each component impacts the building, its occupants, and its contents at different speeds and in different ways.

Within the BFSEM, ignition is defined as self-sustained burning of an item, typically when the first small flame appears (smoldering is defined to occur before ignition). If the ignited material is expected to continue burning (i.e., is not expected to self-terminate), the fire is then classified as having attained *established burning* (i.e., sufficient fuel is present and arranged so as to continue burning if adequate ventilation is present). Assuming no intervention is taken, the fire then grows to full room involvement (i.e., the condition where the surfaces of all combustibles in the room are burning). Full-room involvement can be assumed when flashover occurs. (Flashover is the very rapid ignition of collected fire gases in a room.) After full-room involvement commences, the fire will burn for an extended period of time, until the fuel is nearly consumed or until fire suppression is successful in extinguishing the fire. The literature often describes this stage of the fire as a "post-flashover" or "fully-developed" fire.

In the BFSEM, the term *barrier performance* is used to describe a barrier's ability to prevent fire propagation, where a barrier is defined as any surface that will delay or prevent an ignition into an adjacent space. At any time during the fire, a barrier can be considered as being successful (if it does not permit any ignition to occur in the adjacent space), as having a small failure (e.g., a crack), or as having a massive failure (e.g., door open, large hole, etc.). The *limit of flame movement* is the extent to which the fire spreads before it is terminated. (The term *limit* may be applied to the extent of fire spread either in a space or in a building.)

Evaluation of building performance using the BFSEM is accomplished by applying the above concepts to the following areas: *prevention, flame/heat analysis* (the ability of the building to limit the fire in its spaces and barriers through active and passive fire defenses), *smoke/gas analysis* (the ability of the building to maintain tenable conditions in selected spaces for prescribed time duration), *structural frame analysis* (the ability of the structural frame to avoid unacceptable deformation or collapse for a fire that is not limited), and *people movement analysis* (the time required for building occupants to move within the building or to locations of safety).

Application of the BFSEM provides a comprehensive method for identifying factors that affect the fire safety performance of a building. The method has been widely used and has been adapted by the U.S. Coast Guard to become their ship fire safety engineering methodology (SFSEM).⁹⁹

Summary

Building fire risk analysis is a complex subject. This chapter has provided a brief overview of key issues in the subject area, including discussions on difficulties in defining risk, on risk characterization, on tools and methods to help identify hazards and consequences, and on building fire risk analysis methods. Given the complexities involved in building fire risk analysis, it is intended that this chapter provide a starting point rather than an end point. With this in mind, extensive references and sources for further reading are provided for additional information. A re-

view of other risk-related chapters in this handbook, such as those by Hall, Notarianni, Ramachandran, and Watts is a good place to start. Finally, it is important to remember that when embarking on a building fire risk analysis effort, one should take care to identify and involve the interested and affected stakeholders, carefully consider the range of risk issues involved, and seek the most appropriate approaches, tools, methods, and data for the problem.

CHAPTER 13

Quantitative Risk Assessment in Chemical Process Industries

Thomas F. Barry

Introduction

Fire and explosion risk, which can involve property damage, business interruptions, life safety, environmental issues, corporate image, and future profitability, presents a major threat to corporate goals and survival.

Quantitative fire and explosion risk assessment offers the capability of being able to identify weak links in loss prevention and protection systems before an accident actually occurs. It also affords the capability of optimizing loss control investments with the greatest allocation going to the area giving rise to the highest risk.

Fire and explosion risk assessment is a function of two parameters: (1) the frequency of occurrence of an undesired loss event, and (2) the consequences resulting from its occurrence.

$\text{Risk} = \text{Frequency of the Event} \times \text{Expected Consequences}$

This means that in order to reduce the risks from a defined fire or explosion, one can either seek to reduce the frequency of occurrence of the undesired event, the consequences of its occurrence, or both.

The application of quantitative risk assessment (QRA) techniques enforces a disciplined, analytical thinking approach to fire risk problems and provides quantification of key fire safety issues to aid management understanding and decisions. Primary reasons companies utilize risk assessment as decision support include

1. As part of the engineering design process, to reduce risk to acceptable in-house safety standards. Design

risks are identified and prioritized to optimize safety investment options.

2. To evaluate code equivalency or the relative risk difference between loss prevention or protection design options. Relative risk reduction assessment is used as an effective cost-benefit analysis tool for establishing the optimum balance between prevention, protection, and emergency response.
3. To demonstrate to the community or to an insurance company that, while the hazard may be large, the risk is small. These studies quantify the probability of the occurrence of extremely severe accidents.
4. To predict gas dispersion, fire radiant heat, and explosion overpressure effect zones, for use in emergency response planning and training.
5. The company is required to develop quantitative risk assessment information by federal, state, or local government agencies.

Environmental Protection Agency (EPA) regulations related to the provisions of the 1990 Clean Air Act Amendments (CAAA) may require facilities with threshold amounts of hazardous materials to develop risk assessment and risk management programs. The prevention (reduction of loss event probabilities) component of the EPA CAAA relates to the Occupational Safety and Health Administration's (OSHA) Process Safety Management (PSM) regulation 1910.119, which focuses on process hazard analysis (PHA) and the documentation, implementation, and monitoring of management loss control programs.

In addition, quantitative risk assessment is increasingly being required by state legislation, such as California's Risk Management and Prevention Program, New Jersey's Toxic Catastrophe Prevention Act, and Delaware's Extremely Hazardous Substances Risk Management Act. The specific objectives of these regulations vary, but the emphasis is on risk reduction and emergency planning.

The hazardous materials specified by EPA, OSHA, and state regulations include many flammable and explo-

Thomas F. Barry, P.E., is director of Risk and Reliability Services at HSB Professional Loss Control, Kingston, TN. He has performed and managed numerous quantitative risk assessments (QRAs) of industrial process hazards at government, chemical, and oil and gas facilities. Tom has a masters degree in fire protection engineering from Worcester Polytechnic Institute.

sive materials. As a result, fire protection engineers will become involved as part of the risk assessment teams responsible for hazard analysis, management programs, and regulatory compliance.

The areas in which fire risk assessment is finding application are rapidly expanding. The credibility of these risk assessment studies in the view of the management decision makers is highly dependent on the personnel, procedures, documentation, and quality assurance controls integrated into the process. The risk assessment process can be broken down into systematic steps, as presented in Figure 5-13.1. The focus of this chapter is to familiarize the reader with risk assessment methods by providing an overview of each of the steps and a discussion of general risk assessment techniques.

Quantitative risk assessment is both an interesting and complex subject. The references listed at the end will

supplement and expand on the material summarized in this chapter.

The two objectives of this chapter are

1. To familiarize readers with the general process of fire and explosion risk assessment
2. To provide a basis for the readers' future development and involvement in the areas of risk assessment by providing procedural steps and associated references

Step 1: Define Risk Assessment Objectives

Risk assessment is the process by which the results of a risk analysis (i.e., quantitative risk estimates) are used to support risk management decisions through comparison with acceptable risk levels or prioritization of risk reduction strategies. The key term here is *decision support*.

Prior to the start of risk assessment projects it is imperative to have a clear project scope and to explicitly state and agree upon project objectives.

1. What is the decision?
 - a. Plant siting
 - b. Protection options
 - c. Regulatory compliance
2. What is the focus of the assessment?
 - a. Casualties or injuries
 - b. Property damage
 - c. Loss of production or delivery
 - d. Health risk to employees, public
 - e. Environmental damage
 - f. Legal liabilities
3. What is the level of detail?
 - a. Relative application of risk assessment
 - b. Absolute application of risk assessment
4. What are the acceptable risk limits?
 - a. Hazard severity acceptance limits
 - b. Event likelihood acceptance limits
 - c. Management's risk tolerance profile
5. What are the resources required?
 - a. Involvement of plant personnel
 - b. Use of experienced risk assessment teams
 - c. Quality control procedures and review
 - d. Project scheduling and funding

Ten major issues that should be addressed prior to conducting fire and explosion risk assessments are

1. The type of risk profile presentation format that will be used to aid management decision making
2. Establishing management's acceptable risk criteria for risk comparisons
3. Methods for determining the absolute or relative risk levels
4. Models or algorithms for determining the potential sizes of toxic or flammable vapor clouds, overpressure zones from explosions, fire intensities, and so on
5. The weather conditions that will be applied in gas dispersion consequence models
6. Domino effects caused by the initial failure incident
7. Appropriate sources of failure rate and reliability data and selection methods

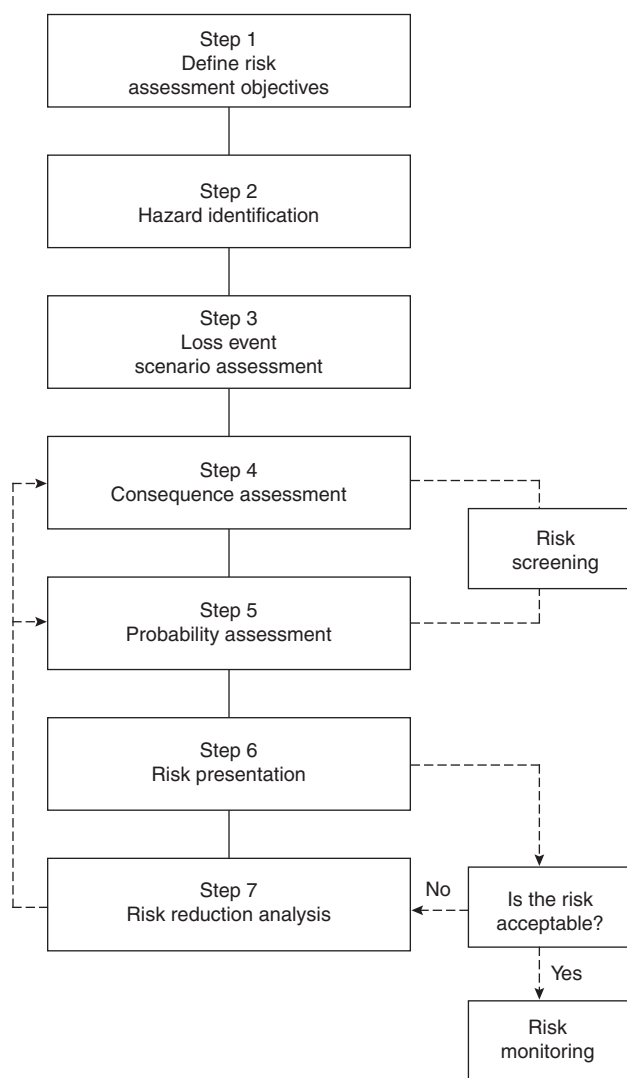

Figure 5-13.1. Fire and explosion risk assessment steps.

8. Methods for incorporating loss event time relationships into event tree scenarios
9. Incorporating human error and management factors into failure probability ranges
10. Procedures for conducting uncertainty (sensitivity) analysis and quality control

Step 2: Hazard Identification

Hazard identification is the foundation for conducting credible risk assessment studies. Fire and explosion hazards that are not properly identified and defined in terms of cause and consequences cannot be properly addressed within the risk assessment framework.

The results of the hazard identification should include

1. Identification of the physical and chemical properties of materials processed, stored, or transported on site that can harm employees, the public, property, environment, or other selected risk targets
2. Identification of weaknesses in the design, operation, and protection of facilities that could lead to toxic exposures, fires, or explosions
3. Evaluation of the significance of potential hazardous events associated with a process or activity to allow categorization of the consequences and ranking the risk

The tasks associated with step 2 include

1. Gathering technical information
 - a. Plant and process data
 - b. Material properties
2. Gathering historical accident data
 - a. Facility tour and process review
 - b. Plant personnel interviews
 - c. Process safety management documentation evaluation
3. Documenting the hazard evaluation(s)
 - a. Use of a selected hazard evaluation method (e.g., PHA, HAZOP, FMEA, ETA)

Plant and Process Data

The fire protection risk analyst must understand plant processes, their interdependence, and the inventories and conditions of materials. Plant and process data must describe the plant as it actually operates, which may be different from the original design. The following examples of risk assessment information required may serve as a checklist:

- Material information [material safety data sheets (MSDS)]
- General process chemistry (including side reactions under normal and abnormal conditions)
- Process flow diagrams (including process description and operating parameters such as flow rates, pressures, temperatures, and stream compositions)
- Process design bases (including external events)
- Process utilities (cooling, steam, electricity, instrument, air, and utility backup systems)
- Waste treatment, pollution control systems

- Equipment specifications (including materials of construction)
- Equipment detail drawings
- Piping and instrument diagrams (P&IDs, including utilities and pressure relief systems)
- Plant layout drawings (plant and immediate surroundings, including elevations and potential ignition sources)
- Fire water and drainage system drawings
- Process and equipment modifications
- Control logic (e.g., instrument loopsheets, relay logic diagrams)
- Operating instructions
- Operating philosophy (storage inventory levels, operating schedule, manning, startup and shutdown, operator training, safety policy)
- Protection systems diagrams (fire protection, emergency relief, interlock, and alarm systems; design basis should also be included)
- Historical systems failure incident and maintenance records
- Maintenance philosophy and programs
- Emergency response procedures
- Past hazard identification information (HAZOPs, audits, surveys, etc.)
- Replacement cost estimates (structures, equipment, inventory)
- Production dependency
- Employee distribution by shift in process area and on plant site
- Weather data (e.g., wind rose) and off-site population distribution
- Operational and loss incident history involving fire and explosions
- Process safety management (PSM) documentation

Material Properties

Accurate information concerning material properties, inventories, processing, and storage conditions is required to perform hazard evaluations. Detailed information is needed on both the physical and chemical properties of materials. Some of these data can be obtained from the MSDS. A nonexclusive list of properties includes

1. Thermodynamic data (including vapor pressure, boiling point, freezing point, critical temperature and pressure, specific and latent heats, heats of combustion)
2. Flammability
3. Dust explosion data (for samples reflecting process conditions)
4. Industrial hygiene and toxicity data
5. Shock sensitivity, thermal analysis data from differential scanning calorimetry, accelerating rate calorimetry, vent sizing package
6. Miscellaneous properties (e.g., peroxide-forming materials, susceptibility to spontaneous ignition, ability to hold static charge, effect of contaminants)

Much of the data available in MSDS or other publications are at atmospheric temperature and pressure. Experimental data appropriate to process conditions will sometimes be needed.

Dust explosion data for explosion venting calculations are presented in NFPA 68, *Guide for Venting of Deflagrations*, which includes additional references. A considerable amount of dust explosion data can be obtained from various U.S. Bureau of Mines and National Fire Protection Association (NFPA) publications.

Historical Accident Data

An important part of fire and explosion hazard identification and risk screening is a review of the history of loss incidents similar to the hazard being analyzed. A review of the available information on loss incidents or the available loss trending data provides

1. A relative breakdown of consequential effects, in terms of type of fire or explosion or in terms of resulting damage (can generally be used for estimating conditional event probabilities)
2. Identification of representative or dominant failure modes (equipment related, human error, system(s) related) that have led to fire or explosion accidents
3. Identification of ignition sources and fire propagation contributing factors
4. Information concerning the duration of the fire and the general effect of loss mitigation factors
5. Information to support the generation of credible fire and explosion incident loss scenarios and the structuring of event tree analysis

Databases are the information foundation of hazard analysis. One of the most effective ways to determine whether a system has a fire or explosion potential is to review past loss incident records. Accident data from specific plant operations (if available) is usually the best source and probably more accurate for specific equipment and operations, since the data reflect the operating and maintenance practices of the specific facility. Fire records of NFPA and American Petroleum Institute (API) provide fire loss incident data for a number of processes, plants, and equipment. Federal and state agencies also collect a wide variety of data related to safety and loss prevention issues. A few loss incident data sources are listed in Table 5-13.1.

These kinds of events are sufficiently serious to be reported fairly widely in publicly available sources (e.g., regulatory agencies, research organizations, the media). Data sources can generally be grouped into three categories

1. Failure mechanisms and causes
2. Consequence effects (e.g., downwind gas concentrations, fire radiation levels, explosion overpressures, etc.)
3. Generic frequency categorization of certain types of incidents

Data sources in the first two categories may be helpful in constructing a fault or event tree model or in understanding the consequences of a specific incident. However, they usually do not provide information on the frequency of incidents. Data sources in the third category provide generic frequency information, but should be used with caution. In most cases, frequency data derived from incident reports may not be applicable to

Table 5-13.1 *Some Sources of Information for Use in Fire Risk Assessments*

Source	Nature of Information
NFPA (National Fire Protection Association)	Fire Incident Data: FIDO (Fire Incident Data Organization) NFIRS (National Fire Incident Reporting System)
DOT (Department of Transportation) NTSB (National Transportation Safety Board), U.S. DOT, Washington, DC	Annual reports on hazardous materials transportation accidents Accident reports: A detailed report is produced for transportation accidents involving hazardous materials Hazardous materials accident spill maps: These maps show the location of the spill, any airborne plume, site of fatalities and/or injured people, at one or more times after the start of the incident
API (American Petroleum Institute) Washington, DC	Annual summaries of petroleum industry loss incidents
Association of American Railroads, Federal Railroad Administration	"Railroad Facts" (annual editions) Accident/incident bulletins (annual)
EPA (Environmental Protection Agency)	Reports on various aspects of hazardous material release incidents
U.S. Department of Transportation, Research and Special Programs Administration, Office of Pipeline Safety Washington, DC	Pipeline leak reports for onshore gas transmission and gathering lines, and liquid lines

the specific risk assessment being conducted. Historical databases are rarely complete. Minor incidents, which could have escalated into major incidents, are sometimes not reported and therefore may not be included in the data. Consequently, the fire and explosion risk analyst must examine sources of data very carefully to determine applicability.

Hazard Evaluation

Hazard evaluation techniques include¹

- Safety review
- Checklist analysis
- Relative ranking indexes
- Preliminary hazard analysis
- "What-if" analysis
- "What-if" checklist analysis
- HAZOP analysis
- FMEA
- Fault tree analysis
- Event tree analysis
- Cause-consequence analysis
- Human reliability analysis

Each technique has specific application benefits, limitations, resource needs (e.g., manpower, time, budget), and documentation requirements. It would be impossible in this chapter to describe each technique. An excellent reference, which addresses those techniques in detail and provides illustrative examples, is the Center for Chemical Process Safety's (CCPS) *Guidelines for Hazard Evaluation Procedures with Examples*.²

Documenting Hazard Evaluation

The synonym for hazard evaluation presently in wide use is process hazard analysis (PHA), as this term is used in OSHA's Process Safety Management (PSM) regulation 1910.119.³

The OSHA PSM regulation requires an analysis that identifies and evaluates hazards involved in a process, and must include

1. Use of one or more of the following to perform a hazard analysis:
 - a. Checklists
 - b. "What-if" checklist
 - c. Hazard and operability study (HAZOP)
 - d. Failure mode and effects analysis (FMEA)
 - e. An appropriate equivalent methodology
2. The hazard analysis must address
 - a. Process hazards
 - b. Engineering and administrative controls
 - c. Consequences of failure of controls
 - d. Consequence analysis of effects on employees
3. Analysis performance by a team with engineering and operations expertise, including at least one person with knowledge specific to the process
4. Establishment by employer of a system for documenting findings and actions taken, then communicating them to employees
5. Review and update hazard analysis at least once every five years.

It should be noted that OSHA's definition of process includes the storage, handling, processing, and transportation of hazardous chemicals, and flammable and explosive materials.

A broad evaluation of hazards should include the following four general techniques:

1. Safety reviews
2. Checklists
3. Preliminary hazard analysis
4. Relative ranking indexes

However, a detailed analysis of the wide range of hazards during design and operational stages should include the following three fundamental methods:

1. "What-if" checklist analysis
2. HAZOP analysis
3. FMEA

Table 5-13.2 provides a general breakdown of some hazard evaluation techniques in terms of their general capability to provide scenario information and ranking of loss events.²

Step 3: Loss Event Scenario Development

Structuring credible fire and explosion loss scenarios is an important aspect of the risk assessment process. The primary components that must be evaluated in the fire and explosion loss scenario development are

1. Initiating failure event(s)
2. Intermediate event(s)
3. Incident outcome(s)

Fire exposure is very time dependent. The most widely used technique in the structure of fire scenarios is the event tree logic, which conveys the initiation, propagation, and consequences of potential fire events for probability versus time assessments.

An event tree provides an inductive, forward logic framework that identifies a failure process, such as fire initiation and propagation. It has a major advantage of being able to incorporate time and sequential conditionality into a scenario. In some cases, it may be weak in identifying specific details that contribute to the consequences. In these cases, fault trees are used to supplement the event tree structure and provide detail to the top events leading to the final consequence.

Risk assessment concerning the release of flammable and explosive materials and expected consequences is a major issue for a fire protection engineer when part of a risk assessment team conducting OSHA and EPA regula-

Table 5-13.2 Scenario and Ranking Capabilities of Some Hazard Evaluation Techniques

Hazard Evaluation Technique	Provides Loss Event Scenario Information?	Loss Event Ranking Possible?
Checklists/Safety reviews	No; specific scenarios usually not identified	No
Dow and Mond indexes	Yes, on a unit or a major system basis	Consequence ranking
Preliminary hazard analysis (PHA)	No; specific scenarios usually not identified	Yes
"What-if" and "what-if"/checklist analysis	No; specific scenarios usually not identified	Consequence ranking
HAZOP analysis	Yes	Consequence ranking
FMEA	Yes	Consequence ranking
Fault tree analysis (FTA)	Yes	Frequency ranking
Event tree analysis (ETA)	Yes	Yes
Cause-consequence analysis	Yes	Yes
Human reliability analysis (HRA)	Yes	Frequency ranking

tory compliance projects and evaluation of risk reduction options.

Figure 5-13.2 presents a breakdown of the general event components from accidental release to consequences.

Initiating Failure Event(s)

Initiating failure events generally include one or a combination of the following:

1. Containment failures
2. Human error
3. Ignitions
4. External exposures (i.e., flooding, earthquake, etc.)

From a review of past fires and explosions associated with the accidental release of flammable liquid or gas, the following causes are evident as major causes of containment failure:⁴

1. Rupture of temporary hose
2. Overfilling of tanks
3. Release from drainage and sampling valves
4. Leaks from gaskets and pump seals
5. Leaks from flanged joints and small pipe connections

6. Piping failures
7. Tank rupture
8. Internal tank overpressures

Containment failures can be created by equipment malfunctions (mechanical or electrical breakdown, instrumentation failures, etc.), human errors, loss of utilities (electricity or cooling water, etc.), and external events (floods, earthquakes, vandalism, etc.).

Human error analysis [or human reliability analysis (HRA)] generally involves the following evaluations:

1. Describing the characteristics of the personnel, the work environment, and the tasks that are performed
2. Evaluating the human-machine interfaces
3. Performing a task analysis of intended operator functions
4. Performing a human error analysis of intended operator functions to assess human error likelihood

Human error assessment methods and details are related to the process or equipment complexity; the operating environment; human-equipment interface factors; hardware design interfaces for emergency actions; and procedures for operations, maintenance, testing, and training.

Intermediate Event(s)

Intermediate events are events that affect the growth, propagation, and mitigation of the initiating event source. These events are a function of time, which is very important to recognize when addressing the conditional probabilities.

Propagating factors within the fire and explosion development scenario include

1. Process parameter deviations
 - a. Pressure
 - b. Temperature
 - c. Flow rate
 - d. Concentration
 - e. Phase or state change
2. Material release type
 - a. Combustibles
 - b. Explosive materials
 - c. Toxic materials
 - d. Reactive materials
3. Ignition
4. Energy release rate
5. Ventilation or weather effects
6. Operator emergency response errors
7. Domino effects of fires or explosions

Mitigating factors include

1. Safety system responses
 - a. Relief valves
 - b. Back-up utilities
 - c. Back-up components
 - d. Back-up systems
2. Barrier effectiveness with time
3. Mitigation system responses
 - a. Vents
 - b. Dikes
 - c. Detection, alarms, shutdown
 - d. Fire protection, suppression

Figure 5-13.2. General flammable liquid/gas event sequence.

4. Control responses and operator responses
 - a. Planned
 - b. Emergency
5. Contingency operations
 - a. Emergency procedures
 - b. Personnel safety equipment
 - c. Evacuations
 - d. Security

Incident Outcome(s)

Potential incidents of primary interest to the fire protection engineer include

1. Radiant heat from a fire
 - a. Pool fire
 - b. Torch fire
 - c. Flash fire
 - d. Fire ball [boiling liquid expanding vapor explosion (BLEVE)]
2. Explosion overpressures
 - a. Unconfined vapor cloud explosion (UVCE)
 - b. Tank or equipment rupture or fragmentation
3. Corrosive smoke or fire products concentration
 - a. Toxic gas concentrations

Figure 5-13.3 presents two generic event trees associated with flammable liquid and gas releases developed by The World Bank.⁴

Step 4: Consequence Assessment

Consequence assessment is the estimation of the undesirable result of an accidental fire or explosion exposure to a target, usually measured in terms of health and safety effects to people, loss of property, or business interruption costs.

This assessment involves the evaluation of two issues

1. The susceptibility or vulnerability of people or damage to targets (structures, equipment, etc.) being evaluated in the risk assessment project
2. The rate of development of a hazardous environment (intensity, distance, time) within the boundaries of the predicted hazardous event (gas dispersion, fire, explosion)

When these issues are evaluated quantitatively, they provide estimates of the loss vulnerability to selected targets versus the predicted (distance and time) exposure from the fire or explosion scenario. The analogy within this assessment is one of source → target exposure and vulnerability, as illustrated in Figure 5-13.4. References 4, 5, 6, and 7 provide additional information on this subject.

The steps involved in the quantification of accidental flammable liquid and gas release exposures include

1. Characterizing failure modes
2. Calculating release rates and durations
3. Evaluating ignition scenarios in terms of immediate or delayed ignition times

4. Calculating fire and explosion intensities
5. Estimating the vulnerability to the target(s) of interest
6. Plotting effect distances

Characterizing Failure Modes

Steps 2 and 3 identify failure scenarios. Failure identification, however, must be broken down into potential failure modes to allow quantification of flammable liquid or gas release rates. For example, release from a pipe failure could involve a failure mode stemming from a pin-hole leak, to a partial fracture of the pipe, to a full rupture of the pipe. With each failure mode there is associated relative failure probability (e.g., very small leaks are much more likely than major pipe fractures) and a release rate.

To manage failure mode evaluation within a time-constrained risk assessment project, industry risk assessment experts generally focus on three to five failure modes related to the equipment release source being studied.

Figure 5-13.5 provides some general information on some equipment-related failure cases and failure sizes, summarized from The World Bank Technical Paper No. 55, with permission from The World Bank.⁴

Calculating Release Rates and Durations

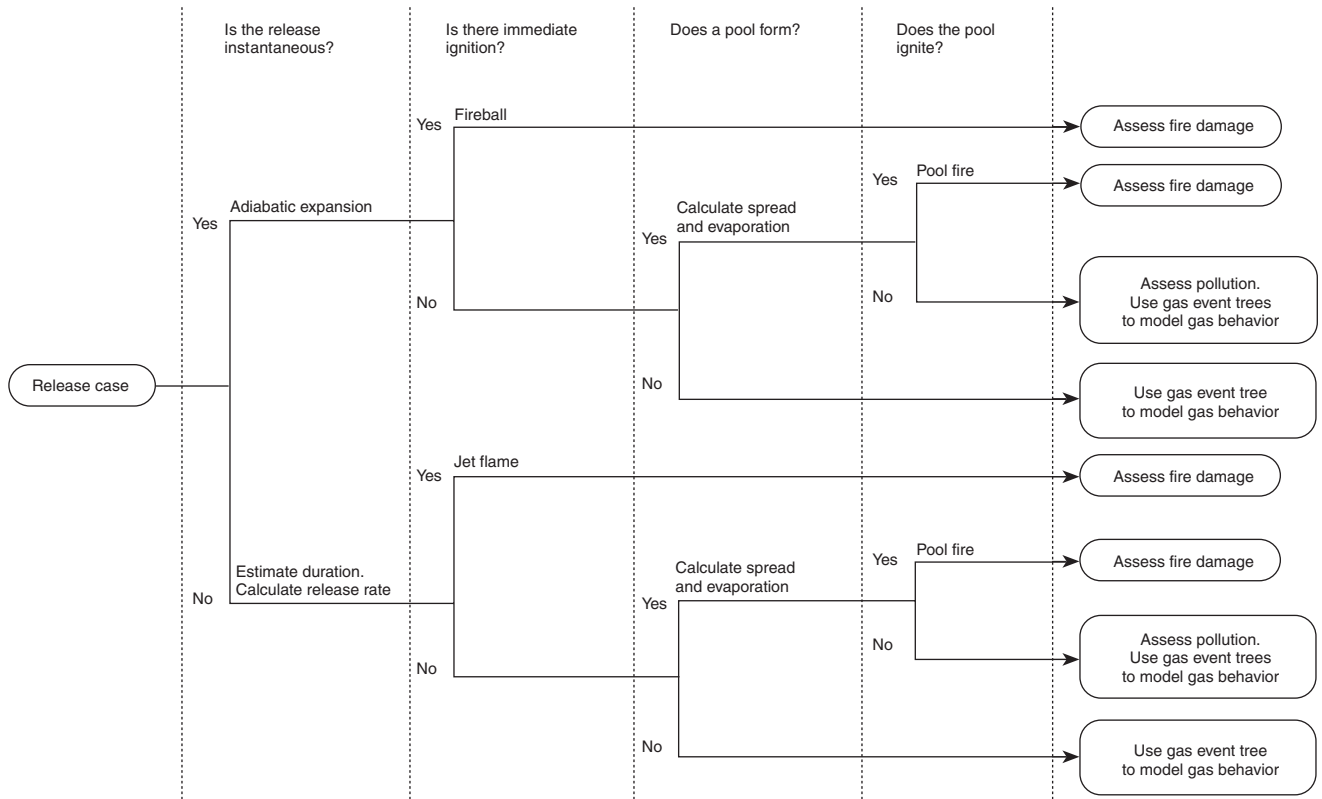

The release from the failure point may be liquid, gas, or a combination of the two (i.e., two-phase flow). It is beyond the scope of this chapter to discuss the benefits and limitations of various calculation methods (see References 4, 5, and 6 for further information).

When calculating release rates and durations, it is important to document both the physical parameters and assumptions, including

1. The type of release opening (i.e., rectangular or circular, and opening coefficient), the elevation, and size. If using a computer program, these are required input.
2. The effects of containment (diking, curbing) and drainage design reliability.
3. The estimated time to either automatic or manual shutdown to limit the duration of the release. This estimated time will be related to a probability of successful shutdown within the event-free framework.
4. For evaluations involving vapor dispersion (e.g., gas release, liquid pool vaporization), which could lead to flash fires or explosion overpressure effect zones, the topography, selected weather conditions, and any other assumptions (e.g., gas dispersion obstructions or explosion overpressure wave deflections) must be documented.

This step is critical, as the release rate and duration dictate the amount of fuel that can be available in the accident scenario. The methods to actuate the emergency shutdown system (ESS) should be described in detail; this includes gas, flame detection, and emergency isolation valves. The estimated time to shutdown and the residual fuel that can be released following shutdown are important considerations in the justification of the

Flammable Liquid Event Tree

Flammable Gas Event Tree

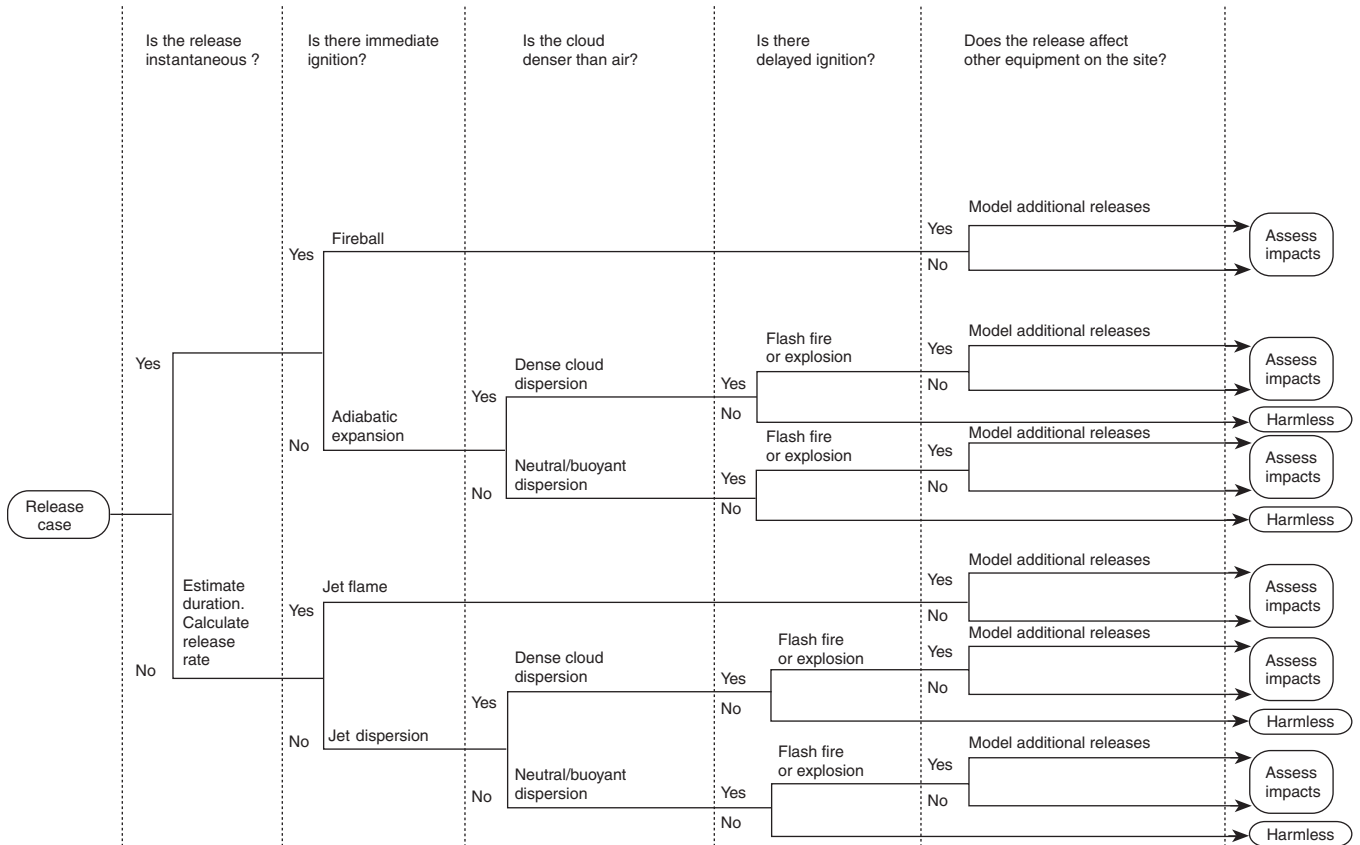

Figure 5-13.3. Generic event trees. (Modified from Reference 4.)

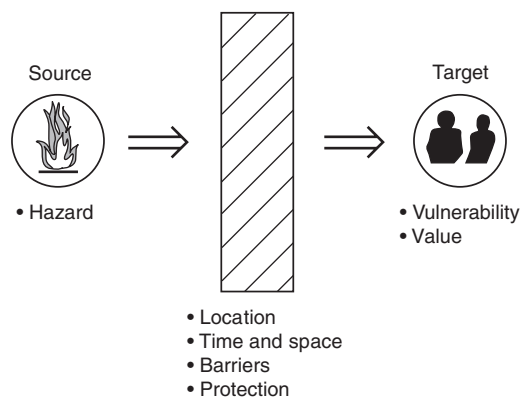

Figure 5-13.4. General illustration of source → target concept.

volume of fuel and the potential duration of exposure if the fuel is ignited.

Isolation of a release: The behavior of a release can be very dependent on its duration. The duration depends on the amount of material available to be released, which in turn depends on the speed and effectiveness of shutdown or isolation. Therefore, isolation can affect the consequences of a release, and it is important to make a realistic estimate of the time required for isolation. This time will depend on the following:

1. *Leak Detection.* It is usual to assume that major ruptures and leaks will be detected quickly, either by process instrumentation or by operators. Smaller leaks may be detected by gas or flame detectors, if installed. The analyst should determine the position, effectiveness, and reliability of such detectors as part of this evaluation.
2. *Shutdown Activation.* The speed of shutdown will depend on whether emergency shutdown actuation is manual or automatic. The response time concerning manual actuation depends on instrumentation and alarm design reliability, operating procedures, and operator emergency response training. Response times of 3 to 15 minutes are typical but must be judged on a plant-specific basis. The analyst should also evaluate the availability and reliability of the shut-down valves and the estimated closing time of the particular emergency shut-down valve design.

Evaluating Ignition Scenarios

Fire and explosion outcomes resulting from the accidental release of flammable liquids or gases can be categorized as follows:^{4,5,6,7}

Pool fire: A fire involving a pool of confined or spreading flammable material. This can include both immediate and delayed ignition scenarios creating both near-field and remote damage effects.

Torch fire (or flame jet): A fire extended from a point of release of flammable liquid or gas, which is being dis-

charged under pressure. This is usually associated with an immediate ignition scenario and usually includes near-field damage effects.

BLEVE fireball: BLEVE (boiling liquid expanding vapor explosion) results from the overheating of a pressurized vessel by a primary fire. This overheating raises the internal pressure and weakens the vessel shell, until it bursts open and releases its contents as a large and very intense fireball. This is generally considered a delayed event (8 to 15 minutes of exposure) and can involve both near-field damage effects and remote personnel exposure.

Flash fire: A fire involving the delayed ignition of a dispersed vapor cloud, which does not cause blast damage. That is, the flame speed is not as high as in an unconfined vapor cloud explosion, but the fire spreads quickly throughout the flammable zone of the cloud and is usually associated with near-field damage effects and remote personnel effects.

Unconfined vapor cloud explosion: A release of a large amount of flammable vapors (usually greater than 1 ton), which forms a large vapor cloud and upon delayed ignition explodes, creating an explosion overpressure exposure to the surrounding area, causing both severe near-field damage effects and remote property and personnel exposure.

Calculating Fire and Explosion Intensities

Deterministic models have been developed to support fire and explosion intensities, and more sophisticated models are continuously being refined and validated. Several chapters within this handbook describe fire and explosion modeling methods and available computer programs.

Available consequence computer models generally include the capabilities to^{5,7,8}

- Estimate discharge rate of liquid or gas
- Estimate area of liquid pool
- Estimate vaporization rate of liquid pool
- Evaluate toxic vapor dispersion hazards
- Evaluate pool fire radiation hazards
- Evaluate fireball radiation hazards
- Evaluate flame jet hazards
- Evaluate vapor cloud and plume fire hazards
- Evaluate vapor cloud explosion hazards
- Evaluate tank overpressurization rupture and fragmentation hazard
- Evaluate solid and liquid explosion overpressure hazards

In addition, various analytical assessment methods described in this handbook can be applied to consequence and risk assessment studies and include methods for

- Estimating heat release rates and flame heights
- Estimating exposure temperatures from uncontrolled fires using fire plume modeling equations
- Estimating the time to critical damage thresholds for specified targets using heat transfer approaches

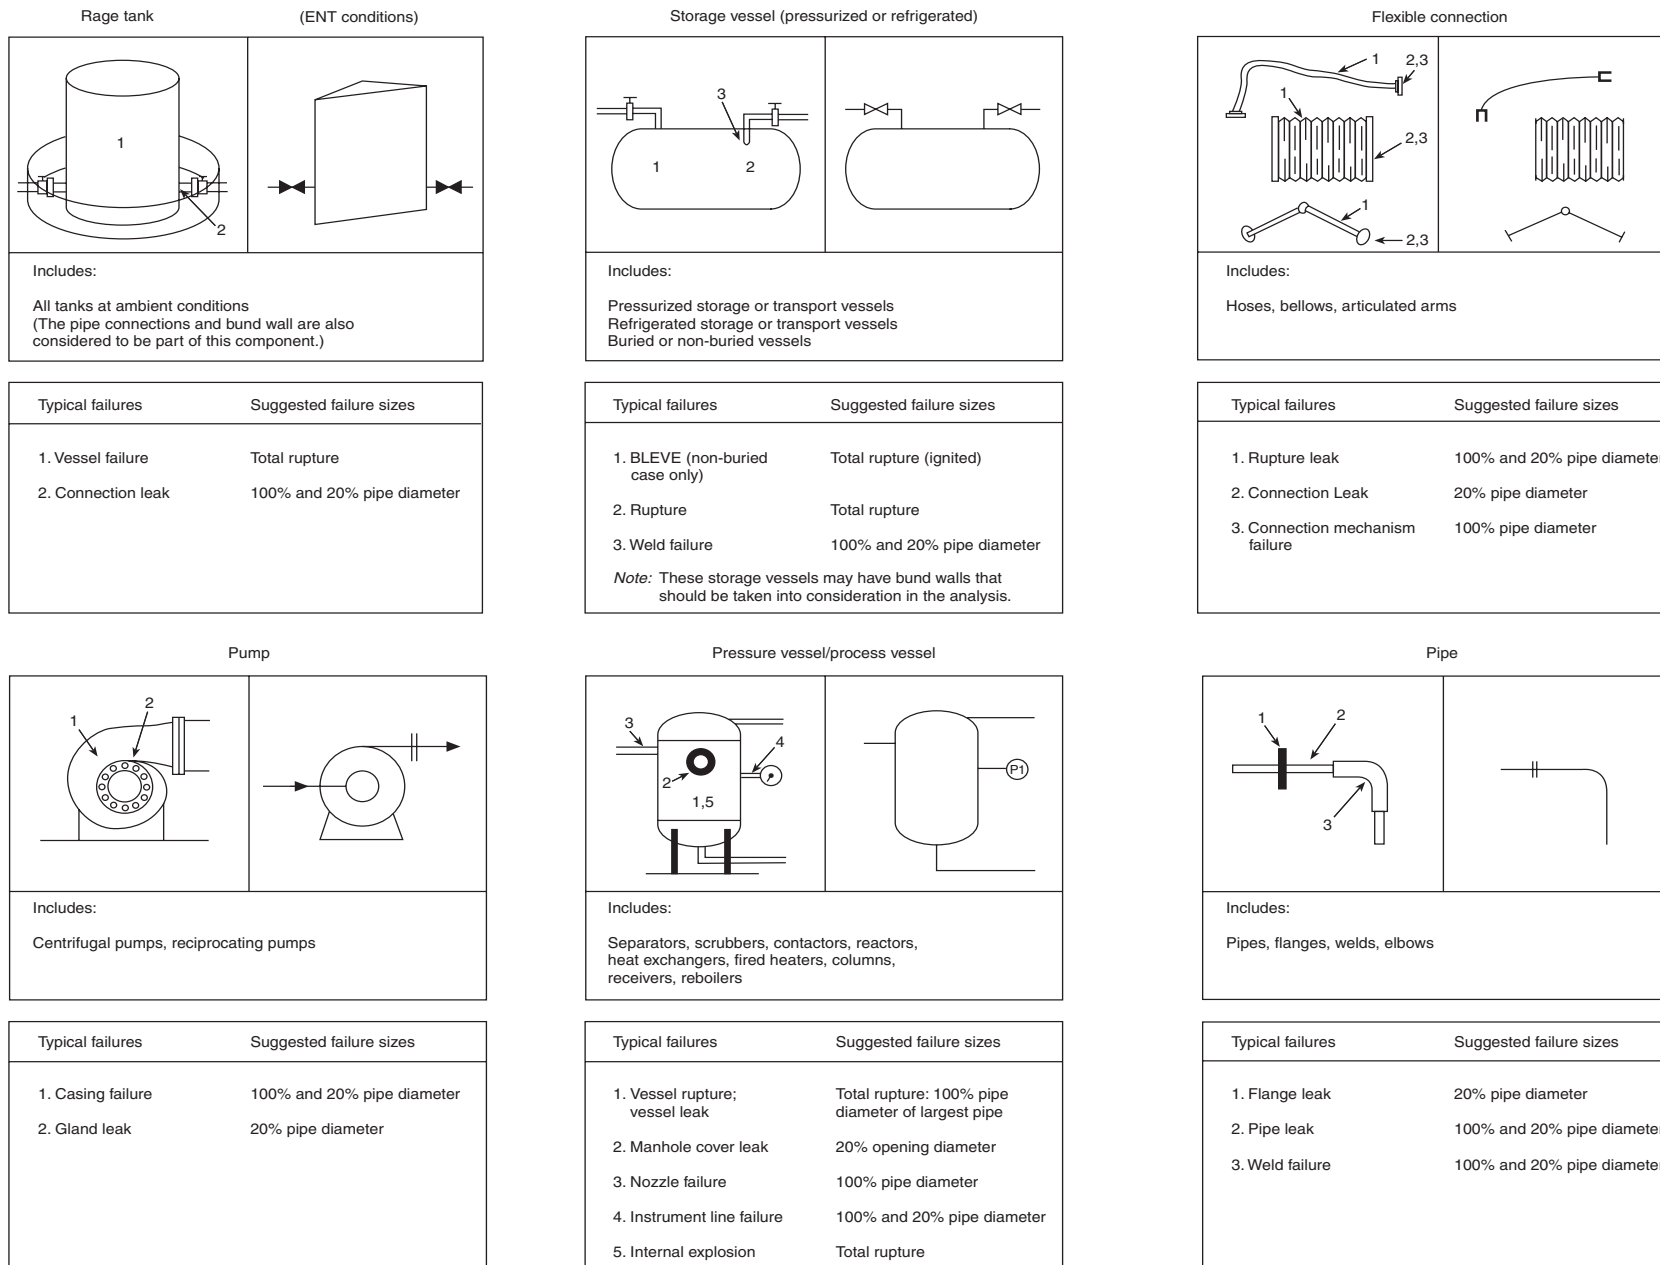

Figure 5-13.5. Suggested failure modes. (Source: The World Bank.)

- Estimating the response of existing fire protection or improvement strategies
- Applying the results of fire modeling efforts to support loss estimates and the benefits of recommended fire protection improvements

Target Vulnerability

In evaluating the vulnerability to selected targets, two levels of target vulnerability assessment can be utilized:

1. Use various tables and references that establish generic criteria for damage to people and property from fire and explosion exposures (i.e., radiant heat, explosion overpressures). This level of vulnerability evaluation provides a good first-order review; however, it is weak in terms of specific time relationships. Since time is usually a very uncertain variable, a number of risk assessment projects usually employ generic threshold damage levels.
2. Apply sophisticated heat transfer or structural impact models to support vulnerability assessments where time or specific conditions (design, layout, emergency response) warrant this level of detail, usually termed second-order vulnerability assessment.

Various tables give criteria for damage to people and property from fire, usually expressed in terms of radiation heat intensity. The effect on people is expressed in terms of the likelihood of death and different degrees of injury for different levels of heat radiation. In Table 5-13.3, the radiative incident flux is related to the levels of damage. This table is based on observations of large fires.⁴

Vapor cloud explosion exposures can be generically correlated with the energy of the explosion overpressure. This correlation is used to relate distances to various levels of damage and people exposure. Table 5-13.4 provides a general breakdown of damage threshold levels.^{4,7}

Table 5-13.3 *Damage Caused at Different Incident Levels of Thermal Radiation*

Incident Flux (kW/m ²)	Type of damage caused	
	Damage to Equipment	Exposure to People
37.5	Damage to process equipment	100% lethality in 1 min 1% lethality in 10 s
25.0	Minimum energy to ignite wood at indefinitely long exposure without a flame	100% lethality in 1 min Significant injury in 10 s
12.5	Minimum energy to ignite wood with a flame; melts plastic tubing	1% lethality in 1 min First-degree burns in 10 s
4.0		Causes pain if duration is longer than 20 s, but blistering is unlikely
1.6		Causes no discomfort for long exposure

Table 5-13.4 *Explosion Overpressure Damage Estimates*

Overpressure (psig)	Characteristic damage	
	To Equipment	To People
2.5–5	Heavy damage to buildings and to process equipment	1% death from lung damage >50% eardrum rupture >50% serious wounds from flying objects
1–2.4	Repairable damage to buildings and damage to the facades of dwellings	1% eardrum rupture 1% serious wounds from flying objects
0.5–1	Glass damage	Injury from flying glass
0.15–0.30	Glass damage to about 10% of panes	Slight injury from flying glass

The general methods for assessing damage and human exposure for flash fires and torch fires is to assume fatalities would occur within the flame envelope of the flash fire or torch fire zone, and to estimate secondary damage potential to equipment or structures within the flame exposure zone.

Plotting Effect Distances

Plotting the results of the fire and explosion consequences associated with defined failure scenarios provides a graphical depiction of potential exposure zones. Figure 5-13.6 provides an illustrative example for plotting effect zones from an uncontrolled liquefied gas release potentially resulting in a torch fire, flash fire, BLEVE, or vapor cloud explosion scenario.

Step 5: Probability Assessment

This section presents an introduction to a complex subject. The mathematics and sensitivity analysis involved in the structuring of detailed event and fault trees is beyond the scope of this section. See References 2, 5, 9, and 10 to gain a more detailed insight into these areas.

Probability assessments must include a team approach. The team assembled to support the fire risk analyst in process risk assessments will generally include members experienced in process design and instrumentation, reliability engineering, safety, and environment issues, as well as team members from the plant knowledgeable in the specific facility hazards and operations. In some cases, the services of a statistician may be required to compile raw plant data from plant insurance reports and OSHA injury logs.

The general structure of the event tree for evaluating the consequences from the release of flammable liquids or gases is presented in Figure 5-13.7.

Note: Estimated LPG fire explosion zones for selected baseline scenarios. Calculated using the Archie Computer Model. Distance in feet from point of LPG accidental release origin.

Figure 5-13.6. General example of plotting effect zones.

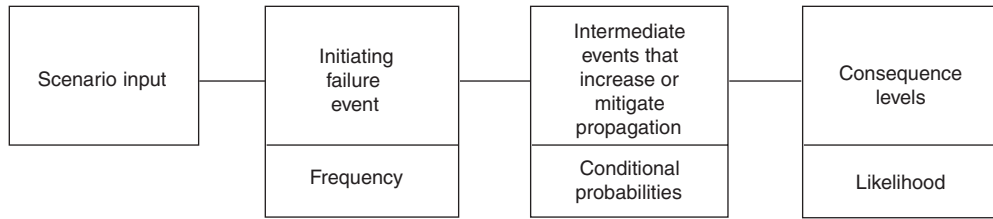

Figure 5-13.7. General event tree sequence.

In mathematical terms, Figure 5-13.7 can be expressed as

$$F_{(\text{Consequences})} = F_{(\text{Initiating events})} \times \sum P_{(\text{Intermediate event probabilities})}$$

Two basic approaches commonly employed in fire and explosion risk assessments to estimate initiating event frequencies and conditional probabilities:

1. Use of relevant historical data
2. Synthesis of event frequencies and probabilities using techniques such as fault trees, human reliability analysis, and expert engineering judgment

In many cases the two approaches are used in a complementary manner to provide an independent check on one another and to increase the validity and confidence in the final results.

The first approach examines (1) relevant historical data in order to assess the frequency with which these events have occurred in the past, and (2) the likelihood of their occurrence in the future. Where sufficient relevant past data are available, historically based frequencies may be adequate in making a reasonable assessment of fire and explosion risks. However, frequencies derived in this way represent only average values and are most applicable to simple systems where there are not a number of variables (i.e., propagation and mitigation factors) that can significantly change the consequential results.

In actual application, assessments of potential fire and explosion risks at a specific facility will usually require adjustments to historical data to reflect the particular facility management and protection deviations. When evaluating the relevance of historical data for use in a specific facility or process risk assessment, the following factors should be taken into account:

1. There are many types of hazardous industrial operations for which historical data are limited or not available to make confident predictions about consequence likelihoods.
2. The general distribution between the primary causes leading to fire explosions shows that human error is the leading cause.¹¹
 - Human factors (e.g., management controls, human operator errors): 70 to 85 percent
 - Equipment failures: 10 to 20 percent
 - External factors (e.g., earthquake, floods): 10 to 20 percent

With the majority of causes being associated with human factors, it would be expected that the majority of risk research would be in this area; however, the quantification of the human element is very difficult, and much research continues in this area.

3. Fire prevention and protection technology is continually being expanded and updated based on new codes, standards, and industry practices that are developed after loss occurrences; and based on continued fire and explosion research efforts.

Considering these factors, the fire risk analyst must take a systematic approach to first determine the best approach for estimating frequencies and probabilities based on available data and specific plant conditions. A general approach is illustrated in Figure 5-13.8.⁵

Risk Assessment Fundamentals

Three primary concerns that the fire risk analyst must address are

1. Integrating failure (equipment, human, external) mechanisms
2. Application of engineering judgment and expert opinion
3. Documentation methods

Integrating failure mechanisms: The method of integrating hardware failures (e.g., equipment, emergency shutdown systems, passive and active protection systems), human errors (e.g., equipment testing and maintenance deficiencies, operational errors), and potential external upsets (e.g., windstorm, flood, earthquake) into top event frequencies must be considered by the risk assessment team. In the majority of fire and explosion risk assessments, top events will have to be supported by fault tree analysis to derive and validate the selected event tree frequencies and conditional probabilities. The general framework is illustrated in Figure 5-13.9.² References 5, 9, and 12 provide good information on fault tree structuring, Boolean algebra, cut-sets, and sensitivity analysis.

Engineering judgment and expert opinion: The method for systematic and consistent application of expert engineering judgment and expert opinions within the risk assessment process is a very important consideration.

Many hazardous situations and potential fire events are often encountered where data will be insufficient.

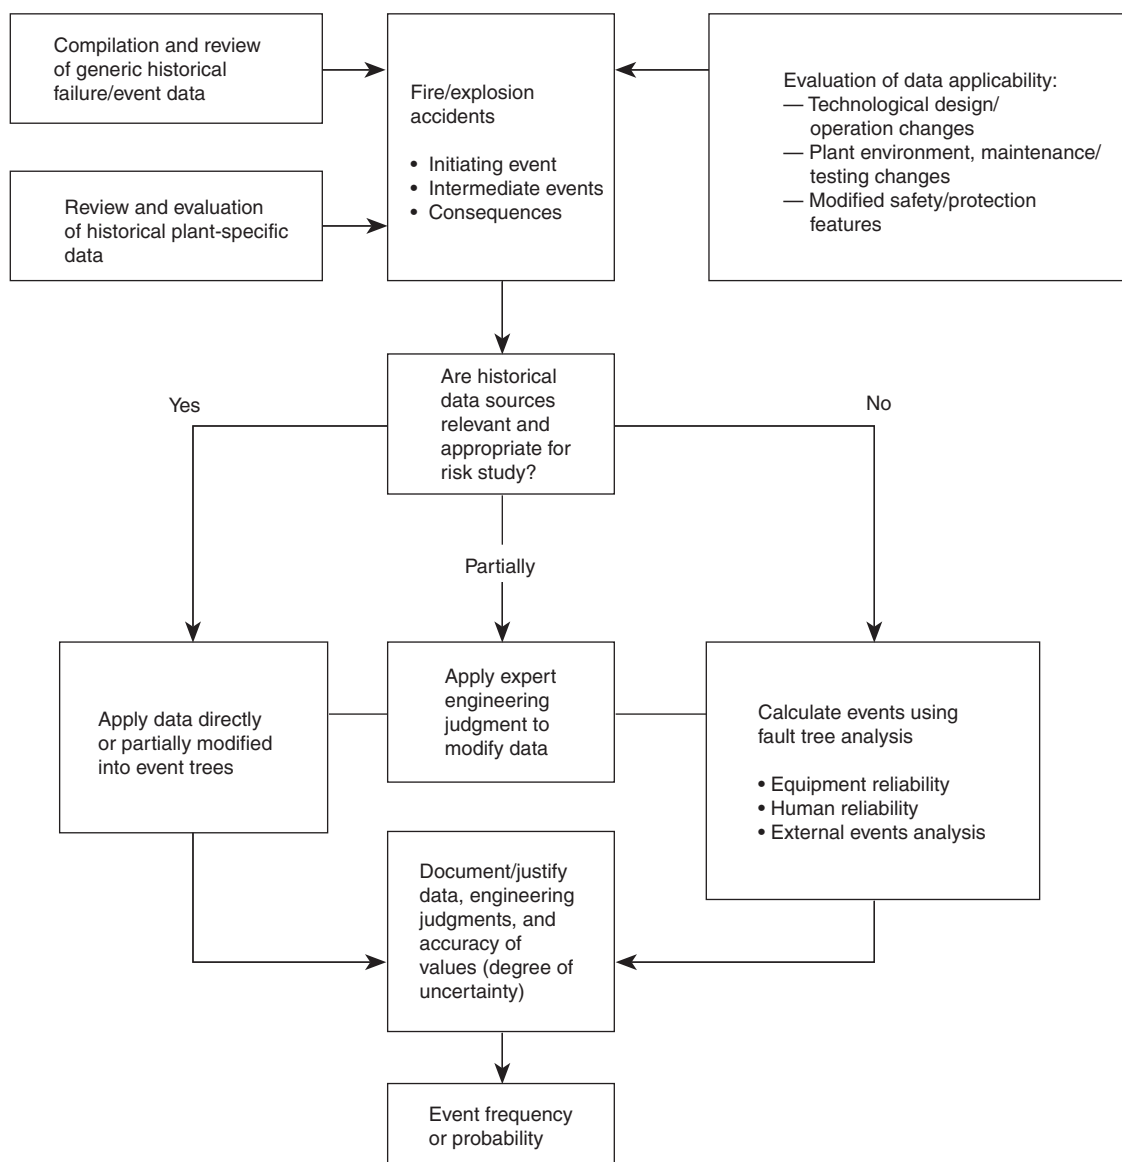

Figure 5-13.8. General procedure for estimating event frequency or probability.

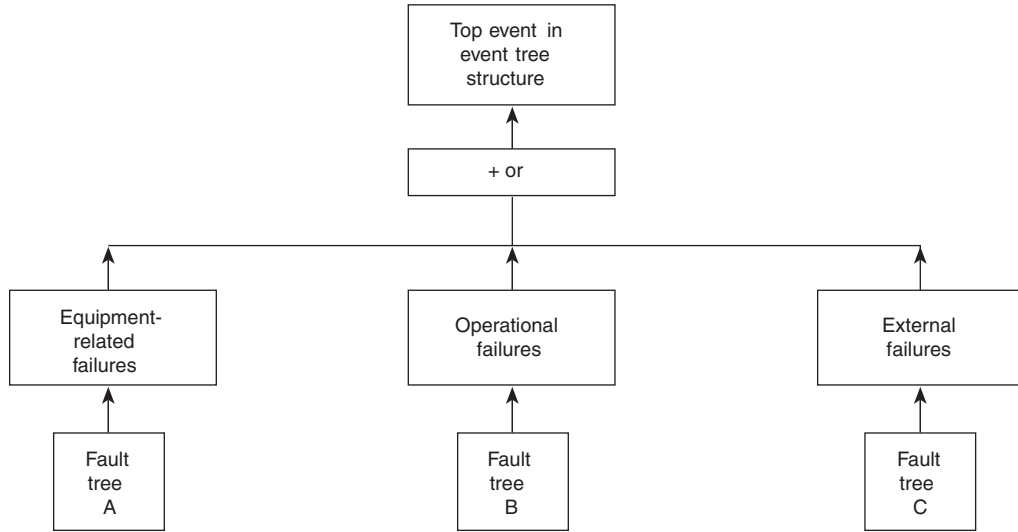

When these situations occur, it is often possible, and many times necessary, to generate data using the engineering judgment and expertise of the risk assessment team and, in some cases, outside experts. Experts, through their past experience with similar hazards or operations, can provide valuable input. Frequency or probability estimates obtained in this manner should combine the judgment and opinions of a group of experts, rather than rely on a single opinion.

Documentation methods: Methods for documenting the frequency and probability selection basis must be determined. To provide documentation, a table is usually constructed for each fire or explosion scenario event tree. Using the event sequences for the release from containment of a flammable liquid or gas, example information is

presented in Table 5-13.5. It is essential in all risk assessment projects to document the data selection basis and the associated uncertainties.

Equipment Failure Data Sources

An excellent source for generic equipment failure data is *Guidelines for Process Equipment Reliability Data, with Data Tables*, developed by the CCPS.¹³ The failure data can also be obtained as a computerized database on diskette. This book provides a listing and general description of all the data sources used to construct the CCPS generic failure rate database. It is essential for the fire risk analyst to understand the sources of these data, the limitations and applicability to the particular environment, and management controls for the specific facility being

Note: Fault trees A, B, and C are generally required to be developed into separate detailed fault tree models.

Figure 5-13.9. General fault tree support framework.

Table 5-13.5 Example of Documentation in Table Format

Event Tree Designation	Event Description	Frequency (F) or Probability (P) Range	Data Source	Frequency (F) or Probability (P) Assigned to Event	Selection Basis and Comments

assessed. This reference provides a good summary of these concerns.

Ignition Likelihood

Ignition likelihood is a measure of the expected ignition occurrence for a defined fire scenario, and may be expressed as

1. Frequency (i.e., number of occurrences per unit of time)
2. Annual probability (i.e., a probability of occurrence during a per-year time interval must be expressed as a number ranging from 0 to 1)
3. Conditional probability of occurrence given that a precursor event has occurred (e.g., release of flammable gas, molten metal spill, etc.)

The objective of ignition likelihood estimation is to estimate, in a systematic and credible manner, the cumulative ignition likelihood from defined fire scenarios. The procedures involved in this method generally require the integration of plant-specific data, deterministic flammable liquid spread, and gas dispersion modeling, as well

as engineering judgment. The sources listed in Table 5-13.1 and industrial insurance companies (such as Factory Mutual Research Corporation, Industrial Risk Insurers, etc.) are good sources for obtaining generic ignition data.

Ignition likelihood estimation steps include

1. Characterize and map ignition source potentials in the area(s) being evaluated.
2. Compile available plant-specific ignition–fire data, based on plant records and interviews.
3. Review available historical incident data sources that are similar to hazards being evaluated. (This should be used for reference and comparison.)

Ignition potential area boundaries (i.e., effect zone radius) should include

1. Potential pathway (area of exposure) where a flammable liquid or gas release could exist
2. Potential area that may be affected by a pressured fluid released (e.g., combustible hydraulic fluid, etc.)
3. Potential radiant heat energy effect area from an exposure fire

Figure 5-13.10 provides a general illustration of plotting ignition source distribution within a potential flammable gas dispersion area. Table 5-13.6 provides an example format for estimating cumulative ignition likelihood.

Ignition source potential(s) within the modeled effect zone area should be characterized by

1. Type and location of ignition sources, including fixed point (FP), linear source (LS), and variable point (VP)
2. Continuous (C) or intermittent (I) source
3. Ignition source energy potential [i.e., strong (S), moderate (M), or weak (W)]
4. Ignition source presence, whether (C) continuous or (I) intermittent. This is the estimated percentage (%) of time the ignition source is present
5. Ignition source energy potential. This is in relation to the fuel's ignition sensitivity, and should include

chemistry, physical state, surface texture, and moisture content

As a first step in evaluating ignition likelihood, all relevant ignition sources must be identified. Ignition sources usually fall under one of the following categories: fixed point, variable point, or linear sources.

Figures 5-13.11, 5-13.12, and 5-13.13 provide some examples of potential ignition sources.

Ignition is a function of time as well as temperature (i.e., potential fuel subjected to a relatively high temperature for a short period of time may not ignite, while the same fuel can undergo ignition when exposed for a longer duration to a lower temperature). For example, wood has a normal ignition temperature of 400 to 500°F (204 to 260°C), but has been found to ignite when subjected to a heat source of 228°F (109°C) for four days.

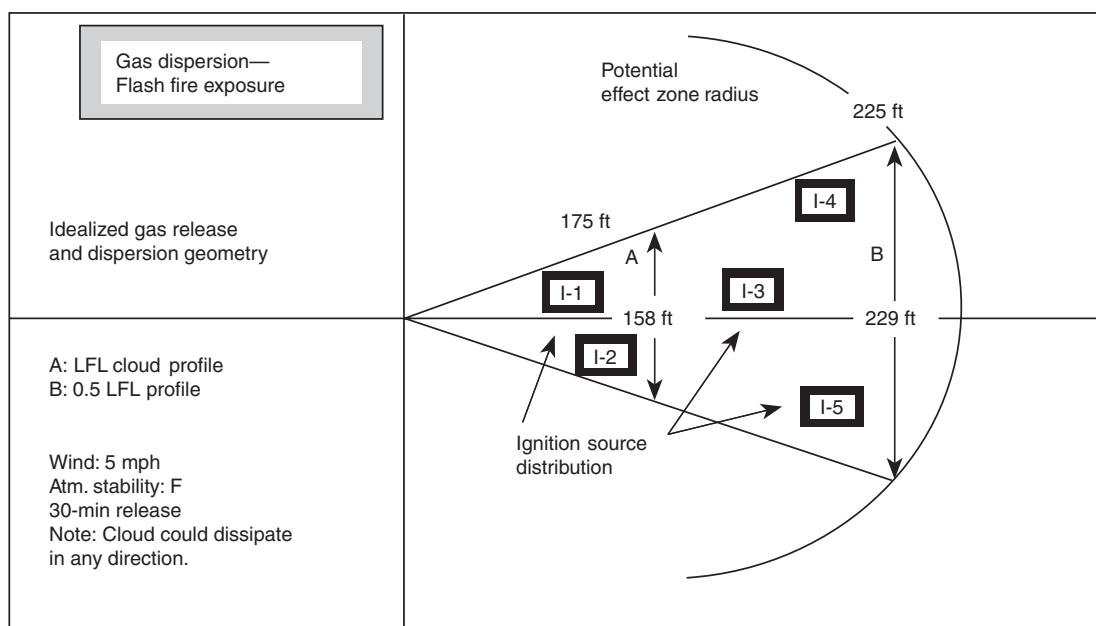

Figure 5-13.10. Illustration of plotting an effect zone to evaluate cumulative ignition likelihood. (See Table 5-13.6 for boldfaced box definitions.)

Table 5-13.6 Example of Estimating Cumulative Ignition Likelihood

(Fig. 5-13.10) Potential Ignition Source(s)	Continuous (C) or Intermittent (I) Ignition Source	Strong (S), Moderate (M), or Weak (W) Ignition Energy Source	Likelihood of Ignition Based on Ignition Source Being Engulfed with Flammable Vapor	If Intermittent Source, Estimated Time (per year) for Which Intermittent Source Is Present and Active	Likelihood of Ignition, Given Release and Flammable Cloud
I-1	I	M	0.06	10%	0.006
I-2	I	S	0.9	15%	0.135
I-3	I	M	0.06	30%	0.018
I-4	C	M	0.06	100%	0.06
I-5	C	S	0.24	100%	0.24
Cumulative likelihood of ignition:					0.46

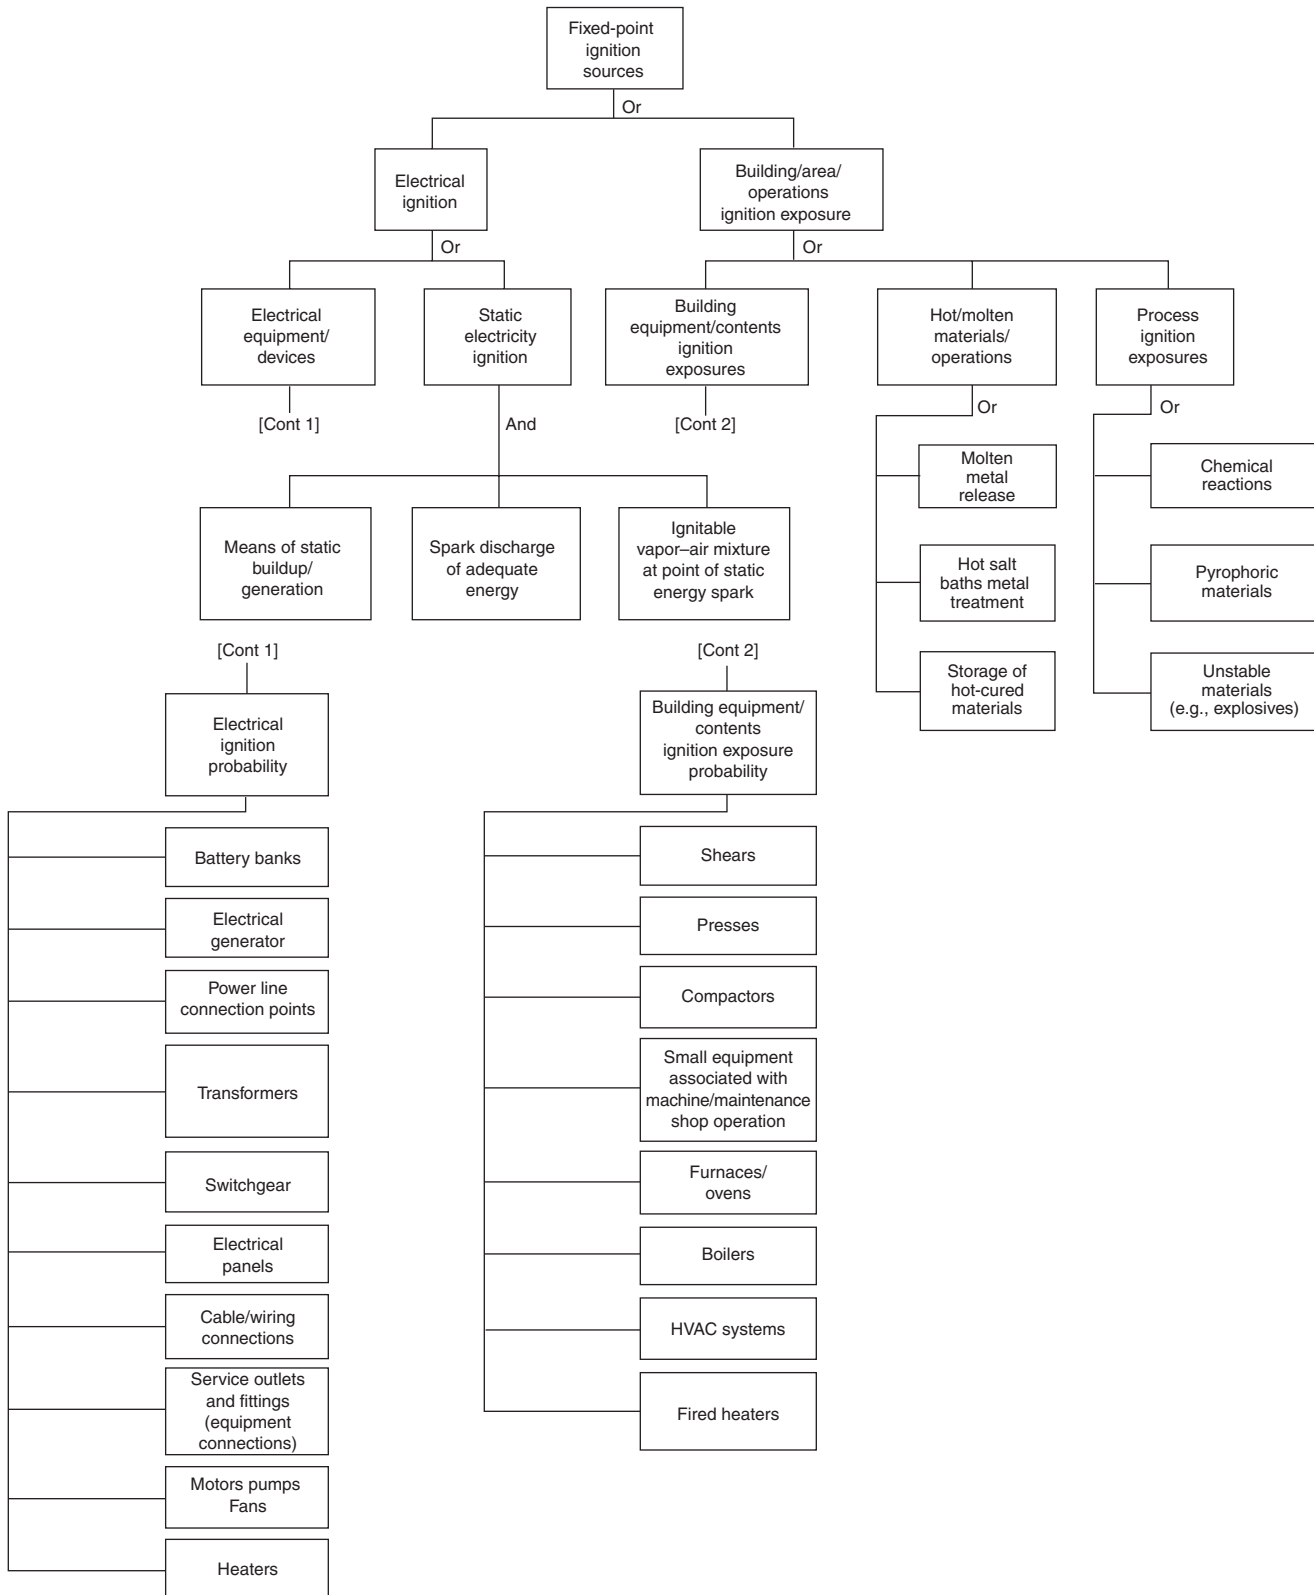

Figure 5-13.11. Potential ignition sources—fixed point.

Figure 5-13.12. Potential ignition sources—variable point.

Examples of conditional ignition likelihood ranges for flammable liquid vapors or gases engulfing ignition sources are provided by References 5 and 14.

Qualitative Ranking	Likelihood Range
(S) Strong	0.25 to 1
(M) Moderate	0.1 to 0.24
(W) Weak	0.01 to 0.09

Ignition likelihood estimation provides for the likelihood of ignition, F_{ig} , and is primarily dependent on the following factors:

- F_{te} Frequency of time the ignition source exposure is present in the immediate area of the combustible material being examined under defined scenario conditions.
- P_{il} Probability the ignition source exposure exceeds the ignition threshold limits (i.e., temperature, energy)

for the combustible material being examined under defined scenario conditions. This probability parameter includes both accedence of ignition threshold limits under normal operating conditions and also under fault (e.g., equipment failure that could result in shorting or overheating, thus exceeding the ignition threshold limits of the material being examined).

- P_{cf} Probability that the configuration (e.g., unobstructed pathway, positioning) between the ignition source and combustible is conducive to initiating ignition.
- P_{ne} Probability the ignition source is *not* eliminated (e.g., automatic, manual shutdown of electrical power, etc.) prior to established ignition.

Therefore, the general sequence of ignition-related events can be represented as

$$F_{ig} = F_{te} \times P_{il} \times P_{cf} \times P_{ne}$$

Figure 5-13.13. Potential ignition—linear sources.

Fire Protection System Performance

The following information was extracted from Reference 10 and is based on a methodology applied at industrial process facilities for quantifying the probability of fire protection system (FPS) performance success.

Figure 5-13.14 presents the primary fire protection system of interest in fire risk assessments and includes

- Detection systems
- Emergency control systems
- Automatic suppression systems
- Propagation limiting measures (i.e., fire barriers)
- Manual loss control intervention

Two items to note in Figure 5-13.14 are

1. Fire protection systems performance success is quantified in terms of *conditional probabilities*.
2. The three primary fire protection system performance measures and objectives include
 - Response effectiveness—maximize system response time
 - Online availabilities—minimize system downtime
 - Operational reliability—minimize failure-on-demand probability

For a defined fire protection system under a scenario-specific demand, performance success can be evaluated in terms of performance measures and indicators which are developed from past system failure experience. Figure 5-13.15 provides an example of some primary success measures.

Fire protection system performance success is the product of these three probabilistic success measures:

The unique feature in the FPS performance success methodology is that it provides a consistent logical approach towards quantifying performance based on

- Specific scenario input
- Risk tolerance criteria
- Defined performance requirements

The methodology provides a breakdown of experience-based performance success expectation based on response effectiveness (design application bases, system response time), online availability (potential downtime factors), and operational reliability (probability of failure on demand from hidden, and common cause failure potentials).

The methodology allows integration of probabilistic failure of equipment, human error aspects, deterministic modeling to support failure or success probabilities, and

Figure 5-13.14. General illustration—loss control systems performance measures.¹⁰

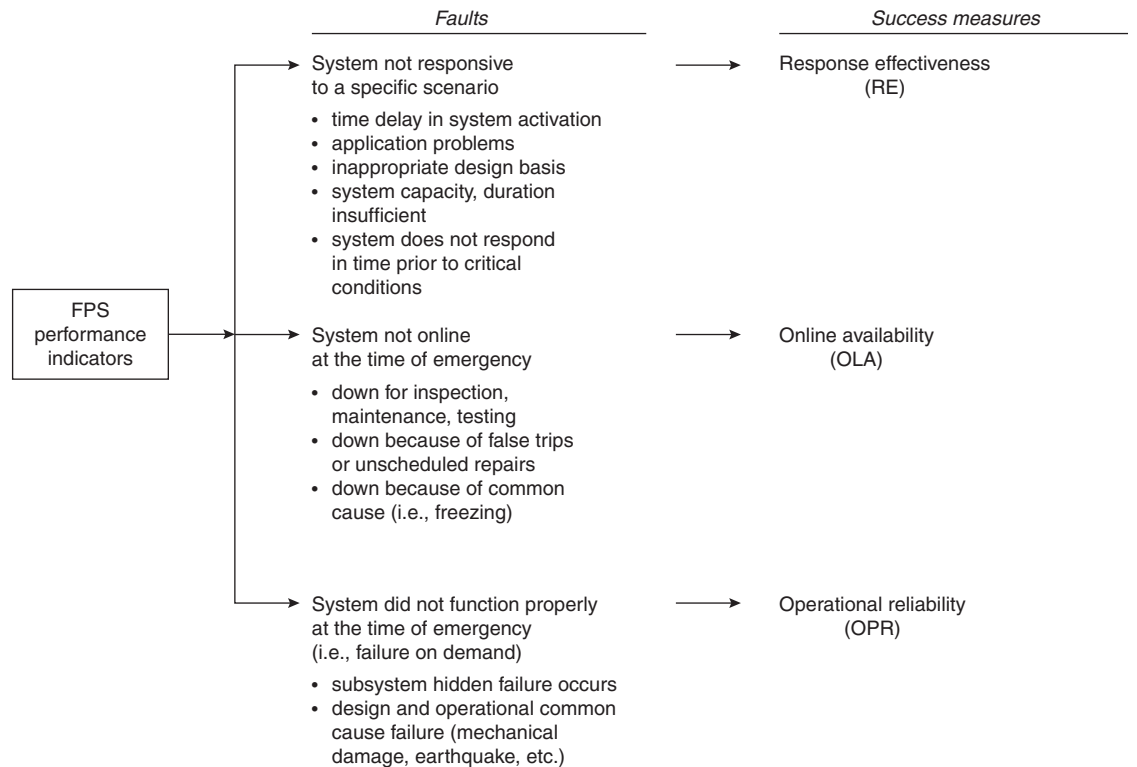

Figure 5-13.15. Example of primary FPS success measures.¹⁰

incorporation of systematic justification of engineering judgment and expert opinion to support subjective probability (i.e., quality scoring of performance integrity measures). The conditional probabilities of FPS performance success following the defined initiation event are then inserted as top events in the ETA where the time line of sequential events leads to incident outcomes and potential consequence levels.

The methodology can be used to evaluate

- Existing systems
- Modifications/inputs to existing designs
- Newly proposed system design

Figure 5-13.16 presents the general fire protection system success tree logic. This figure highlights the time-related performance factors, which in many cases are very critical factors and which are not well addressed in design standards, such as NFPA standards.

As presented in Figure 5-13.17, the response effectiveness (RE) evaluation is quantified in terms of

- DAB—Design application basis
- SRT—System response time

The following information in this section overviews some of the primary response effectiveness success measures and suggests probability estimation approaches.

DAB evaluation involves

- Identifying DAB success measures
- Probability selection based on functional performance requirements

Figure 5-13.18 provides a listing of the primary DAB success measures, based on past fire protection system faults. These include

- Suitability
- Capacity
- Duration

Figure 5-13.19 illustrates the general DAB success tree framework.

DAB—Suitability

The suitability of the fire protection system must be evaluated in terms of the functional performance requirements, which requires knowledge of the specific scenario input and target threshold damage limits.

Some suitability considerations include

- Is the system actuation device suitable?
- Is the suppression mechanism suitable?
- Will suppression agent create excessive damage?
- Are barriers suitable (i.e., heat, smoke resistance)?

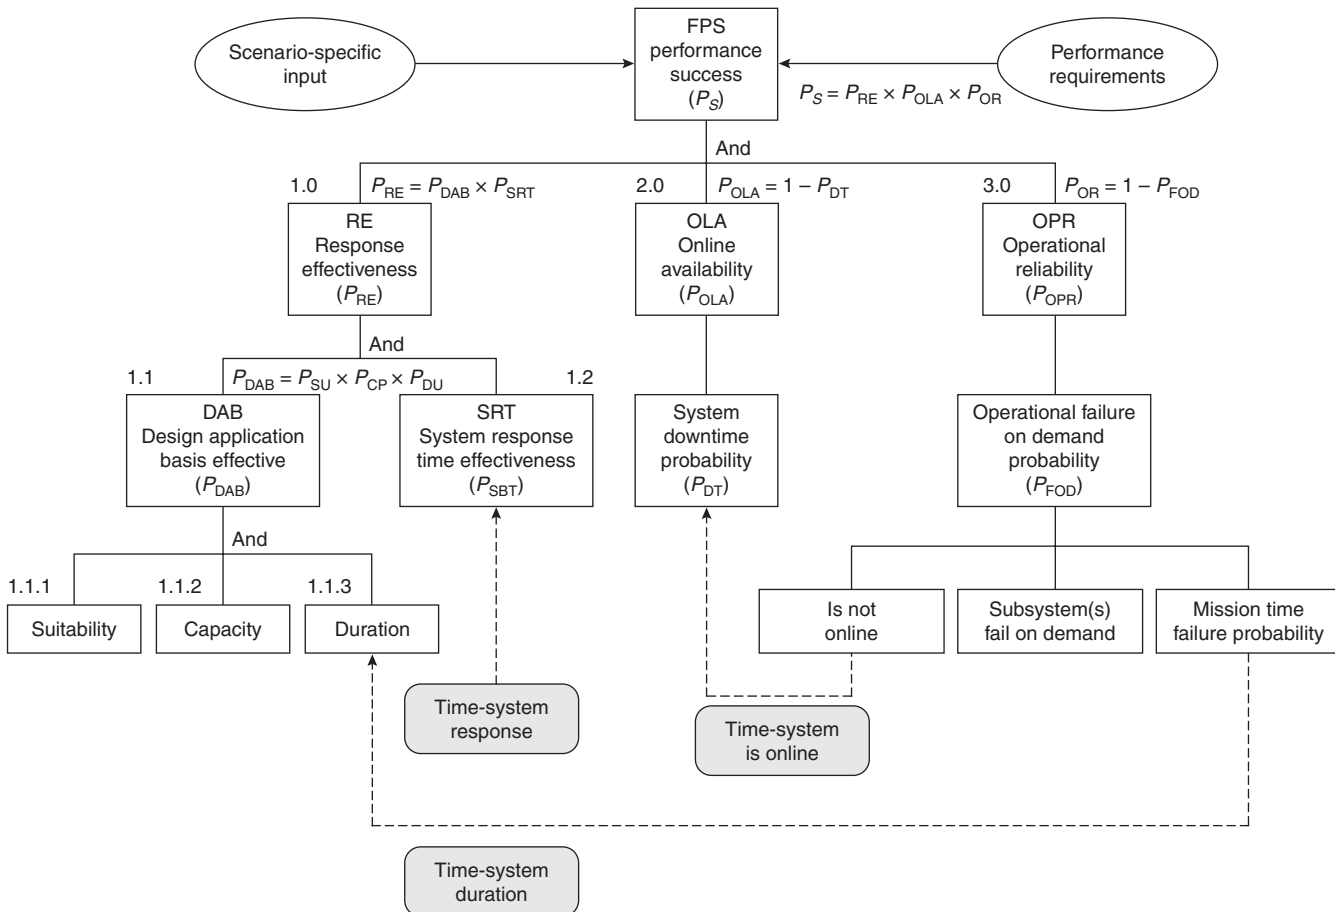

Figure 5-13.16. FPS performance success tree framework—highlighting time-related performance factors.¹⁰

Figure 5-13.17. FPS response effectiveness probability as related to functional performance requirements and success measures for FPS under evaluation.¹⁰

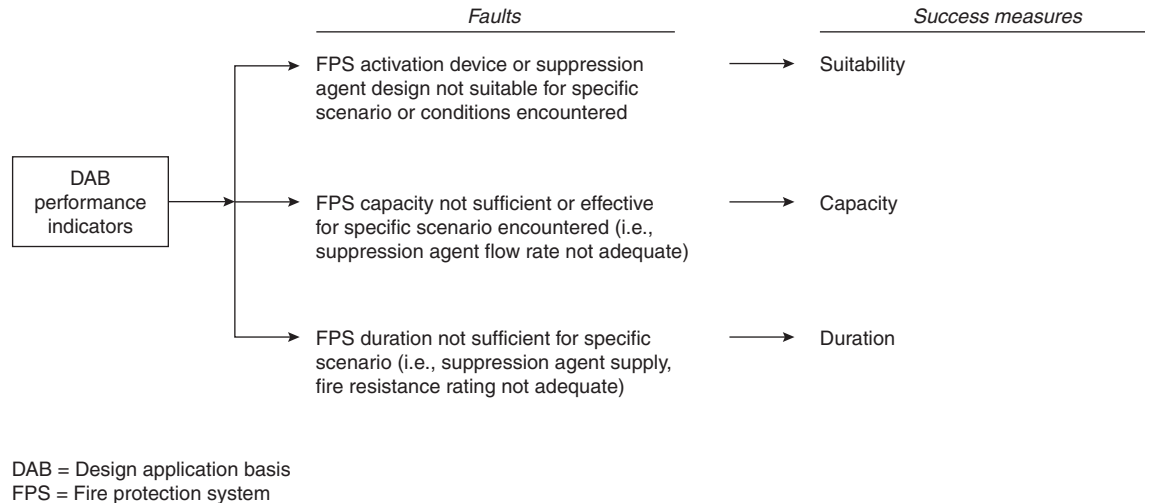

Figure 5-13.18. Example of general DAB success measures.¹⁰

Suitable means appropriate to a particular situation or condition. Experience is the primary dictator of suitability and can include the following information sources

- Standards, industry practices
- Plant-, industry-specific experience
- Loss incident data
- Research and testing
- Engineering judgment (expert opinion)

Suitability questions whether the fire protection system under evaluation is appropriate to the particular situation, conditions, scenario input, and functional performance requirements. It also should be suitable for the

- Hazard
- Limitation of damage
- Impact on people
- Limitation of production equipment downtime
- Environmental concerns

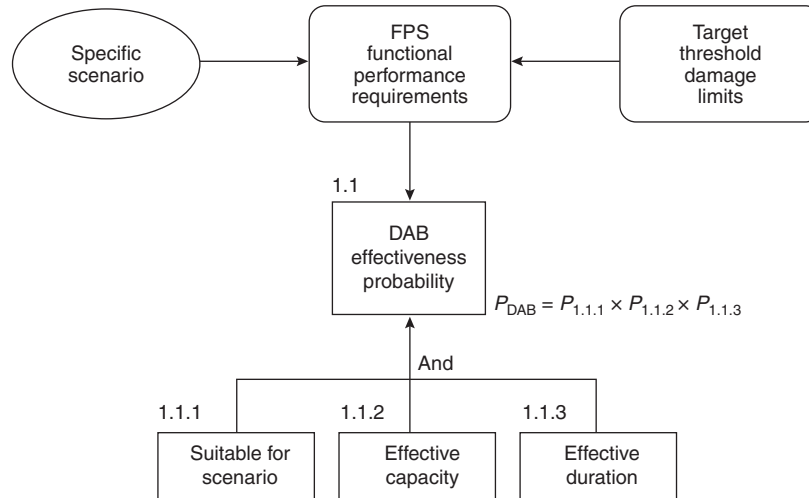

Figure 5-13.19. General DAB success tree framework.¹⁰

Detection systems functional performance scenario-specific suitability objectives could include detection of

- Smoke (aerosols)
- IR and UV radiant energy (flame)
- Thermal energy (heat, temperature rise)
- Gases [direct releases of flammable, toxic, or corrosive gases or products of fire combustion gases such as carbon monoxide (CO), hydrogen chloride (HCN), etc.]
- Pressure (pressure rise detectors such as those associated with explosion suppression system)

With detection systems, in many cases, there is a relationship between the scenario suitability and response time.

- Emergency control systems (ECS) functional objectives could include
 - Emergency system shutdown of production equipment or utilities (i.e., electrical power, gas lines)
 - Emergency system startup of safety systems
- Emergency system shutdown could include
 - Shutdown flammable liquid pumps
 - Shutdown production equipment
 - Shutdown ventilation systems
 - Shutdown electrical power
- Emergency system operation mechanisms could include
 - Startup ventilation on smoke removal system
 - Startup gas depressurization system
 - Startup/activate suppression systems

The suitability question is whether the existing ECS mechanisms or proposed ECS can meet the defined functional performance requirements. In most cases the focus of ECS evaluation is on the operational reliability. However, ECS such as diking, drainage or containment systems, gas blow down–emergency flare systems, ventilation systems, etc., must first be evaluated from a design application viewpoint.

DAB—Capacity Effectiveness

Capacity can be generally defined as the maximum production, or the output, of an existing FPS or proposed design. Capacity issues are primarily related to suppression systems; however, detection system alarm audibility, emergency control systems (such as drainage systems, gas blow-down systems, etc.) would also be examined in terms of capacity. In most cases, the probability associated with design capacity is fairly straightforward, based on the engineering review.

If for example, the capacity effectiveness is associated with the flow rate or density of a water-based extinguishing system (i.e., sprinkler, water-spray, pumping system, etc.), then based on the functional requirements (i.e., need 0.25 GPM/3000 sq. ft. density), one can determine if this is available using water flow hydraulics modeling.

The most important issue here is to clearly define the functional capacity requirements. When doing a risk-informed evaluation, the focus is on how all the fire protection systems perform in mitigating the initiating scenario in relation to the risk tolerance limit. That means in some cases, only control or suppression, not immediate extinguishment, may be needed to meet risk tolerance.

For example, focusing on a water-based fire protection system, various levels of performance can be achieved based on the defined initiating event, as shown in Figure 5-13.20.

- Fire control
- Fire suppression
- Fire extinguishment

DAB—Duration

As a general definition, duration is the period of time that something lasts as determined by an existing or proposed design. This could be the adequacy of the suppres-

Figure 5-13.20. General illustration—control, suppression, extinguishment.

sion agent supply, the fire resistance rating of a fire barrier wall, and so on.

As with the capacity evaluation, duration effectiveness is evaluated based on our functional performance requirements, not codes. In other words, codes could call for a 2-hour water supply or 2-hour fire wall, while the performance requirement could be 30 min. Or vice versa, the performance requirements could be greater than the codes.

Strongly related to duration is supply redundancy. However, the DAB evaluation is based on the total supply available for use versus performance requirements. The probability that multiple or redundant supplies are available at the time of a fire incident are evaluated as an on-line availability probability.

DAB—Probability Sources

Primary probability sources for use in evaluating the DAB segment of the system response effectiveness are

1. Experience
 - Standards, industry practices
 - Plant-, industry-specific experience
 - Loss incident data
 - Research and testing
2. Deterministic modeling

Models to support DAB probability evaluations can include

 - Hydraulic models
 - Heat transfer models

3. Engineering judgment
 In the majority of cases based on items 1 and 2 above, the following probability (*P*) estimation will be selected:

- $P = 1$ DAB is effective
- $P = 0$ DAB is not effective

However, in some cases there may be uncertainty due to insufficient knowledge or experience. Engineering judgment usually involves reviewing information obtained from probability sources 1 and 2 and applying expert opinion and team consensus.

System Response Time

SRT evaluation involves

- Identifying success tree indicators
- Relating scenarios to functional performance requirements
- Probability selection

Figure 5-13.21 provides an example of general SRT success measures.

Figure 5-13.22 presents the SRT effectiveness probability related to functional performance requirements and success measures.

Automatic Response Time

Primary considerations include

- Detection unit activation time
- Sprinkler head activation time
- Automatic time delay features
- Barriers—fire resistance integrity times

The scenario-based exposure profile is needed as input to evaluate the time response of fire protection systems. The exposure profile in Figure 5-13.23 provides an example of a critical time line for actuation responses of some fire protection systems, showing the time line at the bottom of the graph and potential target impact levels on the right side of the graph.

Development of the exposure profile and time line is the primary input for evaluating the SRT success probability.

The time limits establish the system response requirements of the evaluation. Remember, even though the FPS may meet the suitability, capacity, and durational measures, if the system cannot respond (i.e., activate, operate) prior to critical conditions at the target, the overall response effectiveness may be severely compromised.

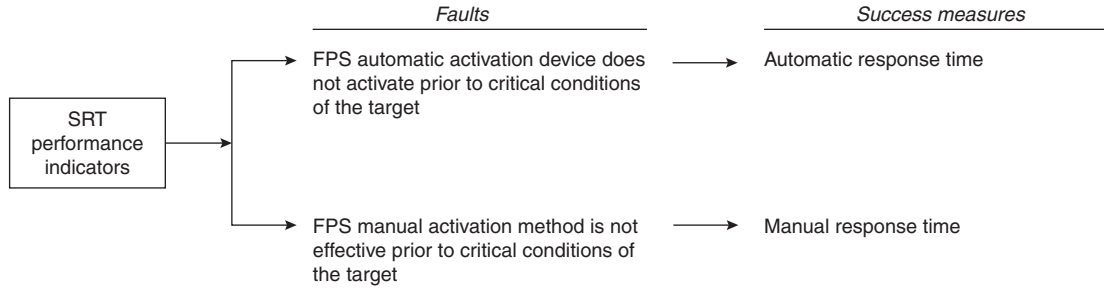

Figure 5-13.21. Example general SRT success measures.¹⁰

Figure 5-13.22. System response time (SRT) effectiveness probability.¹⁰

Probability Sources

Probability sources to support SRT evaluation include

- Deterministic modeling
- Manufacturer’s information
- Research and testing
- Engineering judgment

Deterministic detector and sprinkler head computerized models can provide support in the selection of probabilistic success estimates. Presently available computer models which estimate detection and sprinkler head response use the concept of a response time index (RTI) as related to the detector or sprinkler head under evaluation. In addition, heat transfer computer models are available to estimate the fire resistance of fire barrier components and assemblies.

Online Availability

If the fire protection system (FPS) is not online during an emergency demand, we have a failure. In our sug-

gested FPS performance evaluation methodology, functional failure potential is broken down as follows:

The major difference in this interpretation is that unavailability is primarily related to known or projected downtime potentials, while operational failure on demand is primarily related to hidden failure-on-demand potentials. These are discussed in the next two sections.

In applying performance success tree logic, we have the following correlations:

$$\text{Reliability} = 1 - \text{Functional failure}$$

$$\text{Online availability} = 1 - \text{Unavailability}$$

$$\text{Operational reliability} = 1 - \text{Operational failure on demand}$$

Figure 5-13.23. Example scenario-based exposure profile curve with risk tolerance points.¹⁰

The benefits of examining online availability (OLA) as an individual reliability-based performance measure are

- Existing systems
 - Allows evaluation of downtime factors based on plant experience
 - Identifies downtime and availability factors related to inspection, maintenance, and testing (IMT) efforts, false system activation problems, and common cause problems such as freezing, flooding, and so on.
- New system designs or modifications
 - Identifies opportunities to minimize potential downtime factors and to maximize availability based on design and recognition of common cause failure potentials.
 - Identifies opportunities to optimize downtime potentials associated with IMT efforts

Presented in Figure 5-13.24 is the logic tree for OLA. As illustrated, a fault tree approach is used to evaluate the downtime probability (note OR gate). This is then converted to success tree logic. The entire logic tree could be handled initially as a success tree; however, this conver-

sion of using fault tree analysis and then converting is generally more efficient because information is usually conveyed in plant records as downtime hours, not as uptime or online hours.

Off-line due to IMT: The primary information sources on downtime associated with FPS system IMT activities are the plant’s maintenance logs, records, and interviews with maintenance personnel.

The estimates of this annual probability are derived from the historical or projected time (hours) when the FPS system is not available to perform its intended function, divided by the hours in a year. For example, if the system is taken off-line 80 hours per year to perform IMT efforts, then the annual probability of IMT unavailability is

$$\frac{80 \text{ hr/yr downtime}}{8760 \text{ hr/yr}} = .009$$

Interval unavailability due to periodic IMT is given by

$$\text{Downtime}_{\text{IMT}}(0, T_1) = \frac{t_{\text{TM}}}{T_1}$$

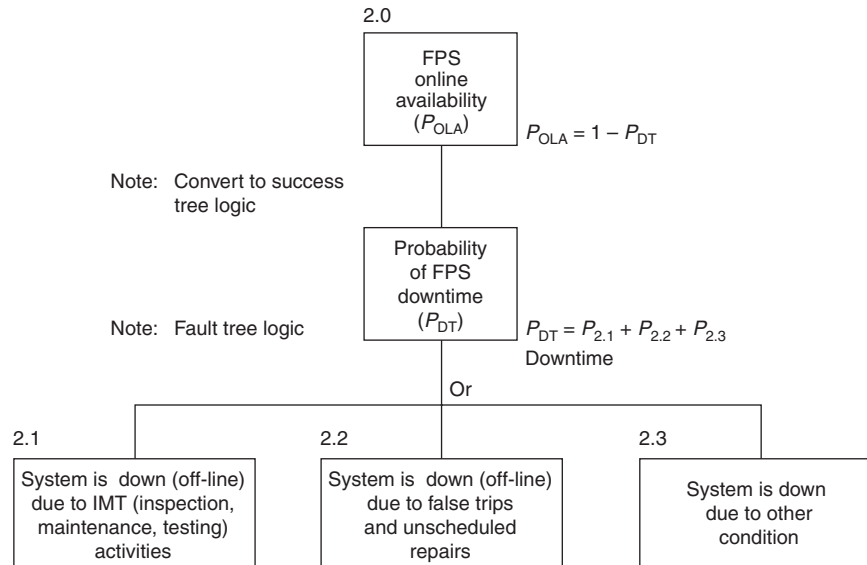

Figure 5-13.24. OLA general fault and success tree logic.¹⁰

where t_{TM} is the average duration of time the system is out of service for each periodic IMT and T_I is the interval of time between successive IMT efforts. (Note: This unavailability does not include the unavailability due to system failure, which is addressed under operational reliability for hidden failures on demand.)

It should be noted that that IMT activities where systems are taken off-line present a negative effect under online availability evaluation. However, IMT efforts to discover hidden or unrevealed factors in the assessment of operational reliability is a very important factor. An optimized balance between the two needs to be considered when trying to achieve a maximum system performance success probability.

Off-line due to false trips: False trips or activation of FPS, also termed nuisance or spurious trips, create a situation where the system is shut down and taken off-line, so that cause can be investigated and repairs made if necessary.

The problems associated with false trips generally involve

- The system is taken off-line and therefore is not available during a fire.
- When numerous false trips and alarms occur, occupants become complacent, responding slowly or sometimes ignoring alarms—a major problem in the event of a real fire.
- In many cases systems are bypassed and taken off-line for extended periods of time.

Most false trip problems are location and design related.

In many cases, facilities reduce detection-related false alarms by disconnecting or jumpering out the alarm until the problem is resolved. While this reduces false trip er-

rors, it increases the probability of having the detection system unavailable during a fire emergency.

Some other common causes of automatic fire detectors' false activation include

- Insect induced
- Owner induced (lack of maintenance)
- User induced (accidental smoke generation or malicious actuation)
- Serviceman induced (improper testing)
- Environmental effects (lightning)

Unscheduled repairs and external factors: Unscheduled repairs following IMT efforts or external downtime causes can take many forms. Having equipment spares, quick access to repairs versus service contracts, and contingency plans to expedite repair and replacement are very important.

For example, unscheduled repairs for components on fire barriers can represent an availability problem. Forklift damage to fire doors or fire barriers can be a constantly occurring problem. I have reviewed many plans from a design standpoint where, based on a first look, the performance success of the fire barrier walls would be rated high. However, after conducting a field survey, problems identified included damaged fire doors painted links, locks on fire doors, doors wedged open and dampers tied open for ventilation reasons, unsealed cables compromising the fire wall, and so on. Therefore, even if the fire barrier has an appropriate fire resistance design basis, the performance success probability related to scenario-specific performance requirements may be low.

External factors that can cause system downtime include freezing weather, flooding, vehicle damage, and so forth.

For example in one project, based on plant records and interviews, it was identified at one plant that the control valves for a sprinkler protection system over the oil-fired burner system for a boiler were shut off for 4 months a year due to fear of freezing. The corporate safety director was unaware of this practice. The annual downtime probability on this system, which was a critical system from a business interruption standpoint, was equated at

$$\frac{4 \text{ months down}}{12 \text{ months}} = .33 \text{ annual probability of downtime, or } .67 \text{ availability}$$

As evident, this was a design and communication problem which in overall methodology would severely affect overall system success probability.

Another example was discovered at a chemical plant. Due to flooding, water runoff, and drainage problems, the fire pump house was flooded three times over a 5-year period. When the fire pump house was flooded, the controllers on the fire pumps were shut off, and the average time for cleanup and repair was 32 hours per incident. This equates to fractional downtime probability of .192, or an OLA of .81.

The fire pumps presented a common cause failure to numerous deluge water spray systems at this plant. Recommendations concerning water runoff channeling and drainage in the pump house area were made to improve this situation.

Target availabilities for systems should be in the range of .98 to .999.

Operational Reliability Evaluation Logic

Fire protection system's operational reliability (OPR) is the ability to operate on demand and perform an operational requirement. OPR is a probability to operate on demand, not an OLA probability. For example, if a sprinkler system control valve is shut off to perform maintenance, repair, or testing, this is an unavailability factor. However, if the control valve partially fails or fully fails when placed in an emergency demand state due to a hidden mechanical degradation failure (i.e., gate valve

drops causing partial or full obstruction to the water supply to the sprinkler system), this is an operational failure at demand.

Depending on the type of fire protection system, operational function may vary. Therefore, the required operational performance functions of the fire protection system must be defined. For example, a sprinkler system's operational functions may be delivering water from the pumping supply to the sprinkler heads in the area of fire incident. Primary operation on demand contributing factors include the electrical-mechanical subsystem functions needed to make this occur. For example, pump starts, valves open, piping is unobstructed, and sprinkler heads fuse and deliver water to the fire origin. The activation-time response of the sprinkler head(s) and the performance-based water flow capacities and duration would be initially evaluated under the response effectiveness probability prior to this point.

Quantifying the probability of FPS OPR involves an evaluation of

1. Identifying performance success measures
2. Qualitative logic structuring
3. Performance integrity measures
4. Quantification of failure-on-demand probabilities

OPR success measure: Figure 5-13.25 presents some of the primary faults and associated success measures related to FPS operational reliability (OPR).

Figure 5-13.26 provides illustration of the general OPR success tree framework.

The framework for addressing the design application basis and the OLA is very similar for numerous fire protection systems. The evaluation of the subsystem failures which need to be examined as part of the OPR differs. However, there can be a common method for addressing the evaluation structure.

Some of the issues which should be recognized include

- Apply a consistent qualitative logic methodology for FPS system and subsystem breakdown.
- Recognize and integrate manual intervention features if relevant to the evaluation.

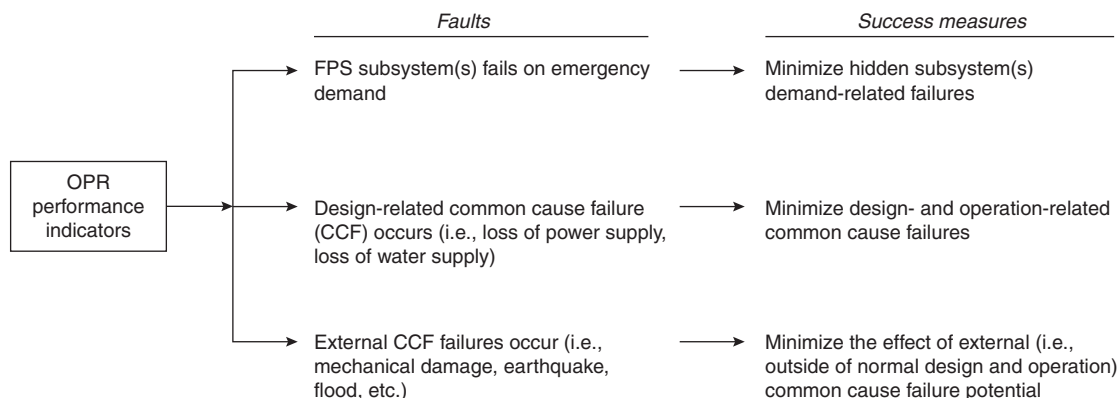

Figure 5-13.25. Example of general OPR success measures.¹⁰

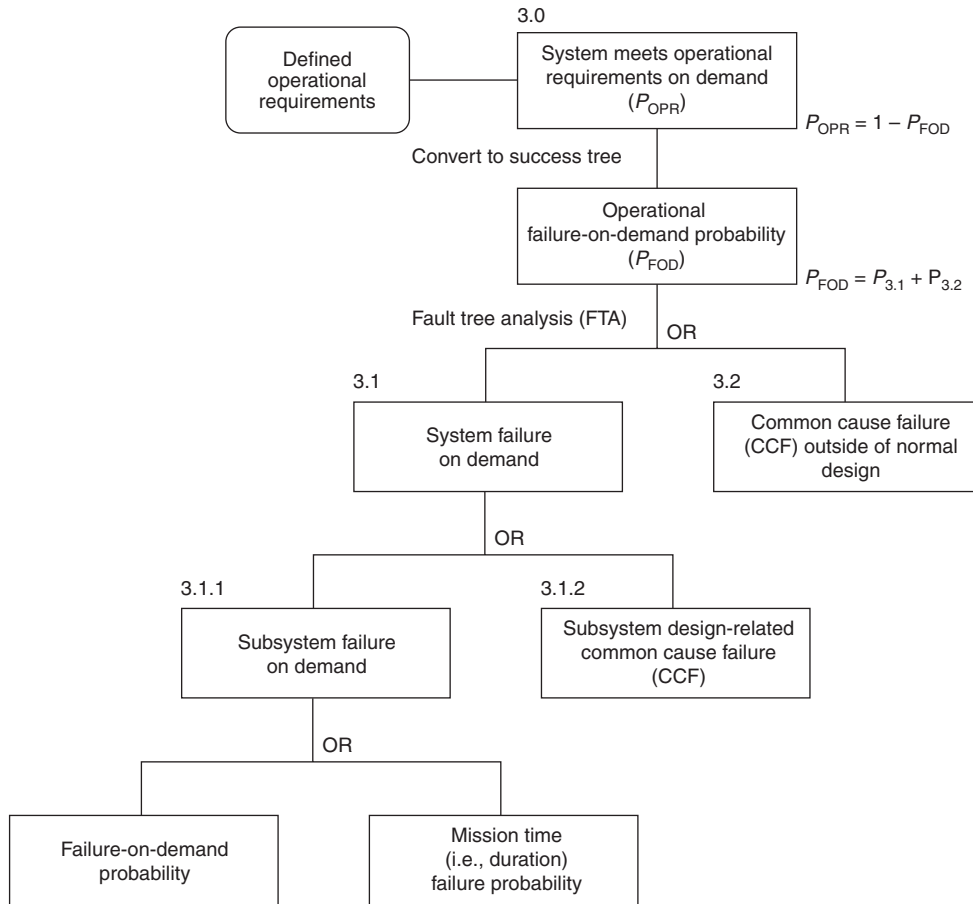

Figure 5-13.26. Operational reliability (OPR) success tree framework.¹⁰

- Properly address operational requirements versus system redundancy features.
- Document the process and assumptions.

When evaluating operational reliability we are initially concerned with a first-order review. That is, the probability of operational success at demand of the subsystem elements and primary components which significantly contribute to the system level operational requirements.

Figure 5-13.27 provides an example of a first-order breakdown:

- System level
- Subsystems
- Subsystem elements or components
- Evaluation breakdown

Input → control → output: In evaluating FPS system failure on demand potential, one can subdivide the system or subsystem interface into an Input → Control → Output evaluation. Table 5-13.7 summarizes this for some systems.

OPR Quantification

As illustrated in Figure 5-13.28, there can be numerous failure data inputs needed to assess the overall

failure-on-demand potential. In many cases the failure data will have to be adjusted or modified based on plant-specific conditions, the quality grading of the performance integrity measures, and engineering judgment.

The failure data sources used in the evaluation should be listed. Remarks might include what failure rate adjustment method was applied if applicable. Some primary failure data sources are listed in Table 5-13.8.

Plant-specific data: Plant data are the best data to compile and apply because they are specific to the process, environment, inspection, and maintenance testing practices.

Drawbacks of this approach are that sufficient plant-specific historical (operational) data may not be available and that available data may not pertain to a specific system but to subsystems or components of different manufacture, design, size, and ratings.

If sufficient operational history pertaining to a particular FPS system or subsystem is available, it may provide accurate estimates of reliability. However, in many situations, the available data may be very limited and the estimation of reliability from such a limited amount of data may be accurate in an order-of-magnitude sense only.

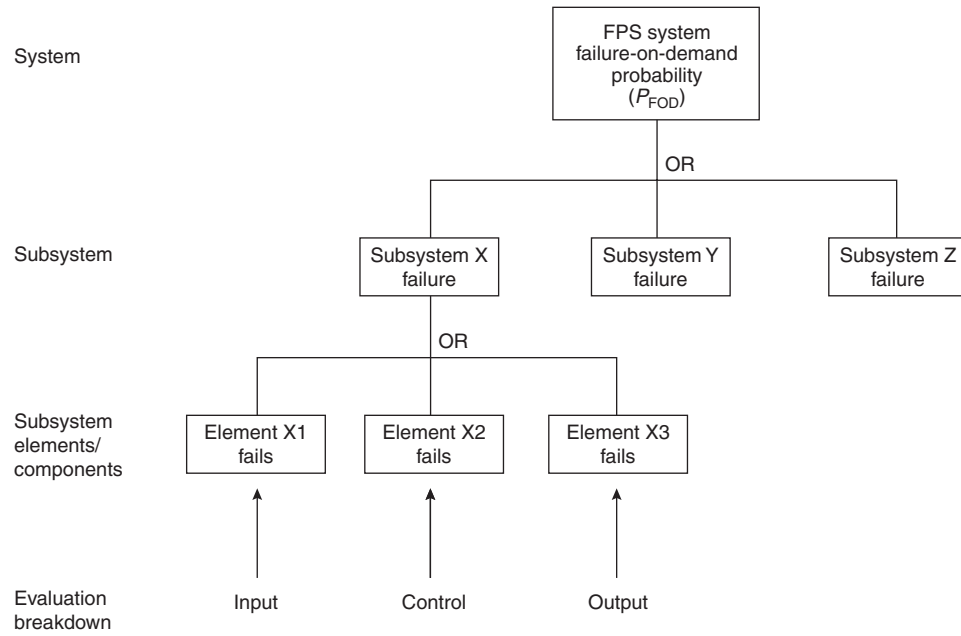

Figure 5-13.27. Example of FPS subsystem breakdown.¹⁰

Table 5-13.7 Example Input → Control → Output¹⁰

System	Input	Control	Output
Detection System	Detection Devices	Control Panel	Alarms/Interlocks
Emergency control system	Detection/alarm inputs	Control unit(s) (PLC—programmable logic controller)	Emergency shutdown or startup interlocks
Fire suppression systems (i.e., a sprinkler or water spray system)	Water supply • tanks • pumps	Water distribution • piping • valves • components	Water flow at nozzles • piping • sprinkler heads/water spray nozzles
Fire barrier system	Barrier components • doors • dampers • penetrations	Barrier integrity • components • structural stability of wall	Fire resistance • tightness • duration

Figure 5-13.28. Failure data inputs.

The advantages of gathering plant-specific data are that they reflect the plant's historical loss profile based on specific

- Design factors
- IMT programs
- Operating procedures
- Management loss control programs

The realities of collecting plant-specific data include

- Many failures and near-loss incidents are not recorded.
- Raw data in maintenance and operation logs may be incomplete and are usually not in a form readily usable for failure and reliability analysis.
- The population or operating time of a facility, process, or equipment may be limited and thus not reflect the long-term failure potential.

Table 5-13.8 Some Failure Data Sources

Data Type	Data Source
Plant-specific data	<ul style="list-style-type: none"> Plant records Plant walkdowns and interviews
Equipment manufacturers' data	<ul style="list-style-type: none"> Equipment components—mean time between failure (MTBF) data System-level reliability data
Relative failure incident data	<ul style="list-style-type: none"> Industry associations Insurance companies
Published failure rate data	<ul style="list-style-type: none"> Industry-specific data Generic failure rate data
Human error data	<ul style="list-style-type: none"> Plant records Generic human reliability data
External event data	<ul style="list-style-type: none"> Plant data Natural event databases
Judgmental data	<ul style="list-style-type: none"> Internal expert opinion

Methods that can be applied to compile plant-specific information include

- Conduct structured interviews with plant personnel who have experience in the operations and maintenance of the facility or operation being evaluated, to categorize the potential likelihood of events based on historical experience.
- Compile plant site raw data into a database format.
- Conduct an audit of the plant's management loss control programs. This can be used as input and support for modifying historical failures based on present plant practices.

Published failure rate data: Failure rate data can be preferably extracted from plant-specific data sources. This is the best source of data, and this type of data may be obtained from operational and maintenance logs and records and from numerous interviews conducted with experienced plant personnel. Engineering judgments concerning the use and adjustment of these data can be based on plant surveys, available data, interviews, and experience. Published popular failure rate data sources include the following:

- Guidelines for Process Equipment Reliability Data*, American Institute of Chemical Engineers, New York (1989).
- IEEE Guide to the Collection and Presentation of Electrical, Electronic, Sensing Component, and Mechanical Equipment Reliability Data for Nuclear Power Generating Stations*, IEEE Std 500-1984, Institute of Electrical and Electronics Engineers, Inc., New York, NY (1983).
- OREDA Participants, *Offshore Reliability Data Handbook*, Penn Well Publishing Company, Hovik, Norway (1984).
- Reliability Programs for Nonelectronic Designs*, RADCTR-83-85, Vols. 1 and 2, Rome Air Development Center, Griffiss Air Force Base, NY (1983).

Nonelectronic Parts Reliability Data, NPRD-3, Reliability Analysis Center, Rome Air Development Center, Griffiss Air Force Base, NY (1985).

Nuclear Plant Reliability Data System: Annual Reports of Cumulative System and Component Reliability for Period from July 1, 1974, through December 31, 1982, NPRD AO2/AO3 (INPO 83-034), Institute of Nuclear Power Operations, Atlanta (1983).

Military Handbook for Reliability Prediction of Electronic Equipment, MIL-HDBK- 217E, U.S. Department of Defense, Washington, DC (1986).

Development of an Improved LPG Plant Failure Rate Data Base, Final report GRI-80/0093, Gas Research Institute, Chicago (1981).

Adjustment factor: In evaluating failure rate data from plant-specific records, published failure data, manufacturers' data, expert opinions, and so on, we will develop in most cases a bandwidth in failure rate range:

Three basic methods are used toward selecting a point failure rate for the OPR evaluation:

1. Select the mean value.
2. Use engineering judgment and expert opinion to adjust the mean value based on experience and plant-specific knowledge.
3. Use a performance integrity measure (PIM) quality rating (i.e., score card approach) to adjust the failure rate.

Method 3, illustrated in Figure 5-13.29, combines the first two methods and is intended to provide a consistent approach toward failure rate selection and is the preferred method.

The basic equation for estimating a likelihood within an equipment failure rate range is

$$\text{Frequency adjusted} = \text{Frequency historical mean or average} \times \text{MF}_{\text{PIM}} \text{ modification factor via performance integrity measures}$$

↑

Likelihood estimate (i.e., adjusted) (frequency)

↑

Data

- Plant
- Industry
- General

↑

Quality grading of

- Management factors
- Facility, operations, equipment-specific factors

Performance integrity measures provide a set of descriptive measures that provide qualitative and semi-quantitative grades of the quality of the FPS system reliability. The term *primary* is intended to indicate that the described set of measures account for greater than 95 percent of the expected reliability performance level.¹⁰

Figure 5-13.29. Example of general framework—adjusting historical data for equipment failure rate.¹⁰

Some primary measures include

- General design standards
- Life cycle (Age)
- Management of change (MOC) program
- Inspection program
- Maintenance program
- Testing program
- Operating environment (vibration, dust, corrosion, etc.)
- Physical damage exposure (i.e., mechanical damage from equipment, vehicles)
- Redundancy
- Common cause failure potentials

Figure 5-13.30 provides an example of using published failure rate data¹³ and applying the performance integrity measure (PIM) weighted-scoring method¹⁰ as a tool for selecting the most likely failure probability. In this figure, the failure rates are converted to failures per year as follows:

$$\begin{aligned} &0.77 \text{ failures}/1,000,000 \text{ hr} \times 8760 \text{ hr/yr} \\ &= .006 \text{ failure/yr probability} \end{aligned}$$

A simplistic linear interpretation of failure range versus PIM score is developed. A low PIM quality score would equate to a higher failure probability, and a high PIM quality score equates to a low failure probability. This method forces identification of factors that contribute to failures and provides a consistent evaluation approach, which includes plant-specific information.

Evaluation of the operational reliability aspect in terms of structuring the fault tree logic of subsystems and equipment components, along with compiling and selecting individual failure-on-demand probability, can be a time-consuming task.

The scope and complexity of the risk-informed, performance-based project that we are undertaking

should dictate the level of detail needed and the overall approach. Approaches can include use of one or both of the following:

- Use of quality grading of PIMs in conjunction with engineering judgment and expert opinion to assign a reliability
- Performing fault tree analysis (FTA)

Figure 5-13.31 provides an example of the general framework for using PIMs to support reliability estimates.

As indicated under selection in Figure 5-13.31, the quality scoring or grading of the PIMs can be used in conjunction with engineering judgment and expert opinion to estimate a reliability or probability of failure on demand range. Table 5-13.9 provides an example of establishing this type of relationship.

This approach can be used as a first-order estimate of equipment or system reliability. Other issues which may still need to be addressed include common cause failures (internal and external).

Design standards versus OPR estimates: It would be nice if there were operational reliability ranges associated with full compliance with industry standards and practices, such as NFPA 20, *Standard for the Installation of Stationary Pumps for Fire Protection*, and NFPA 13, *Standard for the Installation of Sprinkler Systems*.

For example, if templates were developed that provided reliability benchmarks or reliability ranges related to meeting levels in design, in the standards, and in IMT frequencies, this would provide valuable input. However, at this writing, fire protection design codes, standards, and guidelines do not provide this type of information. Hopefully in the future, as the use of performance-based standards progresses, design versus quantitative reliability levels will become available for use.

Figure 5-13.30. Example of failure rate range using PIM quality score.^{10,13}

Step 6: Risk Presentation

It is very important to integrate the large number of fire and explosion incident frequencies into a presentation format that will be easy to interpret and use by the management decision makers.

The most common risk assessment and presentation method is to multiply the frequency of fire and explosion incidents with the consequences and then sum these products for all scenarios considered in the risk assessment project. The aggregated results can be presented in terms of average exposure values; however, a better ap-

Figure 5-13.31. General framework—use of performance integrity measures (PIMs) to support reliability estimates.¹⁰

Table 5-13.9 Example of Relating PIMs to Reliability Ranges¹⁰

Performance Integrity Measure (PIM) Score/Grade	Reliability Range		Probability of Failure on Demand (P_{FOD}) (> 1 - Reliability)	
Very high	Very high	.99–.999	Very low	.01–.001
↓	High	.95 < .99	Low	.05 < .01
	Average	.90 < .95	Average	.10 < .05
	Low	.80 < .90	High	.20 < .10
Very low	Very low	< .80	Very high	> .20

proach is to present the results as a range defined by upper and lower uncertainty bandwidths (confidence limits) that contain the best estimates that can be made.

The objectives of risk presentation are threefold:

1. Provide presentation of estimated risk results in terms of a graphical risk profile or risk contour plot to aid management’s understanding of the existing risk to the targets of interest as stated in the risk assessment objectives and acceptable risk limits.
2. Provide a graphical presentation of the differences in risk afforded by various risk reduction strategies to allow further cost–benefit assessment study, which may be a requirement of the specific risk assessment project.
3. Provide an uncertainty bandwidth (i.e., degree of confidence limits) associated with the above two items to allow management the opportunity to evaluate alternative risk management techniques (i.e., risk transfer by insurance). This is especially important for large consequence potentials which may be quantitatively classified as rare events that may also have a high degree of uncertainty in terms of the likelihood of occurrence.

The information provided in this step focuses on item 1 above (i.e., graphical presentation of risk results).

Risk Profiles

Developing a risk profile consists of structuring a graph that portrays the aggregate relationship between the expected frequencies of fire or explosion incidents and their consequences to selected targets. These graphs can be used to present property risk, business interruption risk, and human risk as illustrated in Figure 5-13.32.

Figure 5-13.32. Example of general risk profiles.

Risk profiles can be used to present the potential degree of individual risk versus distance from the fire or explosive source. Individual risk is the probability of injury or death to a person at a specified location relative to a defined point within the fire or explosion effect zone. An example of an individual risk profile is shown in Figure 5-13.33.

Risk Contours

Individual risk exposure is presented in many risk assessment studies in terms of a risk contour plot. (See Figure 5-13.34.) Developing a risk contour (sometimes called a risk isopleth) consists of structuring a closed line graphical depiction connecting lines of constant potential risk. Points within the contour represent a risk greater than or equal to the risk of the contour edge. Risk contour plots provide a good way of illustrating individual risk versus distance from defined fire or explosion incidents.

Individual risk contours show the geographical distribution of individual risk. The risk contours show the expected frequency of fires or explosions capable of causing a specified level of harm to an individual at a specified location, regardless of whether or not anyone is present at that location to suffer that harm. Reference 5 provides a good discussion on the various measures of individual risk, which includes maximum individual risk and average individual risk.

Societal Risk

Another measure of human risk is societal (sometimes called population) risk, which takes into account the likelihood of multiple casualties resulting from fires or explosions. Societal risk is often presented in the form

Figure 5-13.33. Example of individual risk profile graph.

Example of an individual risk contour plot

Figure 5-13.34. Example of an individual risk contour plot.

Example of a societal risk F-N curve

Figure 5-13.35. Example of a societal risk F-N curve.

of F-N curves, which are plots of the cumulative frequency (F) of multiple fatalities versus the number (N) of fatalities. Referring to Figure 5-13.35, the left axis is the frequency of exceeding a specified number of fatalities.^{5,6}

F-N-type curves can provide useful insight into the degree of risks from a facility or hazardous process to the employees on the plant site and to the community located beyond the plant boundaries. Assessing the risk beyond the plant line boundaries requires a definition of the population at risk (industrial, residential, school, hospital, etc.), likelihood of people being present, and reliability of mitigation factors (people evacuation procedures, etc.).

In constructing *F-N* curves, a logarithmic plot is usually used because the frequency of number of fatalities may range over several orders of magnitude. It is also sometimes useful to identify risk contributors directly in the graph, as illustrated in Figure 5-13.35.

In addition, societal risks can be expressed in the form of various risk indices, which generally provide a summation of risks from each accident and an annual predicted fatality rate. Risk indices usually provide an easily understood, single-value number to present the acute risk and are sometimes quite useful in comparing various engineering design and protection options. A ranking of the events that contribute most to the total risk is also very useful, as this allows the analyst to focus attention on the most critical failures and facilitates efficiency in assessing prevention and mitigation risk reduction options for those events.

Reference 5 provides descriptions of various risk indices and includes

- Fatal accident rate
- Individual hazard index
- Average rate of death
- Equivalent social cost index
- Mortality index
- Economic index

The majority of human risk (i.e., individual risk, societal risk) quantification is conducted on the basis of fatality effects. In evaluating fatal effects, there are uncertainties involved in exactly what constitutes a fatal dose of thermal radiation from a fire, explosion blast effects, or toxic chemicals, and therefore appropriate documentation must be provided for all assumptions and judgments. The same applies when it is desired to estimate potential human injuries in addition to fatalities.

In conducting cost/risk reduction benefit studies, it may be necessary to convert the element of human risk exposure into equivalent monetary terms.

Presentation Format Selection

The specifics of the presentation format should be included in Step 1; that is, define risk assessment objectives. (See Figure 5-13.1.) There is a major time and cost difference between generation of single-point estimates versus detailed generation of a series of risk contours. The following four factors should be considered in deciding which risk presentation forms are chosen:⁵

1. **User Requirements.** The user may have a specific need to see risk estimates in a certain format.
2. **User Knowledge.** Where the user is unfamiliar with presentation formats, sample formats should be pre-

sented to and approved by the user before any effort is made to secure approval for the scope of work.

3. **Effectiveness of Communicating Results.** It is vital that the presentation communicate the results in an acceptable fashion. The presentation should be as simple as necessary to ensure comprehension, but not so simple that resolution is lost or that bias is introduced.
4. **Need for Comparative Presentations.** It may be desirable to present comparisons of the results of a study with other risk assessments or risk data. This type of presentation might involve
 - a. A comparison of alternate design, operation, or protection options
 - b. A comparison of the current risk estimates with risk estimates of other similar systems studied previously, to highlight areas for risk reduction or further study
 - c. A comparison of risk estimates with other voluntary and involuntary risks, to rank the current risk estimate among these reference values

Step 7: Risk Reduction Analysis

If the risk is unacceptable or uncertain, then engineering risk reduction analysis can be conducted. Risk reduction can be defined as the identification and selection of cost-effective options for reducing or mitigating unacceptable risks, including technological measures such as fire protection systems, management safety programs such as mechanical integrity programs, loss prevention programs, operator training, and emergency procedures.⁵ Risk reduction analysis consists of systematic evaluation of measures to reduce the potential frequency and/or the severity of loss event occurrence.

Frequency Reduction

Incident frequency reduction methods include the following:

- Reduce equipment failure potential
 - a. design
 - b. testing
 - c. preventive maintenance
- Reduce ignition potential
- Reduce human error
 - a. operator procedures and training
 - b. PSM programs

Severity Reduction

Fire detection and protection features that reduce potential severity levels can include

- Gas and fire detection systems
- Fireproofing structural steel and vessel supports
- Providing automatic or manual water sprays
- Providing monitor nozzles or hand-hose standpipes
- Installing foam protection systems

CHAPTER 14

Fire Risk Assessment for Nuclear Power Plants

Nathan Siu

Introduction

Probabilistic risk assessment (PRA), the process of (a) identifying potentially important accident scenarios, (b) determining their consequences, and (c) assessing their likelihood,¹ has been used to evaluate the risk associated with the generation of electric power from nuclear plant operation since the landmark “Reactor Safety Study” (WASH-1400) published in 1975.² PRA, also referred to in the literature as probabilistic safety assessment (PSA), provides a systematic approach for assessing plant behavior (including interactions with other systems) under a variety of conditions, sensitivities, and areas of uncertainty and importance. It has proven to be a useful tool for supporting risk management activities by showing where finite resources can be effectively applied to maintain or improve safety.^{3,4} PRA studies have been performed for all operating nuclear power plants in the United States and for many plants abroad. Considerable effort has gone not only into the performance of these studies but also into the development of general and application-specific approaches for using the insights and results that are acceptable to the regulators.⁵

Within the framework of nuclear power plant PRA, fire risk assessment for nuclear power plants (henceforth referred to in this chapter as *fire PRA*) is the process used to determine the risk contribution associated with fires starting within the boundaries of a given plant. Thus, a fire PRA identifies potentially important fire-initiated accident scenarios, determines their consequences, and assesses their likelihood. The results of the assessment are typically used to determine if and what changes should be made to a plant’s fire protection program. Further-

more, although there are a number of methodological issues concerning the fire PRA state of the art, the results of the assessment are often compared with the results associated with other potential accident initiators (e.g., pipe breaks, losses of off-site power, earthquakes) to support the rational allocation of safety resources across a broad spectrum of hazards.⁶

As will be discussed later in this chapter, the results of numerous fire PRA studies have shown that fire can be a significant or even dominant contributor to the overall risk for a given nuclear power plant. Lessons learned from a number of serious events, including Browns Ferry (United States, 1975),⁷ Armenia (Armenia, 1982),⁸ Vandellós (Spain, 1989),⁹ and Narora (India, 1993),¹⁰ further emphasize fire’s potential importance.

Whether or not fire is an important risk contributor at a particular plant is determined by differences in such plant-specific details as the routing of key electrical cables, the separation and orientation of important cable trays, the fire protection scheme used for a particular compartment, and the procedures employed by plant operators in response to a fire. Fire PRA is a quantitative tool for addressing these details and showing how they relate to risk. It provides a systematic framework for addressing the complex phenomenology underlying a fire in an explicit manner. It uses a wide variety of information sources (e.g., model predictions and reported event data), and provides a risk context for discussions of areas with significant controversies and uncertainties.

Numerous papers and reports have been written on fire risk assessment for nuclear power plants. The objective of this chapter is to provide a general review of the subject. The chapter presents some key characteristics of fire PRA, a discussion of the fire PRA methodology employed by most current studies, a summary of the results of a number of analyses, and a brief discussion of current activities and anticipated future developments. The focus is on fire PRA for U.S. plants. Additional details on the topics discussed and on international applications can be

Dr. Nathan O. Siu is a senior technical adviser in the Office of Nuclear Regulatory Research of the U.S. Nuclear Regulatory Commission. His major activities involve the development of improved methods for probabilistic risk assessment, including fire risk assessment.

found in the references and additional reading list provided at the end of the chapter.

Nuclear Plant PRA and Fire PRA

Broadly speaking, fire risk assessment for nuclear power plants (fire PRA) has many of the characteristics of fire risk assessments for nonnuclear industrial facilities (e.g., see Section 5, Chapter 13, “Quantitative Risk Assessment for the Chemical Process Industries”). However, because fire PRA is performed within the context of an overall nuclear power plant PRA and because the latter has evolved a specific structure to support particular decision-making needs, fire PRA has a number of technical characteristics which can distinguish it from fire risk assessments for other applications.

First, as in the overall nuclear power plant PRA, the risk of concern is associated with the health and safety of the general public. (Fire risk assessment methods can be applied to plant worker safety and economic issues, but have not been to date.) One of the conclusions of WASH-1400 was that only accidents involving severe damage to nuclear fuel in the reactor core (i.e., core damage) have the potential for risk-significant radiological releases. Therefore, fire PRA studies focus on accident scenarios that lead to core damage. In particular, because the nuclear fuel is surrounded by cooling water in the most prevalent reactor designs, most studies focus on accident scenarios in which a fire causes a loss of fuel cooling and subsequent core damage. (Note that recent concerns regarding zirconium fires in the spent fuel pools of decommissioning plants have prompted a re-examination of the risk associated with noncore damage events.)

Second, because of the design and operational characteristics of nuclear power plants, the fire PRA studies typically focus on scenarios that involve fire-induced damage to electrical equipment (especially cables) which both initiates and exacerbates an accident scenario. Nuclear power plants are generally designed to spend most of their operating life in a steady-state power-producing mode. The integrity of the reactor core can only be challenged if an upset condition—that is, a plant *transient* (e.g., a loss of normal cooling)—occurs and redundant plant systems provided to mitigate the transient (e.g., by providing emergency cooling) fail to function. Because the independent occurrence of a severe fire, a transient, and the loss of redundant mitigating systems is extremely unlikely, risk-significant fire scenarios typically involve a transient caused by the fire (e.g., a loss of off-site power to plant systems caused by fire-induced damage to equipment, a reactor shutdown performed by plant operators in response to a major fire) and fire-induced loss of some or all of the mitigating systems’ functions. In general, the major mechanical components (e.g., pumps, motors, valves) of the mitigating systems are relatively robust with respect to the effects of a distant fire, separated from redundant components by barriers or open space, and located in areas of relatively low fire hazard. The focus, therefore, is on scenarios that involve fire-induced damage to the less robust electrical equipment supporting these components. Elec-

trical cables are particularly important because cables servicing redundant equipment can, in some key areas in some plants, be vulnerable to the effects of a single fire. (Note that cable failures can occur in various ways, e.g., conductor-to-conductor shorts vs. conductor-to-ground shorts. Because these different cable failure modes can have different system impacts, e.g., component spurious actuations vs. loss of component function, they need to be explicitly addressed in fire PRA.) Electrical cabinets are also important for similar reasons.

Third, fire PRA studies generally use the core damage frequency (CDF) as the principal index of scenario risk significance. (As discussed later in this chapter, the CDF is a measure of the likelihood of core damage.) In other words, the studies usually do not directly assess the public health risk associated with fire-initiated accidents. This focus is largely due to the prominence of CDF in past and current approaches to risk-informed decision making.^{3-5,11} It should be noted that although the analysis of public health risk is complex and subject to considerable uncertainty (the analysis requires, among other things, assessments of postcore damage accident progression, radiological transport in the environment, and the emergency response of the surrounding population), analyses have been performed for a limited number of plants. However, the analysis is not unique to fire-initiated accidents—fire provides only one of a number of potential mechanisms for core damage.

Fourth, those fire PRA studies that quantitatively treat uncertainties do so within the methodological framework employed by the overall plant PRAs. This framework distinguishes between aleatory (also called random or stochastic) uncertainties and epistemic (also called state of knowledge) uncertainties.¹²⁻¹⁵ The former address situations where repeated observations of the variable of interest, under a specified set of conditions, lead to a distribution of outcomes for the variable. This uncertainty is irreducible—until the conditions are more tightly specified. The latter address situations where there is weakness in the state of knowledge of the assessor. These uncertainties can be reduced with additional information (e.g., additional observations). For example, the likelihood of observing a specified number of fire events in a given room over a given time period is typically modeled in fire PRA studies using a Poisson distribution (see the next section for more details). Since the number of fire events is a random variable, this Poisson distribution therefore quantifies aleatory uncertainty. On the other hand, the value of the single parameter which characterizes the Poisson distribution—that is, the room fire frequency—typically is not known with certainty. Since the uncertainties in this parameter can be reduced (with more data for the room or similar rooms), the probability distribution for the room fire frequency quantifies epistemic uncertainty. The distinction between aleatory and epistemic uncertainties is useful for decision making because it helps identify appropriate risk management options (e.g., to reduce uncertainties that are reducible). In addition, it forces a careful consideration of the meaning of the various probability distributions used in a risk assessment.

Finally, fire PRA has not been applied, or has been applied in a very limited fashion, to a number of issues which also have received no or reduced coverage from general PRA studies. These issues include the risk due to accidents during low power and shutdown plant operation modes, the risk due to accidents involving fuel outside of the reactor vessel (e.g., in spent fuel pools), and the risk associated with acts of sabotage. Sabotage is explicitly excluded from the scope of general PRA studies. In fire PRA studies, it is typically assumed that the data used in the analysis are associated with accidental fires. Of course, this assumption will yield conservative predictions concerning accidental fire risk in cases where intentional fires are included in the database.

Fire PRA Structure and Methodology

Overview

Fire risk assessment for commercial nuclear power plants, as it is performed today, is little changed from the analytical process used in the Zion¹⁶ and Indian Point¹⁷ PRA studies of the early 1980s and described by Apostolakis et al.^{18,19} and in the PRA Procedures Guide.²⁰ Weaknesses in the elements of the approach (i.e., the data and tools for specific portions of the analysis) have been identified and progressively addressed in a number of studies.^{21,22} Furthermore, a number of remaining weaknesses in these elements (e.g., in the treatment of fire phenomenology) are the subject of discussion and ongoing research, as discussed at the end of this chapter. However, the basic structure of the analysis has remained relatively constant.

In a typical fire PRA, the core damage frequency contribution due to a given fire scenario (where, in this discussion, a fire scenario is defined by the location and burning characteristics of the initiating fire) can be divided into three components:

1. Frequency of the fire scenario
2. Conditional probability of fire-induced damage to critical equipment given the fire
3. Conditional probability of core damage given the specified equipment damage

Formally accounting for the possibility of different levels of equipment damage and different plant responses following fire initiation, the core damage frequency (CDF) is given by

$$\text{CDF} = \sum_i \lambda_i \left[\sum_j p_{\text{ed},j|i} \left(\sum_k p_{\text{CD},k|i,j} \right) \right] \quad (1)$$

where

λ_i = frequency of fire scenario i

$p_{\text{ed},j|i}$ = conditional probability of damage to critical equipment set j given the occurrence of fire scenario i

$p_{\text{CD},k|i,j}$ = conditional probability of core damage due to plant response scenario k given fire scenario i and damage to critical equipment set j

Note that the second term addresses the issues of fire growth, detection, suppression, and component damage-ability, and that the third term addresses the unavailability of equipment unaffected by the fire and/or operator failures.

The three-term decomposition of fire risk presented in Equation 1 is not unique—alternate decompositions (often involving more terms) can be found in the literature. From the standpoint of this chapter, however, it is useful because each of the three terms tends to be addressed differently in current fire PRA studies. In particular, the fire frequencies are generally estimated using simple statistical models for fire occurrences, the likelihood of fire damage is estimated using combinations of deterministic and probabilistic models for the physical processes involved, and the likelihood of core damage is estimated using conventional probabilistic risk assessment systems models. The three-term decomposition is also useful because it directly corresponds to the elements of fire protection defense in-depth for nuclear power plants: fire prevention, fire detection and suppression, and fire mitigation.

The general process used to perform the fire PRA involves plant familiarization activities (including design reviews and plant walkdowns) as well as activities to assess each of the terms in Equation 1. The plant familiarization activities are performed to identify and characterize, for each fire area in the plant, potentially important fire initiation scenarios and potentially important target components, including cables. (Note that the term *fire area* is used in this chapter in a generic sense to refer to compartments and fire zones which may not be separated by rated fire barriers, as well as areas which are separated.) Qualitative screening (e.g., using criteria provided in FIVE²³) is then done to identify areas and scenarios which need not be quantitatively analyzed because they are not expected to contribute to the fire risk. Following qualitative screening, conservative quantitative analyses are usually performed in initial evaluations of Equation 1 to identify additional areas and scenarios which can be screened from detailed analysis. Iterative approaches using progressively more accurate models are then employed to focus analysis resources on those scenarios that contribute most to risk. For example, in many analyses, the term $p_{\text{ed},j|i}$ is initially assumed to be unity; it is only addressed more realistically for those areas where a detailed analysis is needed. The results of the analysis are typically presented on a fire area by fire area basis.

Descriptions of the general fire PRA methodology used in more recent studies can be found in a variety of references. Bohn and Lambright²⁴ describe the approach used in the NUREG-1150 PRA studies sponsored by the U.S. Nuclear Regulatory Commission (NRC). Guidance developed by the Electric Power Research Institute (EPRI) to address NRC requirements for Individual Plant Examinations of External Events (IPEEEs)^{25,26} is presented in the documentation of the Fire-Induced Vulnerability Evaluation (FIVE) methodology²³ and extended by Parkinson et al. in the EPRI Fire PRA Implementation Guide (FPRAIG).²⁷ A PRA procedures guide, which provides useful information on the interactions between the fire PRA and the overall PRA, has recently been developed to support PRA for Russian reactors.²⁸ This guidance is generic enough to be applicable

to other reactor types as well. Widely available references documenting plant-specific fire PRA studies (including the study methodologies and data) include the NUREG-1150 studies (e.g., see Bohn et al.²⁹), the Risk Methods Integration and Evaluation Program (RMIEP) analysis of the LaSalle plant (see Lambright et al.²²), and the Surry plant shutdown risk study (see Musicki et al.³⁰). More narrowly focused references relevant to specific aspects of the fire PRA methodology are provided in the following discussion of current approaches for performing the analyses underlying the three terms in Equation 1.

Fire Frequency Analysis

A fire frequency analysis involves the definition of representative fire scenarios for the fire area of interest, and the estimation of the frequency (i.e., the quantification) of these scenarios. Depending on the particular objectives of the fire PRA and the potential risk significance of the fire area, the scenarios can be defined in a broad or detailed manner. For example, for areas where a conservative analysis is sufficient, the representative fire scenario can be defined as a fire anywhere in the area. For areas where a more detailed analysis is needed, multiple fire scenarios defined in terms of the precise location and initial magnitude may need to be specified. The quantification process generally involves the statistical analysis of historical data, and the application of judgment.

The statistical analysis is generally done on an area basis or a component basis. The first approach involves the estimation of fire frequencies for different fire areas (e.g., main control room, cable spreading room, switchgear room) or groups of fire areas (e.g., auxiliary building, turbine building). The second approach involves the estimation of fire frequencies for different component types (e.g., pumps, electrical panels, transformers, transient combustibles). In both approaches, it is assumed that fire frequencies are constant over time, that is, that fire occurrences are Poisson events. In other words, the probability of observing N fire scenarios of type i in a time interval of length t is given by the Poisson distribution:

$$P(N \text{ occurrences in time } t) = \frac{(\lambda_i t)^N}{N!} \cdot e^{-\lambda_i t} \quad (2)$$

where λ_i is, as defined previously, the frequency of fire scenario i (e.g., a fire in the cable spreading room). It can be shown that if t_i represents the time to the first occurrence of fire scenario i , the probability of observing such a scenario before a given time t is given by

$$P(\tau_i < t) = 1 - e^{-\lambda_i t} \approx \lambda_i t \text{ when } \lambda_i t < 0.1 \quad (3)$$

As λ_i increases, the probability of observing the first occurrence of scenario i by a specified time also increases. It turns out that the average time to the first event is equal to $1/\lambda_i$.

As noted above, a key assumption in the Poisson model for event occurrences is that the characteristic frequency (λ_i in this case) is constant over time. A recent NRC report shows that the frequencies of reported fires in key U.S. nuclear power plant compartments have not changed dramatically when comparing the periods 1965–1985 and

1986–1994, and thereby supports the use of the Poisson model for U.S. nuclear power plant fire occurrences.³¹

In principle, it should be expected that the fire scenario frequencies will vary from plant to plant due to differences in plant design, operation, and maintenance practices. A number of fire PRA studies have developed plant-specific estimates for the λ_i using standard Bayesian procedures.³² Generic industry data (in the form of n occurrences in time t , grouped by the scenarios defined in the fire PRA, and screened to exclude such events as fires during construction) are used to develop a prior distribution, which is then updated using plant-specific data. A more sophisticated two-stage Bayes approach which statistically accounts for plant-to-plant variability in the generic data, described by Kazarians and Apostolakis,³³ has been used in a few studies. Most studies, however, have used simple point estimates of the fire frequencies based on generic industry data.^{23,27} The epistemic uncertainties in the λ_i , which can be considerable, are unquantified in this point estimate approach.

Regarding the role of analyst judgment in fire frequency analysis, it is especially significant when estimating the frequencies of detailed scenarios, for example, fires in a particular portion (location) of a cable spreading room that have a particular severity. Judgment is needed to partition the statistically estimated frequencies (e.g., for cable spreading room fires) when analyzing detailed scenarios because the available fire data are too sparse to allow direct estimation of the frequencies of such potentially challenging fires. In some fire PRA studies, location fractions are employed to reduce plant area-based fire frequencies to account for geometrical factors. Other studies use plant component-based fire frequencies^{23,27} for this same purpose. In many others, severity fractions are widely used to address the fraction of fires (in a given compartment or involving a given component) that have the potential to cause significant damage in a relatively short amount of time. Note that the use of severity factors implicitly takes some credit for fire suppression activities. Care must be taken when analyzing fire detection and suppression (as discussed in the following section) to avoid double-counting the effectiveness of detection and suppression.

Equipment Damage Probability

Given a fire in a nuclear power plant compartment, the conditional probability of damage to key equipment (i.e., $p_{ed,j|i}$) needs to be determined. In a detailed fire PRA study, the assessment typically involves the following:

1. A prediction of the fire-induced environmental conditions
2. An assessment of the equipment response to these conditions
3. An assessment of the effectiveness of fire barriers
4. An assessment of the likelihood that the fire will not be detected and suppressed before equipment damage occurs

Regarding the third item, the index j in $p_{ed,j|i}$ accounts for the possibility of multiple equipment damage scenarios due to a single initiating fire scenario. Therefore,

as appropriate, the analysis also needs to consider the effectiveness of fire barriers in preventing fire damage to protected equipment in the room of fire origin and in preventing fire propagation to neighboring compartments.

Based upon the results of the fire environment, equipment response, and suppression analyses, the probability of equipment damage is, in principle, determined using a competing risks model formulated by Apostolakis et al.^{18,19} This model states that damage occurs if the time to fire-induced damage is less than the time to fire suppression, that is,

$$p_{ed, j|i} = P(T_{d, j|i} < T_{s|i}) \tag{4}$$

where $T_{d, j|i}$ is the damage time for equipment set j given fire scenario i , and $T_{s|i}$ is the suppression time for fire scenario i .

The elements of the model are represented schematically in Figure 5-14.1. This figure shows model-predicted environment temperatures over time, the resulting time-dependent response of a target (which determines when target damage is predicted to occur), and a stochastic model for the suppression time whose results are compared against the predicted damage time. Note that the presence of barriers will affect the environment seen by the target. Current approaches used to perform these analyses and quantify $p_{ed, j|i}$ are discussed below.

Fire Environment Analysis

Characterization of the fire-induced thermal environment for the purposes of fire PRA requires the estimation of the time-dependent temperature and/or heat fluxes in the neighborhood of the safety equipment of interest (i.e., the targets). This estimation requires the treatment of a

variety of phenomena as the fire grows in size and severity. These phenomena include the spread of fire over the initiating component (or fuel), the characteristics of the fire plume and ceiling jet, the spread of the fire to non-contiguous components, the development of a hot gas layer, and the propagation of the hot gas layer or fire to neighboring compartments.

It should be noted that potentially risk-significant nuclear power plant fire scenarios have a number of characteristics which may not be directly addressed by fire models not explicitly designed to model these scenarios. These characteristics include a variety of source fire types (e.g., cable tray, electrical cabinet, liquid pool fires), the possibility of propagation through fuel arrays (e.g., cable tray stacks) prior to flashover, the lack of openings to the environment, the elevated location of many important fuel arrays (note that many plume correlations have been based on experiments where the fire is at ground level) and local obstructions (e.g., cable tray stacks) and barriers. In addition, since the overall concern of this portion of the fire PRA is the fire-induced damage of plant equipment, the analysis needs to address the response of the equipment to the fire. Fire models not designed for fire PRA may not have integrated component response models (discussed in the following subsection), which are convenient for an efficient analysis.

It should also be noted that fire PRA studies often require that fire modeling be done for a number of fire scenarios within a compartment. Different fire scenarios can be defined depending on the number of fixed and transient combustible sources and the variety of ventilation conditions, including possible changes (e.g., the opening of a fire door). Given that multiple compartments may need to be analyzed, the number of scenarios to be mod-

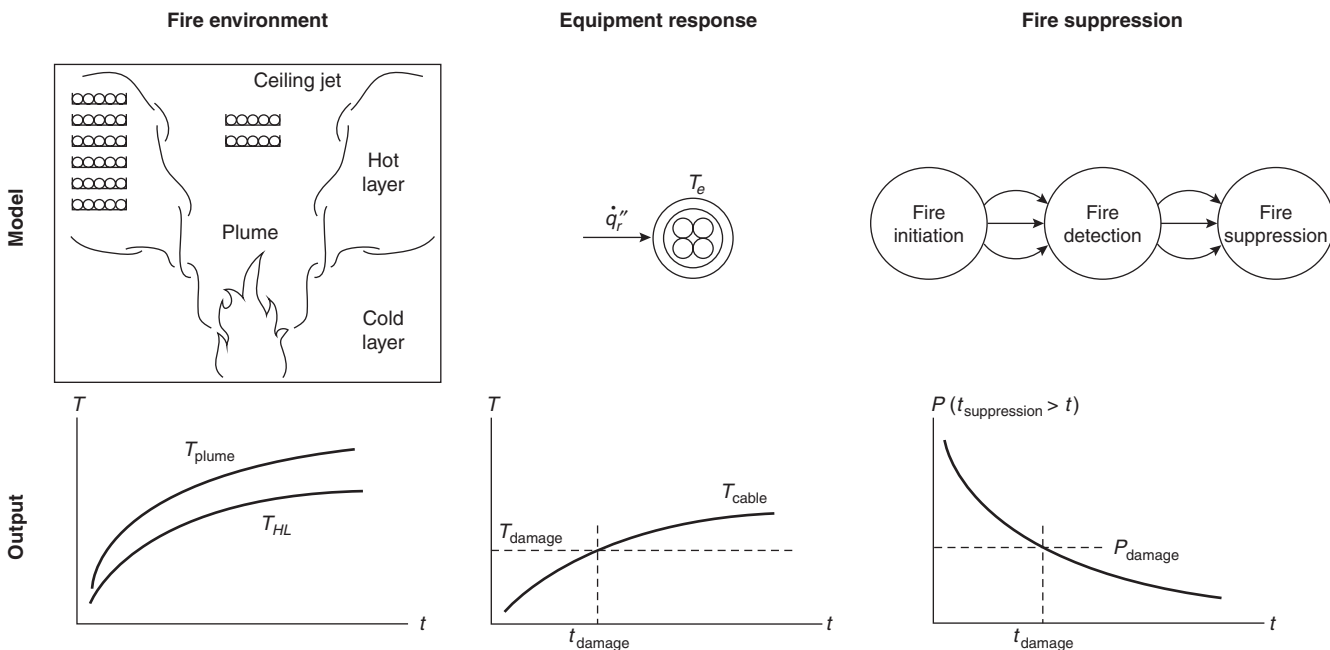

Figure 5-14.1. Equipment damage analysis submodels.

eled can be quite large. Furthermore, in analyses involving formal uncertainty analysis, multiple analyses are required for a single scenario.

A variety of fire-modeling tools have been developed to address the above needs. In U.S. fire PRA studies, including the recent Individual Plant Examinations of External Events (IPEEEs), the most commonly used tools are those provided by the FIVE methodology,²³ COMPBRN IIIe,^{34,35} and the methods described in the FPRAIG.²⁷ The scenarios addressed include cable fires, switchgear fires, oil pool fires, and transient fueled fires.

The FIVE fire models are designed to be used in a vulnerability analysis and are intended to be conservative. They are generally used to determine if, given a specified fire and targets, fire damage is possible. The models consider three key regions within the room: the plume, the ceiling jet, and the hot gas layer. Radiant transfer to targets outside of these regions is also considered. Fire growth is not modeled explicitly; the user is required to specify the physical characteristics (e.g., the location and intensity) of the fire.

The COMPBRN IIIe zone modeling code, similar to its predecessors, is designed to be used as an integrated part of a fire PRA. Thus, one of its key outputs is the predicted time to component damage, which can be compared with the suppression time, as shown in Equation 4. Moreover, recognizing that there are significant uncertainties in the model parameters (e.g., see Brandyberry and Apostolakis³⁶), the code uses the distributions quantifying these uncertainties when developing a distribution for the time to damage. (Uncertainties in the model structure are treated separately, as discussed by Siu and Apostolakis³⁷⁻³⁸ and Siu et al.³⁹)

COMPBRN IIIe explicitly addresses fire growth over fuel arrays (including lateral spread over cable trays) and allows for the possibility of growth to noncontiguous fuel cells (which will lead to multiple, interacting fires). It models radiative and convective transfer both inside and outside of the fire plume(s) and hot gas layer. Target heatup is addressed using a one-dimensional transient heat conduction model. The hot gas layer is treated quasi-statically (note that it does change as the fire changes). Intercompartment fire spread is not treated.

The COMPBRN series of codes has undergone a limited amount of integral validation. (The code's submodels are largely based on experimental correlations and are therefore individually validated for those situations where the correlations apply.) The 20-ft separation tests documented by Cline et al.⁴⁰ have been used to benchmark COMPBRN III (see Ho et al.⁴¹) and IIIe (see Ho and Apostolakis³⁴). The code appears to perform reasonably well, especially regarding the target temperature, which is the principal measure of interest. COMPBRN has also been applied to the Heissdampfreaktor (HDR) tests with mixed results (see Nicolette and Yang⁴²). The results of the original version of COMPBRN were compared to data from a variety of fire configurations (including a set of heptane pool fires, a wood crib fire, and a vertical cable tray fire).⁴³ Finally, COMPBRN IIIe explicitly addresses issues raised in an NRC-sponsored review.²¹

The fire models recommended in the FPRAIG²⁷ are either based on FIVE (e.g., for the prediction of hot gas

layer temperatures) or upon a reinterpretation of existing experimental data (e.g., for the prediction of fire growth through a stack of cable trays). A review of the FPRAIG, including a discussion of the recommended fire models, is provided by Lambright and Kazarians.⁴⁴ In response to this review, some of the FPRAIG recommendations concerning fire modeling have been modified or clarified. It is expected that the revised guidance will be published in the near future.

Information relevant to fire modeling for fire PRA, including data on cable properties (e.g., ignition and damage thresholds, mass burning rates, heat release rates), is contained in several reports.⁴⁵⁻⁵⁰ Other required parameters (e.g., for cable thermal conductivity, specific heat, density) are typically estimated using data for generic materials. Fire spread from other equipment (e.g., major pumps, switchgear) is generally addressed using pool fire models. In some cases (e.g., for pump fires), the pools are taken to represent spilled lubricants, and the properties of the fire are then dictated by the relevant properties of the lubricants. In other cases, the pool is used as a simple representation of the actual fuel source, and the properties of the fire are determined by the assumed flammability properties of the component. Discussions on appropriate heat release rates for electrical cabinet fires, based on experimental data reported by Chavez⁵¹ and Chavez and Nowlen,⁵² are provided in the FPRAIG²⁷ and its review.⁴⁴

Application of fire modeling to scenarios of interest in fire PRA studies has led to a number of general insights. Some key insights are as follows:

1. For many of the configurations analyzed in the fire PRA studies, fairly severe fires (e.g., equivalent to 1-m-diameter oil fires) are needed to cause damage to critical components (primarily cables). Furthermore, if the fire is of sufficient severity to cause damage, it usually is predicted to do so in a fairly short amount of time (on the order of 10 min or less).
2. Due to the sensitivity of model simulation results to initial fire size, more attention needs to be paid to the definition of the initial conditions of the fire scenarios (and their likelihood).
3. It is important to explicitly treat uncertainties. Such an analysis not only can yield useful results (e.g., the probability that a given fire is incapable of causing damage), but also can indicate whether improvements in fire modeling sophistication are likely to change the risk insights for a given scenario.

Regarding the last point, the predictions of fire models are, of course, subject to significant uncertainties. Applications of fire models which neglect these uncertainties (e.g., applications which neglect the possibility of damage to critical cables because they are a few centimeters above the damage height predicted by a given model) can easily lead to nonconservative assessments of fire risk.

The uncertainties in the predictions of the fire models arise from modeling simplifications employed by the analyst or inherent to the modeling tools used, and from a lack of knowledge concerning the values of key model parameters.

The modeling simplifications introduce both conservative and nonconservative biases. As examples of con-

servative simplifications, analyses often ignore (1) the effect of intervening obstacles when calculating heat transfer to a specified target, (2) the heat sink effect of room equipment and the impact of local oxygen starvation on heat release rates, (3) the limiting effect of forced ventilation, and (4) the time required for the fire to reach the "initial" size used to start the fire model simulation. Examples of nonconservative simplifications include the neglect of radiation feedback to the burning fuel in some models, and the common assumption that fires in closed metal cabinets will stay confined within these cabinets. Engineering methods for quantifying fire model uncertainty using integral test data have been developed and applied in a small number of studies.³⁷⁻³⁹

The uncertainty in model parameter values is due to the sparsity of experimental data for some of the parameters (e.g., piloted and nonpiloted ignition temperatures for cables) and the uncertainty as to the applicability of the existing data to the situation in the field (i.e., the particular fire scenario being analyzed). Distributions for a number of parameters have been developed (e.g., see Brandyberry and Apostolakis³⁶) and used in a number of fire PRA studies.

Equipment Response Analysis

Given a predicted environment for a piece of equipment, a detailed fire PRA needs to assess the equipment response and determine the likelihood of equipment failure and the mode of failure. Because of the common cause failure potential of cable fires, the key concern is the fragility of electrical cables. However, the fragilities of other potentially vulnerable equipment (e.g., electromechanical and electronic components in electrical cabinets) are also of interest.

Current fire PRA treatments of equipment failure due to heat are very simple. It is generally assumed that damage will occur if a representative temperature (e.g., the surface temperature of a cable) exceeds a threshold value. In some analyses, component damage is also assumed if the incident heat flux exceeds a critical value. When component temperature criteria are used, conservative approaches (e.g., assuming the component is at the local environment temperature) or simple heat transfer models (e.g., lumped capacitance models or one-dimensional transient heat conduction models in the case of cables) are employed. Information relevant to the estimation of thermal fragilities of key equipment is provided in a number of reports.^{46-48,50,53-55} Information on the effects of smoke on sensitive equipment is more limited.⁵⁶ These effects are not yet explicitly addressed in detailed fire PRA analyses. (The effects of smoke and fire suppressants on sensitive equipment are implicitly addressed in those screening analyses which assume that any fire within a compartment will damage all equipment within that compartment.)

Regarding the treatment of failure modes and their likelihood, all fire PRA studies address fire-induced circuit failures that lead to loss of function. A few also address failures that can lead to spurious actuation of plant equipment. The latter failure mode, typically assumed to be caused by hot shorts (i.e., electrical faults between cable conductors without a loss of conductor integrity or a si-

multaneous short to ground), has been shown to be an important and sometimes even dominant contributor to fire risk in a number of U.S. studies. The probability of a single hot short is, in many studies, based on a generic probability distribution derived subjectively from a limited amount of information.⁵⁷ (The distribution, assumed to be lognormal, has a 5th percentile of 0.01 and a 95th percentile of 0.20; its mean value is 0.07.) In a number of studies, the probability of multiple hot shorts is often obtained by multiplying this probability an appropriate number of times. Note that the latter procedure ignores the potentially significant impact of state-of-knowledge dependencies.

Fire Barrier Analysis

As part of determining the immediate environment of equipment potentially affected by a fire, the fire PRA needs to consider the effectiveness of fire barriers. In the United States, the most extensive investigation of multicompartment fires and the effect of intercompartment barriers was performed by the RMIEP study.²² In that study, which was intended to extend the PRA state of the art in a number of areas, the possibility of fire propagation across rated fire barriers between up to three fire areas was treated explicitly. Screening analyses using barrier failure probabilities and assuming the loss of all equipment in all affected fire areas were employed to eliminate unimportant combinations of fire areas. (The computer code SETS was used to perform the logic calculations.) More refined analyses which distinguished between active barriers (e.g., doors, dampers) and passive barriers (e.g., penetration seals) and employed less conservative barrier failure probabilities (but still assumed the failure of all equipment in all affected areas) were then performed for the remaining combinations of fire areas. As it turned out, no combinations passed the study's CDF screening criterion of 10^{-8} /yr, and so multi-area fires were determined to be insignificant contributors to fire risk at the LaSalle plant.

More recently, many of the IPEEE studies have investigated the potential for fire vulnerabilities associated with the spread of fire between compartments in a single fire area. (Fire spread between fire areas has not been treated by these studies—it is assumed that the 2- or 3-h-rated fire barriers generally separating fire areas will contain the fire.) Some of the IPEEEs have used the FIVE methodology,²³ which employs engineering judgment in conjunction with a number of screening criteria. Other IPEEE studies have used the more quantitative procedure described in the EPRI FPRAIG.²⁷ This procedure addresses fire-modeling concerns (the potential for hot gas layer formation) as well as barrier, fire protection, and safe-shutdown reliability concerns. None of the IPEEE studies investigating multicompartment fires has concluded that these fires are sources of fire risk vulnerabilities, and only a very small number of studies have identified multicompartment scenarios which are potentially visible contributors to fire risk.

Regarding the treatment of local fire barriers (i.e., barriers separating equipment within compartments), the barriers are usually either assumed to be completely reliable or are conservatively neglected. Even when physical models for barrier performance are employed (e.g.,

COMPBRN IIIe provides a one-dimensional steady state heat conduction model³⁵), these models do not address such behaviors as gross distortion and mechanical failure of the barrier system. Fire tests have shown that such behaviors are strongly affected by installation practices (e.g., the method of sealing joints). Furthermore, the physical properties of the barriers needed to address such complex issues are not readily available.

Fire Detection and Suppression Analysis

Equation 4 shows that within the context of a fire PRA, the objective of a detection and suppression analysis is to determine the likelihood that a fire will be detected and suppressed before the fire can damage critical equipment. This objective requires an assessment of the performance of automatic systems and of the effectiveness of manual fire-fighting efforts.

Siu and Apostolakis⁵⁸ describe a state-transition methodology which assesses the likelihood of multiple detection/suppression scenarios and their associated suppression times using generic fire protection system reliability estimates and detection/suppression time data obtained from nuclear power plant fire events. (A condensed and somewhat simplified version of this methodology which employs data from operational experience has also been developed.⁵⁹) The methodology has been used in a few fire PRA studies (e.g., see Musicki et al.³⁰). An alternate methodology which has been used in the RMIEP study of the LaSalle plant,²² (1) does not explicitly identify different detection and suppression scenarios, (2) uses physical models included in FPETool⁶⁰ to estimate detector and sprinkler actuation times, and (3) uses expert judgment to estimate other characteristic delay times in the fire detection/suppression process.

Most fire PRA studies have used a simpler detection/suppression model in which automatic systems, if they actuate, are assumed to be immediately effective. (See the guidance provided in the EPRI FPRAIG.²⁷) The results of calculations for equipment damage times are sometimes compared with the results of FIVE²³ worksheet calculations for fire detector and sprinkler actuation times to determine if automatic systems should be credited. If automatic suppression is unsuccessful, the likelihood that manual suppression efforts will be effective before equipment damage is then determined. A weakness with many fire PRA studies which model both automatic and manual suppression is that a number of potentially important dependencies between automatic and manual suppression activities (e.g., the reliance on a common fire water supply) are not treated. This deficiency can lead to nonconservative results. Another weakness is that analyses typically neglect delays in fire suppression following fixed-system actuation. However, because the fire growth models used in fire PRA studies do not account for the retarding effects of suppression activities, the risk impact of this neglect is not clear.

Fire Mitigation

For each fire scenario involving damage to a set of equipment, the fire PRA must assess the conditional prob-

ability of core damage given that damage. This assessment must address the response of plant hardware and staff under fire conditions. It also must include the possibility of equipment failures and human errors not caused by the fire. (For example, accident mitigating equipment may be undergoing maintenance and may be unavailable at the time of the demand.) Finally, it typically addresses manual recovery actions taken by the plant operators to restore lost equipment functions (e.g., starting a redundant train of cooling when the fire causes the loss of the operating train).

Because fire risk assessment for nuclear power plants is generally performed within the context of an overall PRA and because the overall PRA provides a model for plant behavior under a wide variety of challenges (typically in the form of an event tree/fault tree model, as discussed in the PRA Procedures Guide²⁰), the primary concern of the fire PRA analyst is to ensure that the overall PRA model is appropriately modified to address the conditions imposed by the fire scenarios analyzed. Thus, the model needs to be modified to address (a) the failure of plant equipment directly caused by the fire and (b) the effect of the fire on plant operator performance. The former issue is easily accomplished with current PRA software (e.g., SAPHIRE⁶¹), for example through the use of logical flags to indicate which equipment has been lost. In fact, when such software is used, explicit calculation of the term $p_{CD,kl,j}$ (commonly referred to as the conditional core damage probability, or CCDP) is generally not required. The latter issue is much more difficult to address. A number of studies increase the PRA base case human error probabilities (HEPs), which can be developed using a number of different methods [e.g., the well-known Technique for Human Error Reliability Prediction (THERP) by Swain⁶²] by subjectively determined factors to account for the additional stress induced by the fire. Other studies argue that stress during significant accidents is already high and that additional modifications of the HEPs are not needed. Most studies do not take credit for ex-main control room actions in the affected fire area (because of the heat and smoke present) or for the repair of fire-damaged equipment.

Assembly of Results

Equation 1 shows that, given the evaluation of the terms λ_i , $p_{ed,j|i}$, and $p_{CD,kl,j}$, the determination of the fire-induced CDF (and other useful intermediate results, such as the CDF associated with a particular fire scenario) is generally a straightforward matter. If standard PRA software tools are used, the calculation (including the propagation of uncertainties) is routine and can be done without the explicit calculation of $p_{CD,kl,j}$ since this term is implicit in the structure of the PRA event tree/fault tree model. (Most fire PRA studies have calculated this term, since it indicates what the risk consequences of a severe fire might be.) If Equation 1 is evaluated using general purpose software tools (e.g., spreadsheets or equation solvers), some additional work must be done to propagate the uncertainties in the λ_i , $p_{ed,j|i}$, and $p_{CD,kl,j}$ through the equation. A variety of methods can be used to perform this propagation, but direct Monte Carlo simulation is

perhaps the easiest, given currently available software. It should be noted that this propagation of uncertainties deals with epistemic uncertainties: the PRA model structure accounts for the aleatory uncertainties through the terms λ_i , $p_{ed,j|i}$, and $p_{CD,k|i,j}$ (which are parameters of aleatory distributions, following the discussion in the section on fire frequency analysis).

Fire PRA Results

The earliest fire risk assessment for a nuclear power plant was performed in 1975 as a supplement to WASH-1400 (the Reactor Safety Study²). The assessment was aimed at providing a quick estimate of the risk implications of the Browns Ferry cable fire in 1975. The analysis indicated that the CDF associated with that fire was around $10^{-5}/\text{yr}$, or about 20 percent of the total plant CDF associated with the causes (e.g., pipe break accidents, plant transients) addressed in the main body of the study. It also noted the usefulness of developing a more detailed fire PSA methodology (including improved models and data).

Another early fire PRA was performed in 1979 as part of a PSA for a proposed high-temperature gas-cooled reactor design.⁶³ The analysis focused on the risk contribution of cable spreading room fires, and it concluded that the core heatup frequency due to such fires was also around $10^{-5}/\text{yr}$, or about 25 percent of the total core heatup frequency due to all causes.

The first comprehensive, detailed fire PSAs for commercial nuclear power plants were performed in 1981 and

1982 as part of the Zion¹⁶ and Indian Point¹⁷ PRA studies, respectively. A key question addressed by both PRA efforts was if additional accident mitigation systems (e.g., filtered, vented containments) were needed for the two plants. The study results indicated that the fire risk for Zion Units 1 and 2 was relatively small (the mean CDF was about $5 \times 10^{-6}/\text{yr}$ for each unit, about 10 percent of the total mean CDF) and that the fire risk at the Indian Point plants was relatively large. (For example, the mean fire-induced CDF for Unit 2 was about $2 \times 10^{-4}/\text{yr}$, or about 40 percent of the total mean CDF.) Because the Zion and Indian Point fire PRA studies were performed by the same analysis team using the same analysis methodology and tools, these studies demonstrated how plant-specific features could greatly affect fire risk. More importantly, the studies also identified plant design changes for reducing risk (e.g., fire barriers, a self-contained charging pump, provisions for an alternate power source in the event of damaging fires) that were far more cost-effective than the proposed accident mitigation systems prompting the studies.

Since the Zion and Indian Point studies, a number of fire PRA studies have been performed. Table 5-14.1 summarizes the results from a number of these studies. These results show that fire can be a significant and even dominant contributor to the overall risk for a given plant. A significant number of studies have resulted in estimates of mean fire-induced core damage frequencies (CDF) of $10^{-4}/\text{yr}$ or greater, predicted contributions to total CDF (i.e., CDF from all contributors) of 20 percent or greater, or both.

In 1991, recognizing the value of systematic assessments of fire (and other so-called "external events"), the

Table 5-14.1 A Partial List of Fire PRAs for U.S. Nuclear Plants (Not Including IPEEEs)

Plant	Sponsor	Date	Fire CDF (/yr)	Total CDF (/yr)	Important Contributors ^a
HTGR (design)	USDOE	1979	1.1×10^{-5b}	4.1×10^{-5b}	CSR (only the CSR was analyzed)

NRC issued a requirement that licensees perform Individual Plant Examination of External Events (IPEEE) studies for their plants.²⁵ The primary goal of the fire risk portion of the IPEEE program was for plant licensees to identify plant-specific vulnerabilities to fire-induced severe accidents that could be fixed with low-cost improvements. Four supporting objectives were for licensees to, with respect to external events, (1) develop an appreciation of severe accident behavior, (2) understand the most likely severe accident sequences that could occur under full-power conditions, (3) gain a qualitative understanding of the overall likelihood of core damage and fission product releases, and (4) reduce, if necessary, the overall likelihood of core damage and radioactive material releases by modifying, where appropriate, hardware and procedures that would help prevent or mitigate severe accidents. Guidance on the performance of an IPEEE analysis is provided by Chen et al.²⁶

The results of a preliminary review of the IPEEE submittals are presented by Rubin et al.⁶⁴ The results confirm that fire continues to be a significant contributor to overall risk at a number of plants. In addition, they also show that over half of the IPEEE submittals have identified cost-effective improvements. Finally, as discussed earlier in the section on fire modeling, the review process also identified a number of technical issues associated with the guidance provided in the EPRI FPRAIG²⁷ and led to modifications of that guidance, which are expected to be published in the near future.

Current Activities and Future Directions

In recent years, interest has increased on the parts of both the NRC and industry in the broader use of PRA technology to deal with fire protection issues. This interest, which is consistent with the NRC's policy statement on the use of PRA,⁶⁵ is supported by activities in a number of areas. A key activity is the development of a consensus standard, NFPA 805, "Performance-Based Standard for Fire Protection for Light Water Reactor Electric Generating Plants," 1998 edition, which uses risk information in evaluating a plant's fire protection program.⁶⁶ As a related activity, the NRC has initiated the development of a risk-informed, performance-based fire protection rule.⁶⁷ It is anticipated that the new rule, or regulatory guidance associated with the rule, will indicate how NFPA 805 may be used by licensees in developing or modifying their fire protection programs.

Other notable application activities involving fire PRA or fire PRA methods include the evaluation of the safety significance of exemptions to certain fire protection requirements;⁶⁸ the support of fire protection issue identification and prioritization (e.g., the effect of smoke on manual fire-fighting effectiveness); the support of inspection activities (e.g., by identifying areas of focus and evaluating the safety significance of findings); and the development of risk information to support the resolution of generic fire protection issues (e.g., fire-induced circuit failures).

It is important to note that, when the results of PRA studies are used to explicitly support decision making, they are generally not used as the sole basis for the deci-

sion making. Other sources of information, including other engineering analyses, are also used to support the decision. In other words, the decision-making process is risk informed, rather than risk based. Under this risk-informed approach, the decisionmaker can make use of information from imperfect or even flawed PRA models, as long as the use of the PRA results and insights improves the non-risk-informed decision-making approach for the problem of interest.

This factor is an important consideration for the use of fire PRAs because the current fire PRA state of the art is not as mature as that for assessing the risk contributions of many other important accident initiators. A review of the fire PRA state of the art by Lambright et al.²¹ in 1989 identified a number of methodological weaknesses that are still concerns in many current studies. Reviews of fire PRAs have shown that variations in key analytical assumptions can lead to orders of magnitude variations in estimates of fire-induced CDF and qualitatively different risk insights.

The uncertainties in fire PRA results are not due to the general analytical approach described at the beginning of this chapter. All current nuclear power plant fire PRAs use this approach or some slight variant on it. Rather, a good deal of the uncertainty is due to weaknesses and gaps in the current treatment of a number of application details, and to the assumptions used by analysts when addressing these weaknesses and gaps. Significant uncertainties can arise in the estimation of the likelihood of important fire scenarios (e.g., when addressing the frequency of large, transient-fueled fires or of self-ignited cable fires), the modeling of fire growth and suppression (e.g., when treating fire propagation through a stack of cable trays), the prediction of fire-induced loss of systems (e.g., when quantifying the likelihood of spurious actuations, when addressing the effect of smoke on equipment), and the analysis of plant and operator responses to the fire (e.g., when modeling operator actions during a severe control room fire).⁶⁹

To address these areas, the NRC initiated a fire risk research program in 1998 (see Siu and Woods⁷⁰). The program's technical objectives are aimed at developing the following:

- Improved estimates of the frequencies of challenging fires
- Improved fire-modeling tools for risk-significant scenarios, including guidance for proper application (accounting for limitations and uncertainties)
- Mode-specific thermal fragilities for cables and other key components
- Guidance for identifying scenarios for which smoke effects may be risk significant
- Improved estimates of the probability of fire and fire effects containment (including active and passive barriers)
- Configuration- and condition-sensitive fire protection system reliability estimates, including guidance for application
- Improved tools for assessing the risk impact of circuit interactions
- Improved understanding of the implications of major fire events for fire PRA

Initial results of the research include an evaluation of experimental data regarding cable failure modes and circuit failures and a review of a number of major fire events.

Concluding Remarks

Fire PRA is a systematic tool for dealing with the complex issues that need to be addressed when assessing fire safety at a nuclear power plant. It is a useful tool for supplementing deterministic analyses on which the reactor design and fire protection are based, as it highlights the strong and weak points of a plant's design and operation with respect to fire hazards. It has proven useful in supporting design, operational, and regulatory decision making, and this use is expected to increase in the coming years as (1) ongoing research and development efforts lead to improvements in the state of the art, and (2) improvements in the application of the state of the art lead to more consistent results.

CHAPTER 15

Fire Hazard Assessment for Transportation Vehicles

Richard W. Bukowski

Introduction

One of the areas in which fire hazard assessment techniques have been applied within regulation is for transportation vehicles. In particular, commercial aviation and passenger rail have utilized fire hazard assessment as a means to achieve safety goals well before these techniques became common in buildings. This chapter will review the methods employed and the recent evolution of predictive tools specific to transportation. The reader should refer to the general chapter on Fire Hazard Analysis for an introduction to the basic principles. The American Society for Testing and Materials (ASTM) has developed a Standard Guide for Fire Hazard Assessment of Rail Transportation Vehicles, ASTM E2061.¹ This document provides a detailed procedure for the conduct and documentation of a fire hazard assessment including specific design fire scenarios that should be considered.

Current Methods for Regulating Transportation Vehicle Fire Safety

Aviation

The Federal Aviation Administration (FAA) has pioneered the use of fire hazard assessment in the safety regulation of commercial aviation. As with most regulatory systems, the general objective is to protect passengers and crew from unreasonable risk of death or injury in accidents. The issue then becomes to reach some agreement on what is a reasonable or “acceptable” risk. Compared to other transportation modes, and especially private automobiles, the flying public is highly risk (and hazard) averse. Reflecting this concern, commercial aviation is

highly regulated and (statistically) the safest mode of transportation.

A review of aviation accidents reveals that most occur on takeoff or landing. From a fire safety viewpoint, in-flight fires are extremely rare, especially in the United States. When fire becomes a threat, it generally involves jet fuel spilled as a result of a crash. Where the crash itself involves high-impact forces, passenger and crew survivability is not possible. This observation led to the early recognition of a specific class of incident known as the “impact survivable, post-crash fire” scenario. This is where most passengers and crew survive the crash and are subsequently capable of escaping the wreckage if given sufficient time.

Research conducted by the FAA on commercial aircraft exposed to an external fuel fire indicated that the time available for passenger egress before flashover occurred in the cabin was approximately 90 s. Thus, the FAA established a regulation that commercial aircraft must be able to demonstrate that a full load of passengers can be evacuated within 90 s. Aircraft materials are tested to demonstrate that they are slow to ignite and burn such that the cabin environment can be kept safe for the 90 s needed for evacuation.

In the 1980s, the FAA promulgated a regulation that required aircraft seats to be protected against fire by a blocking layer between the outer covering and the cushioning. This regulation was supported by a cost-benefit analysis performed by the National Institute of Standards and Technology (NIST).² This analysis incorporated the impact of the mitigation strategy on the risk of death of passengers from in-flight, post-crash, and on-ground fires, and included normalization by exposure (in passenger miles) to allow extrapolation to potential future losses accounting for industry growth. The analysis further considered the historical record of aircraft fires as a means to establish current losses and scenarios. Because of the scarcity of incidents, worldwide incidents were included, but only those involving U.S.-built jet aircraft.

Richard W. Bukowski, P.E., is senior research engineer, NIST Building and Fire Research Laboratory, Gaithersburg, MD.

Another interesting approach from this study was the way in which evacuation times were considered. As discussed earlier, FAA regulations require that any aircraft be able to be evacuated within 90 s. But the study needed to determine the value of additional safe egress time provided by seat blocking that delayed flashover. Thus, the authors estimated the passenger evacuation rate from each exit: one per second from main doors (slower if the exit was partially obstructed) and one per 2 s for window exits or fuselage breaks. If a strategy resulted in an additional 4 s of safe egress time and there were two main doors and two window exits available, the strategy was credited with saving 12 passengers.

Rail

While all serious passenger rail accidents are investigated by the National Transportation Safety Board (NTSB), there has not been public pressure for strong safety regulation of rail transportation vehicles until recently. Following the 1996 Silver Spring accident where a Marc commuter train collided with an Amtrak passenger train, resulting in 11 deaths, there was increased interest by the Federal Railroad Administration (FRA) to replace safety guidelines originally issued in 1984 (and slightly revised in 1989) with regulations. These regulations, based on the guidelines but updated with information derived from NIST research, were promulgated in 1999.³

The FRA tests and performance criteria cited in the 1999 regulations focus on providing a high level of fire performance for combustible materials found in vehicles. Like aircraft materials, these are to be difficult to ignite and slow burning, producing limited smoke. Unlike aircraft, which suffer severe operational penalties associated with weight, intercity and commuter rail vehicles and rail transit vehicles employ stronger construction, including fire resistance requirements for floors and for roofs when the vehicle is powered from an overhead catenary. Vehicles that make many stops recognize the energy penalties associated with weight, and all involve much lighter construction than intercity passenger trains. The evolution of higher speed trains for intercity applications is bringing the energy issue forward here as well, so weight/cost tradeoffs are becoming more universal. It should be noted that the FRA tests and performance criteria are based on Federal Transit Administration recommended practices for rail transit vehicles published in 1984.

A review of rail accident scenarios reveals that collisions with vehicles at grade crossings or with other trains lead the list. Similar to aircraft, liquid fuel spilled from the vehicle or train is the most common fire exposure. An example is an accident that occurred near Bourbonnais, Illinois, in 1999⁴ when a train struck a truck at a grade crossing. Leaking fuel from one of the locomotives ignited and engulfed a sleeping car, where all the deaths occurred. Autopsies showed that four of the victims died due to fire, one died from carbon monoxide poisoning, and six died from physical injuries. Interior fires in moving vehicles are extremely rare, with most such incidents involving small quantities of smoke from malfunctioning/overheating equipment. There was a single fatality in-

volving an Amtrak bi-level sleeping car (cigarette on a mattress) that occurred in 1982 in Gibson, California.⁵

Busses

Busses are covered by only a few fire safety requirements. There are some controls on the flammability of interior linings and seats [Federal Motor Vehicle Safety Standards Section 302 (FMVSS302)],⁶ fire resistive barrier around the engine compartment, and recent requirements for physical protection of the fuel tank against penetration. The great majority of bus fires are engine fires, and the barrier provides adequate time to stop the bus and discharge the passengers. Some busses are equipped with fixed extinguishing systems for the engine compartment.

Following a 1988 accident in which a post-crash fire took the lives of 27 persons when a pickup truck struck a church bus in Kentucky, NIST conducted studies of the flammability of bus seats.⁷ Similar to the impact survivable post-crash aircraft fire scenario discussed above, this accident involved a leak from the bus fuel tank with fire penetrating through cracks in the floor and impaired exits. The crash destroyed the front door, and the rear emergency exit was blocked by luggage in the aisle and rear seat.

An issue with school buses was the use of extra padding on seat backs and handrails to protect occupants from injury in accidents (required by FMVSS222) because the use of seat belts was considered impractical. This additional padding increased the fuel load and fire development in a post-crash fire. Following the tests of current and potential seating materials in bench- and full-scale, HAZARD I (NIST's fire hazard assessment software) was used to examine the development of fire hazard to occupants from seating fires. The conclusions were that while two seating assemblies developed incapacitating conditions and one lethal condition within 3 min, three other assemblies did not produce untenable conditions within the same time period.⁸ In 1993, the FTA published recommended practices for bus materials and engine compartments which cited the same tests and almost the same performance criteria as for rail transit.

Ships

The regulation of commercial vessels is primarily conducted under international law. The International Maritime Organization (IMO) promulgates regulations and test methods for fire resistance and flame spread on interior materials. The U.S. Coast Guard (USCG) enforces these and some other safety and sanitation requirements for foreign flag vessels that operate in U.S. waters.

As a result of U.S. regulatory reform, the USCG initiated and chaired an NFPA technical committee to develop consensus standards as an alternative to the current fire regulations and NVICs.⁹ Various NFPA 301, *Code for Safety to Life from Fire on Merchant Vessels*, requirements are described for vessels carrying more than 12 passengers.¹⁰ Materials requirements are similar to the USCG regulations and the NVIC 9-97, with some exceptions. The passenger capacity, type of service (day or overnight), and whether or not the space is protected with automatic

sprinklers determine flame spread limits. NFPA 301 means-of-egress provisions appear to be adapted for the marine environment from NFPA 101®, *Life Safety Code*®,¹¹ and depend on the number of passengers and whether or not overnight accommodations are provided.

NFPA 301 includes an appendix intended to allow the vessel designer and operator to comply with the Code while accommodating new or unique vessel uses or incorporating new or transfer technology. The appendix provides a standardized hazard analysis and risk assessment methodology to use in demonstrating equivalent safety. The methodology includes a description of several analysis techniques (e.g., preliminary hazard analysis, fault tree analysis, criticality analysis), data inputs (e.g., vessel physical description, design and operating assumptions and conditions), hazard correction measures, and verification and documentation of equivalence.

Application of Fire Hazard Assessment to Transportation

The general process of fire hazard assessment as applied to buildings is also applicable to transportation. In this section the steps for conducting a FHA will be discussed in this context. The steps are

1. Selecting a target outcome
2. Determining the scenarios of concern
3. Selecting design fires
4. Selecting appropriate calculation methods
5. Performing an evacuation calculation
6. Analyzing the impact of exposure
7. Accounting for uncertainty

Selecting a Target Outcome

The objective of safety regulations for transportation is to minimize loss of life and injuries in accidents. Preservation of property, in particular the limitation of damage to the vehicles, is not considered. Thus, regulations focus on vehicle design, material selection, and emergency procedures that would be expected to mitigate human losses in accident scenarios drawn from operating experience. However, since transportation accidents that involve fire are exceedingly rare, hazard scenarios that have been considered include possibilities that may not have actually occurred.

Determining the Scenario(s) of Concern

Scenarios to be evaluated can be drawn from the detailed NTSB accident investigation reports and the operational experience of the industry, but should be supplemented by reasonable scenarios that could result in significant threat to passengers or crew. For example, NIST research conducted for the FRA identified trash bags found on overnight trains as a potentially significant fire exposure (250 kW) to seats and interior materials, even though there are no records of fires involving these trash bags on trains.

Vandalism is a source of fires in subways and commuter rail systems. Scenarios may involve newspapers and small amounts of flammable liquids used to ignite seats that may be slashed to expose interior padding. Some operators require fire testing of seats that have been slashed in an X pattern low on the back and through the upholstery.

Tunnels represent a significant complication in a rail environment. Accidents that may occur in a tunnel pose an additional threat to passengers and crew because the fire effluent is contained around the train where it can continue to expose people who have exited the vehicles. Tunnels, bridges, or other elevated track sections also restrict the ability of people to move to a safe location away from the train. These issues need to be addressed where trains operate in long tunnels or have extended elevated sections.

Selecting the Design Fire(s)

In both the aviation and rail environments, the materials employed for seating and finish are high fire performance materials and systems. Thus, burning rate data on actual materials should be used wherever possible because data on typical materials will not be applicable. Care should be exercised because burning rates may be reported only at higher incident fluxes because the materials do not burn at typical flux levels. The T-squared fire curve still can be used where large-scale burning rate data on actual transportation materials is available and can be shown to correlate to the T-squared growth rate employed.

Selecting Appropriate Methods for Prediction

Particular care should be exercised in the selection of appropriate prediction methods for transportation applications. Planes and trains are spaces with large aspect ratios, so some aspects of zone models may not be appropriate. Aircraft operate under conditions of pressurization to about 8000 ft, so oxygen levels and partial pressures are lower than normal. Their ventilation systems are unique and can have a significant influence on fire development and smoke movement. Train ventilation systems are more like those found in buildings and should not represent special circumstances.

Performing an Evacuation Calculation

In all transportation modes except aircraft, it is necessary to perform an evacuation calculation to estimate the time needed for passengers and crew to move to a safe location. In aviation, passengers and crew must await landing the plane before any egress actions can begin. Once the aircraft comes to a stop, as defined in FAA regulations it can be assumed that everyone can be evacuated within 90 s through half of the available exits. This 90-s emergency evacuation performance is demonstrated for every

commercial aircraft and configuration with a full load of passengers having a distribution of gender and age approximating that of the flying public in order for an aircraft to be certified.

The limitations are that these evacuation certification tests are performed under nearly ideal conditions with the aircraft upright and level and without smoke. Most of the test subjects are employees of the aircraft manufacturer (and as such are usually experienced in emergency evacuation of the aircraft), and none attempt to take carry-on items, as is often reported in actual aircraft evacuations.

In a rail environment, there is no such requirement for evacuation performance and little research or testing from which to obtain details of passenger egress behavior. In trains, passengers are always free to move about, so passengers might be expected to begin egress behavior from one car to another while the train is still moving, although they would have to sit or hold on during any emergency braking. Current emergency procedures for rail vehicles emphasize movement to safe areas in adjacent cars, even when the train is stopped. However, if passengers get off the train, they may be struck by other trains passing on an adjacent track; use of escape windows is only a last resort because many are located too high off the ground. If an emergency occurs while a train is in a tunnel, the train would continue moving until it is clear of the tunnel, if possible. Compared to aircraft usually consisting of a single main cabin and a specified number of flight crew for the number of passengers, a train has many fewer crew per passenger, and passengers may be seated in several separate cars. Train crew would use the public address system to issue emergency instructions but would likely have less direct contact with passengers.

A number of special evacuation characteristics for train cars should be considered in any evacuation calculation. Horizontal travel speeds in a moving train car would be expected to be significantly slower than walking speeds in buildings. Some commuter and intercity trains use bi-level car designs with one or two stairways per car. These stairways are narrower and steeper than building stairs, so travel speeds should be slower. Most such cars have lateral connections on both levels, but there are some notable exceptions—Amtrak double deck sleepers have no lateral connections to adjacent cars on the lower deck. Such details should be accounted for in evacuation calculations.

Analyzing the Impact of Exposure

In any fire hazard assessment, the impact of exposure of people to fire effluent is related to concentration and time. An aircraft experiencing an in-flight fire scenario would be expected to involve a significant exposure time since the typical time to affect an emergency diversion is estimated by the FAA to average about 30 min. Thus, even low concentrations of fire gases can lead to impaired egress performance. For the impact survivable, post-crash fire scenario the exposure time is (by FAA definition) not greater than 90 s, so only thermal threats would be of significance.

In a rail environment, most scenarios of interest would find safe areas in adjacent cars with short movement times to areas of relative safety. Thus, most rail scenarios would involve short exposure times where primary threats would be from thermal insults. One exception is in sleeping cars not equipped with fire detection systems and when the incident occurs in a long tunnel.

Accounting for Uncertainty

One of the more difficult aspects of conducting a fire hazard analysis is the estimation of uncertainty. Where there are data from full-scale tests, these can be used to estimate the uncertainty of a calculation method applied to the same conditions (see following section for an example). In the absence of data, a sensitivity analysis might be performed to quantify the effect of uncertainty on the outcome.

Alternative Uses for Fire Hazard Assessment

The preceding has focused on the use of fire hazard assessment in the evaluation of the performance of a specific transportation system design against the objective of passenger and crew safety. Another application of fire hazard assessment techniques might be to determine the minimum performance level of a major system component necessary to meet the target outcome. An example of such appears in the Phase III report of NIST's research for FRA¹² of passenger rail fire safety, where the hazard assessment supports the regulation of the fire performance of materials in their context of use in the vehicles.

For the car designer or regulator, the objective is to determine the limiting performance level so that the designer has the freedom to use any material in any way that will not violate this bounding condition. Thus, a *fire performance curve* was calculated with NIST's CFAST fire model and applying tenability criteria to obtain time to impaired evacuation and incapacitation as a function of fire growth rate for a typical intercity rail (single deck) coach car. The fire performance curve shows that any fire that does not exceed the medium (*t*-squared) growth rate will not pose a threat to passengers or crew.

Figure 5-15.1 shows the fire performance curve determined from experimental measurements in the gas burner tests along with fire model predicted curves calculated for the test vehicle. For a medium growth rate *t*-squared fire, the time to incapacitation determined from the replicate gas burner tests was (126 Å 7) s. For other growth rate fires, the time to incapacitation ranged from (40 Å 4) s for the ultra-fast growth rate fire to (230 Å 12) s for the slow growth rate fire. On average, the uncertainty of the experimentally determined times to these untenable conditions was less than 7 percent (based on one standard deviation). Once the bounding condition, in this case a medium *t*-squared fire growth rate, is known, the vehicle designer or regulator can use any of several means to assure the limit is not exceeded—including material selection, limiting quantities of combustibles, active

Figure 5-15.1. Fire performance curve.

mitigation strategies such as suppression or smoke venting, and so forth.

Application of Fire Hazard Assessment to Passenger Rail

Recent revisions to 49CFR, Part 238, Section 238-103(d) require that railroad operators conduct a fire safety analysis on all categories of existing passenger railroad equipment and service. The industry, through the American Public Transit Association is developing guidelines for conducting this analysis. The following is intended to demonstrate that process and to produce a recommended practice to guide the industry in meeting the intent of the regulation.

The first issue that needs to be addressed is to understand the intent of the regulation. This is to conduct a systematic analysis of railroad equipment and service that will identify potential fire hazards to passengers and crew and to take steps to mitigate these potential hazards. Where multiple potential hazards are identified, mitigation should be prioritized in order of decreasing risk.

This intent embraces several important concepts. The first is the fire scenario. A *fire scenario* is a description of the sequence of events that must occur to result in an uncontrolled fire. A fire scenario description generally includes an ignition source and an initial item ignited, but may include other special conditions that are required to result in the consequence to be avoided. For example, some fire scenarios may represent a threat to passengers and crew only if they occur in a tunnel that increases the smoke exposure or if the passengers have limited ability to evacuate without assistance.

The second concept is fire hazard assessment. A *fire hazard assessment* is a systematic examination of all potential fire hazards that might occur, resulting in the conse-

quence to be avoided, in this case an injury or fatality to passengers or crew. Note that a fire hazard assessment is not limited to fire hazards that have at some time occurred, but should also consider fire hazard scenarios that are possible, even if they would require several things to go wrong simultaneously.

The third concept is fire risk assessment. A *fire risk assessment* begins with a fire hazard assessment and weights the consequences by the likelihood of the fire scenario. By discounting the consequence by likelihood, the scenario with high consequences and low likelihood and the scenario with low consequences that occurs frequently represent equal risk. Thus, fire risk analysis is a way of normalizing different hazards so that they can be compared or summed to produce a total threat index.

Define Scenarios

The first step in the process is to define the scenarios which could lead to potential injury to passengers and crew. These will include both those fire scenarios that have occurred and those that are possible but have not yet occurred. Traditionally, the former are identified from accident statistics and reports, although, in most cases, the reporting systems have significant shortcomings and the databases are incomplete. Federal regulations (49CFR, Part 225) require that incidents that result in a fatality or injury, or result in damage to property exceeding a threshold (\$6700 for 1998) be reported. A recent search of this database identified 156 fire incidents of interest for 1985 to 1998.

Additionally, there are other fire databases that can be examined, such as the National Fire Incident Reporting System (NFIRS). A recent search of NFIRS for passenger rail fire incidents for the 10-year period from 1988 through 1997 identified 71 fires resulting in two civilian deaths and four injuries. Note that such searches should not be limited to those that resulted in fatality or injury because the intent is to identify scenarios that may result in fatality or injury. No scenario should be excluded unless it is determined that it cannot result in harm under any condition.

Defining scenarios that have not occurred requires judgment and experience. They may involve new combinations of ignition sources and fuels, or they may involve new items not previously found in the rail environment. An example would be electronic equipment introduced to entertain passengers or to facilitate work during transit. At this stage, it is best to include everything possible and to cull the list later with justification. Also, since the rail operator is performing the analysis, it should be possible to identify incidents that did not exceed the reporting threshold but are documented internally or in the experience of employees.

Inventory of Equipment—Identification of Hazards

The fire safety analysis will need to be conducted around an inventory of equipment and materials that make up the vehicle. Anything that uses energy or materials that are easily ignited by small sources such as matches or smoking materials should be identified as

potential ignition sources. Any combustible material can be a first item ignited, or a fuel item. The inventory should also identify items in both categories that may be brought aboard by passengers, such as luggage, packages, and even coats and pillows.

Each of these items needs to be characterized in terms useful to the fire safety analysis. Ignition sources are characterized by maximum potential energy; fuel items, by heat release rate (HRR) and yields of smoke and gases, as well as some measure of ignitability.

At the same time, the equipment or design features present that may mitigate hazards or impact on the evolution of hazards should be identified. These vehicle characteristics include number, type, and location of doors and escape windows/hatches; number of levels and stairways; detection, extinguishing, communication, emergency lighting and signage, or smoke management systems.

Analysis of Operating Environment

The operating environment of vehicles has a significant influence on the fire hazards that may be encountered. Operating speeds, grade crossings and their protection, bridges and tunnels, shared right-of-way with freight operations, and even terrain can affect the analysis and should be identified.

Description of Fire Scenarios

Using this inventory, the combination of ignition sources and fuels that can result in a significant fire becomes the basis of a fire scenario description. For example, if a piece of electrical equipment is protected by a fuse so the maximum fault energy is limited, and it is enclosed or separated by a distance from any combustible material so that this maximum fault energy cannot ignite the fuel, then this scenario can be eliminated at this step. Of course, the possibility of the wrong size fuse resulting in a higher fault energy or the presence of combustible materials that are "not supposed to be there" need to be considered as separate scenarios.

Fire Hazard Assessment

For each of the identified fire scenarios, the consequences of the hazards in terms of potential injuries or fatalities to passengers or crew is evaluated. This evaluation is done in any of several ways. First, the judgment of experienced people can be used to determine likely outcomes of some scenarios—especially those for which historical experience exists.

Second, there are various tools to assist in making a determination. These include fault trees such as NFPA550 or simple calculational procedures such as FPEtool. These methods depend on judgment supported by individual calculations to provide quantitative results.

Third, there are more detailed modeling tools, such as HAZARD I, that are increasingly being applied to special areas such as rail. In addition to providing predictions of the outcome of specific scenarios, these tools can be used to estimate general, bounding conditions in the form

of fire performance curves as demonstrated in the NIST Phase III report (in press).

The important criterion in the fire hazard assessment is not only to identify conditions or design features that relate to identified hazards, but to determine that the conditions or features actually mitigate the hazard. For example, a fire-rated floor may provide protection against ignition from an overheated wheel, but if combustible lubricants are allowed to build up on the wheel assembly, the overheated wheel may ignite the grease that then may present too great a heat source for the floor to provide adequate protection.

Risk Ranking

Once each of the fire hazard scenarios have been evaluated, those which may potentially result in injury or fatality to passengers or crew and are not already addressed by design or operating procedures will have been identified. Mitigation strategies for each should be suggested and evaluated for effectiveness by rerunning the hazard calculation with the strategy in place. Only where it is not practical to eliminate all identified hazards is it necessary to perform a risk ranking to prioritize those situations to be addressed first.

Here, the likelihood of the remaining scenarios is estimated from historical data or experience. Then this likelihood is used to discount the consequences of each remaining scenario so that the risk of each can be compared. For example, if one scenario is expected to result in 10 passenger injuries and another in 50 passenger injuries, but the first is 10 times more likely, the first is the higher risk and should be addressed first.

Ideally, one would like to be able to define a level of "acceptable risk" below which it is not necessary to take remedial action. Unfortunately this is a very difficult task since risk perception and risk acceptance are quite variable. Normally the "reasonable person" does not expect to be protected from reasonably unexpected hazards or hazards clearly beyond control. An example of the former is to design a train to withstand being struck by a falling airplane. An example of the latter is designing against a terrorist attack.

Beyond these "reasonableness" tests, experience has shown that the public is more hazard averse than risk averse. Transportation accidents resulting in large numbers of fatalities or injuries are considered unacceptable, regardless of a demonstrable low likelihood. Thus, the concept of "acceptable risk" may not be applicable.

Conclusions

Modern fire hazard assessment techniques that are becoming common in the building regulatory arena can be adapted and applied to transportation. While transportation has an excellent fire safety record, these new techniques are desirable because they provide increased design flexibility particularly with respect to the introduction of innovative materials.

Recent research into fire hazard assessment for passenger rail has resulted in the promulgation of regulations and the development of procedures that can be used

by the industry for compliance. These techniques also have application to other transportation sectors such as transit and may be adapted for use there in the future.

APPENDIX A

Conversion Factors

Table A.1 Names and Symbols of SI Units¹

Quantity	Name of Unit	Symbol
SI BASE UNITS		
Length	Meter	m
Mass	Kilogram	kg
Time	Second	s
Electric current	Ampere	A
Thermodynamic temperature	Kelvin	K
Luminous intensity	Candela	cd
Amount of substance	Mole	mol
SI-DERIVED UNITS		
Area	Square meter	m ²
Volume	Cubic meter	m ³
Frequency	Hertz	Hz
Mass density (density)	Kilogram per cubic meter	kg/m ³
Speed, velocity	Meter per second	m/s
Angular velocity	Radian per second	rad/s
Acceleration	Meter per second squared	m/s ²
Angular acceleration	Radian per second squared	rad/s ²
Force	Newton	N
Pressure (mechanical stress)	Pascal	Pa
Kinematic viscosity	Square meter per second	m ² /s
Dynamic viscosity	Newton-second per square meter	N·s/m ²
Work, energy, quantity of heat	Joule	J
Power	Watt	W
Quantity of electricity	Coulomb	C
Potential difference, electromotive force	Volt	V
Electric field strength	Volt per meter	V/m
Electric resistance	Ohm	Ω
Capacitance	Farad	F
Magnetic flux	Weber	Wb
Inductance	Henry	H
Magnetic flux density	Tesla	T
Magnetic field strength	Ampere per meter	A/m
Magnetomotive force	Ampere	A
Luminous flux	Lumen	lm
Luminance	Candela per square meter	cd/m ²
Illuminance	Lux	lx
Wave number	1 per meter	m ⁻¹
Entropy	Joule per kelvin	J/K
Specific heat capacity	Joule per kilogram kelvin	J/(kg·K)
Thermal conductivity	Watt per meter kelvin	W/(m·K)
Radiant intensity	Watt per steradian	W/sr
Activity (or a radioactive source)	1 per second	s ⁻¹
SI SUPPLEMENTARY UNITS		
Plane angle	Radian	rad
Solid angle	Steradian	sr

Table A.2 Definitions of SI Units¹

Meter (m)	The <i>meter</i> is the length equal to 1 650 763.73 wavelengths in vacuum of the radiation corresponding to the transition between the levels 2 p ₁₀ and 5 d _s of the krypton-86 atom.	Watt (W)	The <i>watt</i> is the power that gives rise to the production of energy at the rate of 1 joule per second.
Kilogram (kg)	The <i>kilogram</i> is the unit of mass; it is equal to the mass of the international prototype of the kilogram. (The international prototype of the kilogram is a particular cylinder of platinum-iridium alloy that is preserved in a vault at Sèvres, France, by the International Bureau of Weights and Measures.)	Volt (V)	The <i>volt</i> is the difference of electric potential between two points of a conducting wire carrying a constant current of 1 ampere, when the power dissipated between these points is equal to 1 watt.
Second (s)	The <i>second</i> is the duration of 9 192 631 770 periods of the radiation corresponding to the transition between the two hyperfine levels of the ground state of the cesium-133 atom.	Ohm (Ω)	The <i>ohm</i> is the electric resistance between two points of a conductor when a constant difference of potential of 1 volt, applied between these two points, produces in this conductor a current of 1 ampere, this conductor not being the source of any electromotive force.
Ampere (A)	The <i>ampere</i> is that constant current, which, if maintained in two straight parallel conductors of infinite length, of negligible circular cross section, and placed 1 meter apart in a vacuum, would produce between these conductors a force equal to 2×10^{-7} newton per meter of length.	Coulomb (C)	The <i>coulomb</i> is the quantity of electricity transported in 1 second by a current of 1 ampere.
Kelvin (K)	The <i>kelvin</i> , unit of thermodynamic temperature, is the fraction 1/273.16 of the thermodynamic temperature of the triple point of water.	Farad (F)	The <i>farad</i> is the capacitance of a capacitor between the plates of which there appears a difference of potential of 1 volt when it is charged by a quantity of electricity equal to 1 coulomb.
Candela (cd)	The <i>candela</i> is the luminous intensity, in the perpendicular direction, of a surface of 1/600 000 square meter of a blackbody at the temperature of freezing platinum under a pressure of 101 325 newtons per square meter.	Henry (H)	The <i>henry</i> is the inductance of a closed circuit in which an electromotive force of 1 volt is produced when the electric current in the circuit varies uniformly at a rate of 1 ampere per second.
Mole (mol)	The <i>mole</i> is the amount of substance of a system that contains as many elementary entities as there are carbon atoms in 0.012 kg of carbon 12. The elementary entities must be specified and may be atoms, molecules, ions, electrons, other particles, or specified groups of such particles.	Weber (Wb)	The <i>weber</i> is the magnetic flux that, linking a circuit of one turn, produces in it an electromotive force of 1 volt as it is reduced to zero at a uniform rate in 1 second.
Newton (N)	The <i>newton</i> is that force that gives to a mass of 1 kilogram an acceleration of 1 meter per second per second.	Lumen (lm)	The <i>lumen</i> is the luminous flux emitted in a solid angle of 1 steradian by a uniform point source having an intensity of 1 candela.
Joule (J)	The <i>joule</i> is the work done when the point of application of 1 newton is displaced a distance of 1 meter in the direction of the force.	Radian (rad)	The <i>radian</i> is the plane angle between two radii of a circle that cut off on the circumference an arc equal in length to the radius.
		Steradian (sr)	The <i>steradian</i> is the solid angle that, having its vertex in the center of a sphere, cuts off an area of the surface of the sphere equal to that of a square with sides of length equal to the radius of the sphere.

The names of multiples and submultiples of SI units can be formed by application of the prefixes in Table A.3. The International Organization for Standardization (ISO) recommends the following rules for the use of SI prefixes:

1. Prefix symbols are printed in roman (upright) type without spacing between the prefix symbol and the unit symbol.
2. An exponent affixed to a symbol containing a prefix indicates that the multiple or submultiple of the unit is raised to the power expressed by the exponent.

$$\text{Example: } 1 \text{ cm}^3 = 10^{-6} \text{ m}^3 \\ 1 \text{ cm}^{-1} = 10^2 \text{ m}^{-1}$$

3. Compound prefixes, formed by the juxtaposition of two or more SI prefixes, are not to be used.

$$\text{Example: } 1 \text{ nm} \quad \text{but not: } 1 \text{ m}\mu\text{m}$$

ISO has issued additional recommendations with the aim of securing uniformity in the use of units. According to these recommendations,

1. The product of two or more units is preferably indicated by a dot. The dot may be dispensed with when there is no risk of confusion with another unit symbol.

$$\text{Example: } \text{N}\cdot\text{m} \text{ or } \text{Nm} \quad \text{but not: } \text{mN}$$

2. A solidus (oblique stroke, /), a horizontal line, or negative powers may be used to express a derived unit formed from two others by division.

$$\text{Example: } \text{m/s}, \frac{\text{m}}{\text{s}}, \text{ or } \text{m}\cdot\text{s}^{-1}$$

3. The solidus must not be repeated on the same line unless ambiguity is avoided by parentheses. In complicated cases negative powers or parentheses should be used.

$$\text{Example: } \text{m/s}^2 \text{ or } \text{m}\cdot\text{s}^{-2} \quad \text{but not: } \text{m/s/s} \\ \text{m}\cdot\text{kg}/(\text{s}^3\cdot\text{A}) \text{ or } \text{m}\cdot\text{kg}\cdot\text{s}^{-3}\cdot\text{A}^{-1} \\ \text{but not: } \text{m}\cdot\text{kg/s}^3/\text{A}$$

Table A.3 SI Prefixes¹

Factor by Which Unit Is Multiplied	Prefix	Symbol
10 ¹²	Tera	T
10 ⁹	Giga	G
10 ⁶	Mega	M
10 ³	Kilo	k
10 ²	Hecto	h
10	Deka	da
10 ⁻¹	Deci	d
10 ⁻²	Centi	c
10 ⁻³	Milli	m
10 ⁻⁶	Micro	μ
10 ⁻⁹	Nano	n
10 ⁻¹²	Pico	p
10 ⁻¹⁵	Femto	f
10 ⁻¹⁸	Atto	a

Table A.4 lists physical constants from the work of B. N. Taylor, W. H. Parker, and D. N. Langenberg.² Their least-squares adjustment of values of the constants depends strongly on a highly accurate (2.4 ppm) determination of e/h from the ac Josephson effect in superconductors, and is believed to be more accurate than the 1963 adjustment, which appears to suffer from the use of an incorrect value of the fine structure constant as an input datum. See also *NBS Special Publication 344*, issued March 1971.

Table A.4 Physical Constants²

Quantity	Symbol	Value	Error (ppm)	Prefix	Unit
Speed of light in vacuum	c	2.997 925 0	0.33	$\times 10^8$	$\text{m}\cdot\text{s}^{-1}$
Gravitational constant	G	6.673 2	460	10^{-11}	$\text{N}\cdot\text{m}^2\cdot\text{kg}^{-2}$
Avogadro constant	N_A	6.022 169	6.6	10^{26}	kmol^{-1}
Boltzmann constant	k	1.380 622	43	10^{-23}	$\text{J}\cdot\text{K}^{-1}$
Gas constant	R	8.314 34	42	10^3	$\text{J}\cdot\text{kmol}^{-1}\cdot\text{K}^{-1}$
Volume of ideal gas, standard conditions	V_0	2.241 36	—	10^1	$\text{m}^3\cdot\text{kmol}^{-1}$
Farady constant	F	9.648 670	5.5	10^7	$\text{C}\cdot\text{kmol}^{-1}$
Unified atomic mass unit	u	1.660 531	6.6	10^{-27}	kg
Planck constant	h	6.626 196	7.6	10^{-34}	$\text{J}\cdot\text{s}$
	$h/2\pi$	1.054 591 9	7.6	10^{-34}	$\text{J}\cdot\text{s}$
Electron charge	e	1.602 191 7	4.4	10^{-19}	C
Electron rest mass	m_e	9.109 558	6.0	10^{-31}	kg
		5.485 930	6.2	10^{-4}	u
Proton rest mass	m_p	1.672 614	6.6	10^{-27}	kg
		1.007 276 61	0.08	—	u
Neutron rest mass	m_n	1.674 920	6.6	10^{-27}	kg
		1.008 665 20	0.10	—	u
Electron charge to mass ratio	e/m_e	1.758 802 8	3.1	10^{11}	$\text{C}\cdot\text{kg}^{-1}$
Stefan-Boltzmann constant	σ	5.669 61	170	10^{-8}	$\text{W}\cdot\text{m}^{-2}\cdot\text{K}^{-4}$
First radiation constant	$2\pi^5 h c^5/15$	3.741 844	7.6	10^{-16}	$\text{W}\cdot\text{m}^2$
Second radiation constant	hc/k	1.438 833	43	10^{-2}	$\text{m}\cdot\text{K}$
Rydberg constant	R_∞	1.097 373 12	0.10	10^7	m^{-1}
Fine structure constant	α	7.297 351	1.5	10^{-3}	
	α^{-1}	1.370 360 2	1.5	10^2	
Bohr radius	a_0	5.291 771 5	1.5	10^{-11}	m
Classical electron radius	r_e	2.817 939	4.6	10^{-15}	m
Compton wavelength of electron	λ_C	2.426 309 6	3.1	10^{-12}	m
	$\lambda_C/2\pi$	3.861 592	3.1	10^{-13}	m
Compton wavelength of proton	$\lambda_{C,p}$	1.321 440 9	6.8	10^{-15}	m
	$\lambda_{C,p}/2\pi$	2.103 139	6.8	10^{-16}	m
Compton wavelength of neutron	$\lambda_{C,n}$	1.319 621 7	6.8	10^{-15}	m
	$\lambda_{C,n}/2\pi$	2.100 243	6.8	10^{-16}	m
Electron magnetic moment	μ_e	9.284 851	7.0	10^{-24}	$\text{J}\cdot\text{T}^{-1}$
Proton magnetic moment	μ_p	1.410 620 3	7.0	10^{-26}	$\text{J}\cdot\text{T}^{-1}$
Bohr magneton	μ_B	9.274 096	7.0	10^{-24}	$\text{J}\cdot\text{T}^{-1}$
Nuclear magneton	μ_n	5.050 951	10	10^{-27}	$\text{J}\cdot\text{T}^{-1}$
Gyromagnetic ratio of protons in H ₂ O	γ'_p	2.675 127 0	3.1	10^8	$\text{rad}\cdot\text{s}^{-1}\text{T}^{-1}$
	$\gamma'_p/2\pi$	4.257 597	3.1	10^7	$\text{Hz}\cdot\text{T}^{-1}$
Gyromagnetic ratio of protons in H ₂ O	γ'_p	2.675 196 5	3.1	10^8	$\text{rad}\cdot\text{s}^{-1}\text{T}^{-1}$
Corrected for diamagnetism of H ₂ O	$\gamma'_p/2\pi$	4.257 707	3.1	10^7	$\text{Hz}\cdot\text{T}^{-1}$
Magnetic flux quantum	Φ_0	2.067 853 8	3.3	10^{-15}	Wb
Quantum of circulation	$h/2m_e$	3.636 947	3.1	10^{-4}	$\text{J}\cdot\text{s}\cdot\text{kg}^{-1}$
	h/m_e	7.273 894	3.1	10^{-4}	$\text{J}\cdot\text{s}\cdot\text{kg}^{-1}$

Table A.4 (Continued)

Unitless Numerical Ratios	Value	Error (ppm)	Prefix
(c^2) kg/eV	5. 609 538	4.4	10^{35}
(c^2) u/eV	9. 314 812	5.5	10^8
u/kg	1. 660 531	6.6	10^{-27}
(c^2) m_c /eV	5. 110 041	3.1	10^5
(c^2) m_p /eV	9. 382 592	5.5	10^8
(c^2) m_n /eV	9. 395 527	5.5	10^8

μ'_p/μ_B	1. 520 993 12	0.066	10^{-3}
μ_p/μ_B	1. 521 032 64	0.30	10^{-3}
μ'_p/μ_n	2. 792 709	6.2	
μ_p/μ_n	2. 792 782	6.2	

Other Important Constants

$$\begin{aligned} \pi &= 33.141\,592\,653\,589 \\ e &= 2.718\,281\,828\,459 \\ \mu_0 &= 4\pi \times 10^{-7} \text{ H/m (exact), permeability of free space} \\ &= 1.256\,637\,061 \times 10^{-6} \text{ H/m} \\ \epsilon_0 &= \mu_0^{-1} c^{-2} \text{ F/m, permittivity of free space} \\ &= 8.854\,185 \times 10^{-12} \text{ F/m} \end{aligned}$$

The following tables express the definitions of miscellaneous units of measure as exact numerical multiples of coherent SI units, and provide multiplying factors for converting numbers and miscellaneous units to corresponding new numbers and SI units.

The first two digits of each numerical entry represents a power of 10. An asterisk following a number expresses an exact definition. For example, the entry $-02\,2.54^*$ expresses the fact that 1 inch = 2.54×10^{-2} meter, exactly, by definition. Most of the definitions are extracted from National Bureau of Standards (NBS) documents. Numbers not followed by an asterisk are only approximate representations of definitions, or are the results of physical measurements.

The conversion factors are listed alphabetically in Table A.5 and by physical quantity in Table A.6. The listing by physical quantity (Table A.6) includes only relationships that are frequently encountered, and deliberately omits the great multiplicity of combinations of units that are used for more specialized purposes. Conversion factors for combinations of units are easily generated from numbers given in the alphabetical listing (Table A.5) by the technique of direct substitution or by other well-known rules for manipulating units. These rules are adequately discussed in many science and engineering textbooks and are not repeated here.

^aDefinition: One atmosphere (standard) = 76 cm of mercury at 0°C.

^bTo convert height h of a column of mercury at t degrees centigrade to the equivalent height h_0 at 0°C, use $h_0 = h[1 - (m - l)t/(1 + mt)]$ where $m = 0.0001818$ and $l = 18.4 \times 10^{-6}$ if the scale is engraved on brass; $l = 8.5 \times 10^{-6}$ if on glass. This assumes the scale is correct at 0°C; for other cases (any liquid) see *International Critical Tables*, Vol. 1 (1968).

^c1 g/cm² = 10 kg/m².

The *horsepower* used in Tables A.17 and A.18 is equal to 550 foot pounds per second by definition. Other definitions are one horsepower equals 746 watts (U.S. and Great Britain) and one horsepower equals 736 watts (continental Europe). Neither of these latter definitions is equivalent to the first; the *horsepowers* defined in these latter definitions are widely used in the rating of electrical machinery.

^aMean calorie and Btu used throughout. One gram-calorie = 0.001 kilogram-calorie; one Ostwald calorie = 0.1 kilogram-calorie. The IT cal, 1000 international steam table calories, has been defined as the 1/860th part of the international kilowatt-hour (see *Mechanical Engineering*, Nov., 1935, p. 710). Its value is very nearly equal to the mean kilogram-calorie, 1 IT cal = 1.00037 kilogram-calories (mean). 1 Btu = 251.996 IT cal.

^bAbsolute joule, defined as 10^7 ergs. The international joule, based on the international ohm and ampere, equals 1.0003 absolute joules.

Table A.18 Power or Rate of Doing Work (ML^2T^{-3}) or (FLT^{-1})

to Obtain ↓	Multiply Number of →									
	by →		British Thermal Units per Minute	Ergs per Second	Foot Pounds per Minute	Foot Pounds per Second	Horsepower	Kilogram Calories per Minute	Kilowatts	Metric Horsepower
British thermal units per minute	1		5.689	1.285	7.712	42.41	3.969	56.89	41.83	5.689

kg-cal/s·m ²	3.681×10^{-4}	6.07×10^{-6}	1.434×10^4	1.4341×10^1	1.434×10^3	

Table A.20 Specific Heat ($L^2T^{-2}t^{-1}$, $t = \text{temperature}$)

To change specific heat in gram calories per gram per degree centigrade to the units given in any line of the following table, multiply by the factor in the last column.

Unit of Heat or Energy	Unit of Mass	Temperature Scale ^a	Factor
Gram calories	Gram	Centigrade	1
Kilogram calories	Kilogram	Centigrade	1
British thermal units	Pound	Centigrade	1.800
British thermal units	Pound	Fahrenheit	1.000
Joules	Gram	Centigrade	4.186
Joules	Pound	Fahrenheit	1055
Joules	Kilogram	Kelvin	4.187×10^3
Kilowatt hours	Kilogram	Centigrade	1.163×10^{-3}
Kilowatt hours	Pound	Fahrenheit	2.930×10^{-4}

^aTemperature conversion formulae:

$$t_C = \text{temperature in centigrade degrees}$$

$$t_f = \text{temperature in Fahrenheit degrees}$$

$$t_K = \text{temperature in kelvin degrees}$$

$$1^\circ\text{F} = \frac{5}{9}^\circ\text{C}$$

$$1 \text{ K} = 1^\circ\text{C}$$

$$t_C = \frac{5}{9}(t_f - 32)$$

$$t_f = \frac{9}{5}t_C + 32$$

$$t_K = t_C + 273$$

APPENDIX D

Configuration Factors

Figure D-1. View factor for parallel, rectangular plates.⁸

$$F_{12} = \frac{2}{\pi} \left[\frac{X}{\sqrt{1+X^2}} \tan^{-1} \frac{Y}{\sqrt{1+X^2}} + \frac{Y}{\sqrt{1+Y^2}} \tan^{-1} \frac{X}{\sqrt{1+Y^2}} \right]$$

$$X = \frac{A}{C}$$

$$Y = \frac{B}{C}$$

Figure D-2. View factor for parallel, rectangular radiator.⁸

Figure D-3. View factor for rectangular plates at various angles.⁸

$$F_{12} = \frac{1}{2\pi} \left\{ \tan^{-1} \left(\frac{1}{L} \right) + V(N \cos \phi - \phi L) \tan^{-1} V \right. \\ \left. + \frac{\cos \phi}{W} \left[\tan^{-1} \left(\frac{N - L \cos \phi}{W} \right) + \tan^{-1} \left(\frac{L \cos \phi}{W} \right) \right] \right\}$$

$$V = \frac{1}{\sqrt{N^2 + L^2 - 2NL \cos \phi}}$$

$$W = \sqrt{1 + L^2 \sin^2 \phi}$$

$$N = \frac{a}{b}$$

$$L = \frac{c}{b}$$

Figure D-4. View factor for rectangular radiator to differential area at various angles.⁸

$$F_{12} = \frac{1}{\pi D} \tan^{-1} \left(\frac{L}{\sqrt{D^2 - 1}} \right) + \frac{L}{\pi} \left[\frac{A - 2D}{D\sqrt{AB}} \tan^{-1} \frac{\sqrt{A(D-1)}}{\sqrt{B(D+1)}} - \frac{1}{D} \tan^{-1} \frac{D-1}{\sqrt{D+1}} \right]$$

$$D = \frac{d}{r} \quad L = \frac{L}{R}$$

$$A = (D + 1)^2 + L^2 \quad B = (D - 1)^2 + L^2$$

Figure D-5. Cylindrical radiator to parallel receiver.⁸

$$F_{12} = \frac{1}{\pi} \left[\tan^{-1} \frac{\sqrt{X^2 + R^2}}{\sqrt{X^2 - R^2}} - \frac{(1.0 + X^2 - R^2)}{(1.0 + X^2 + R^2)} \tan^{-1} \frac{\sqrt{X^2 + R^2}}{\sqrt{X^2 - R^2}} \right]$$

$$X' = \frac{X}{H}$$

$$R' = \frac{R}{H}$$

Figure D-6. View factor for cylindrical radiator to normal target.⁸

Two infinitely long, directly opposed parallel plates of the same finite width

$H = \frac{h}{w}$
 $F_{1-2} = F_{2-1} = \sqrt{1+H^2} - H$

$$F_{d1-2} = \frac{1}{2\pi} \left(\frac{X}{\sqrt{1+X^2}} \tan^{-1} \frac{Y}{\sqrt{1+X^2}} + \frac{X}{\sqrt{1+Y^2}} \tan^{-1} \frac{X}{\sqrt{1+Y^2}} \right)$$

Identical, parallel, directly opposed rectangles.

$Y = \frac{a}{c}$ $Y = \frac{b}{c}$

Plane element dA_1 to rectangle in plane 90° to plane of element

$X = \frac{a}{b}$ $Y = \frac{c}{b}$

$$F_{1-2} = \frac{2}{\pi XY} \left\{ \ln \left[\frac{(1+X^2)(1+Y^2)}{1+X^2+Y^2} \right]^{1/2} + X\sqrt{1+Y^2} \tan^{-1} \frac{X}{\sqrt{1+Y^2}} \right. \\ \left. + Y\sqrt{1+X^2} \tan^{-1} \frac{Y}{\sqrt{1+X^2}} - X \tan^{-1} X - Y \tan^{-1} Y \right\}$$

$$F_{d1-2} = \frac{1}{2\pi} \left(\tan^{-1} \frac{1}{Y} - \frac{Y}{\sqrt{X^2+Y^2}} \tan^{-1} \frac{1}{\sqrt{X^2+Y^2}} \right)$$

Two infinitely long plates of unequal widths h and w , having one common edge and having an angle of 90° to each other

$H = \frac{h}{w}$
 $F_{1-2} = \frac{1}{2} \left(1 + H - \sqrt{1+H^2} \right)$

Two finite rectangles of same length, having one common edge and having an angle of 90° to each other

$H = \frac{h}{l}$ $H = \frac{w}{l}$

$$F_{1-2} = \frac{1}{\pi W} \left(W \tan^{-1} \frac{1}{W} + H \tan^{-1} \frac{1}{H} - \sqrt{H^2+W^2} \tan^{-1} \frac{1}{\sqrt{H^2+W^2}} \right. \\ \left. + \frac{1}{4} \ln \left[\frac{(1+W^2)(1+H^2)}{1-W^2+H^2} \left[\frac{W^2(1+W^2+H^2)}{(1+W^2)(W^2+H^2)} \right]^{W^2} \left[\frac{H^2(1+H^2+W^2)}{(1+H^2)(H^2+W^2)} \right]^{H^2} \right] \right)$$

Plane element dA_1 to right circular cylinder of finite length l and radius r ; normal to element passes through one end of cylinder and is perpendicular to cylinder axis

$L = \frac{l}{r}$ $H = \frac{h}{r}$

$X = (1+H)^2 + L^2$
 $Y = (1-H)^2 + L^2$

$$F_{d1-2} = \frac{1}{\pi H} \tan^{-1} \frac{1}{\sqrt{H^2-1}} + \frac{L}{\pi} \left[\frac{X-2H}{H\sqrt{XY}} \tan^{-1} \sqrt{\frac{X(H-1)}{Y(H+1)}} - \frac{1}{H} \tan^{-1} \sqrt{\frac{H-1}{H+1}} \right]$$

Figure D-7. View factor equations for various geometries.⁹

 high expansion foam system, 4-140–4-144, Fig. 4-5.8
 WASH-1400. *See* Reactor Safety Study (WASH-1400)
 Wastebasket fires, 2-271, 3-257, Fig. 3-10.14
 heat release rates, 3-28, Fig. 3-1.49–3-1.51, Table 3-1.14
 Water
 discharge coefficients, Table 4-2.7
 enthalpy of, Table 1-6.5
 flame suppression/extinguishment by, 3-148–3-154, Table 3-4.30, Table 3-4.31
 large-scale tests, 3-149, 3-153–3-154, Fig. 3-4.50
 small-scale tests, 3-149–3-153
 heat of formation, Table 1-5.4
 properties of, A-27
 vaporization rate, Fig. 3-4.20
 Water hammer, 4-65–4-67, 4-110, Fig. 4-2.19, Table 4-2.18
 Water mist fire suppression systems, 4-311–4-335
 application systems, 4-327–4-329
 local application (LA) systems, 4-328
 total compartment application (TCA) systems, 4-327–4-328
 zoned application (ZA) systems, 4-328–4-329
 design fundamentals, 4-313–4-320
 required extinguishing medium portion (REMP), 4-313–4-314, 4-317
 spray heat absorption ratio (SHAR), 4-313, 4-317
 engineering concepts, 4-327–4-335
 acceptance testing, 4-333–4-334, Fig. 4-14.9, Fig. 4-14.10
 application systems, 4-327–4-329
 method of spray generation, 4-329–4-330
 extinguishment/suppression mechanisms, 4-313–4-317, Figs. 4-14.1–4-14.3
 cycling, 4-315
 enclosure effects, 4-314–4-315
 explosion hazard mitigation, 4-315–4-316, Figs. 4-14.1–4-14.3
 flammable vapor dilution, 4-314
 gas phase cooling, 4-313–4-314, 4-320
 oxygen depletion, 4-314, 4-320, 4-321
 radiation attenuation, 4-314
 wetting/cooling fuel surface, 4-314, 4-320, 4-321
 modeling, 4-320–4-325
 CFD (field) models, 4-323–4-325
 quasi steady-state zone model, 4-321–4-322
 transient zone models, 4-322–4-323
 pressure regimes, 4-330–4-333
 high-pressure systems, 4-331–4-333, Figs. 4-14.7–4-14.8
 low-/intermediate-pressure systems, 4-330–4-331
 spray characteristics, 4-317–4-319
 additives and health concerns, 4-319–4-320
 discharge rate, 4-317
 drop size distribution, 4-317, 4-318–4-319, Figs. 4-14.4–4-14.5
 flashing of superheated water, 4-330
 spray cone angle, 4-317
 spray momentum, 4-317–4-318
 spray velocity, 4-317, 4-319, Fig. 4-14.6
 twin-fluid/single-fluid nozzles, 4-329–4-330
 system types, 4-327
 testing importance, 4-325–4-327
 fire test protocols, 4-325–4-327, Table 4-14.1
 water mist, defined, 4-311
 Water vapor
 absorption of thermal radiation by, 3-281–3-284
 heat of formation, Table 1-5.4
 specific heat, Table 1-5.2
 total emissivity, 1-79, Fig. 1-4.5
 Weber-Fechner's law, 2-45
 Weibull distribution, 1-189, 5-30–5-31, Fig. 5-3.9, Table 1-11.4
 Wet pipe sprinkler system, 4-72
 WFSC comparative data. *See* World Fire Statistics Center (WFSC), comparative data
 Wien's displacement law, 1-74
 Wildland fires. *See* Forests
 Wind
 characteristics, 1-20
 effect on flame height, 2-15
 effect on flame spread (*see* Liquid fuel fires, Surface flame spread)
 effect on smoke movement, 4-277, 4-285–4-286
 effect on vapor clouds, 3-303
 effect on venting, 3-220–3-221, 3-225–3-226, 3-236
 Wind flows, 1-20–1-25
 and buildings, 1-21–1-23, Fig. 1-1.28, Fig. 3-9.7
 external/internal effects, Fig. 1-29(a-c), Fig. 1-30
 induced internal flows, 1-22
 leakage ratio, 1-22
 gradient height, 1-21
 gradient wind speed, 1-21
 loading, 1-20–1-21
 stagnation point, 1-21, 1-22
 terrestrial boundary layer, 1-21, Fig. 1-1.27
 Windows
 heat fluxes from, 2-292–2-293, Figs. 2-14.48–2-14.50
 plastic, heat release rates, 3-32
 as vents, 2-32, 2-33
