$$F_{s(out)} = \frac{F_{s(in-1)}W_{e(in-1)} + F_{s(in-2)}W_{e(in-2)}}{W_{e(out)}} \quad (10b)$$

where the subscripts (in - 1) and (in - 2) indicate the values for the two incoming flows.

(c) For cases involving other merger geometries, the following general relationship applies:

$$[F_{s(in-1)}W_{e(in-1)}] + \dots + [F_{s(in-n)}W_{e(in-n)}] = [F_{s(out-1)}W_{e(out-1)}] + \dots + [F_{s(out-n)}W_{e(out-n)}] \quad (10c)$$

where the letter n in the subscripts (in - n) and (out - n) is a number equal to the total number of routes entering (in - n) or leaving (out - n) the transition point.

4. Where the calculated specific flow, F_s , for the route(s) leaving a transition point, as derived from the equations in rule 3, exceeds the maximum specific flow, F_{sm} , a queue will form at the incoming side of the transition point. The number of persons in the queue will grow at a rate equal to the calculated flow, F_c , in the arriving route minus the calculated flow leaving the route through the transition point.
5. Where the calculated outgoing specific flow, $F_{s(out)}$, is less than the maximum specific flow, F_{sm} , for that route(s), there is no way to predetermine how the incoming routes will merge. The routes may share access through the transition point equally, or there may be total dominance of one route over the other. For conservative calculations, assume that the route of interest is dominated by the other route(s). If all routes are of

concern, it is necessary to conduct a series of calculations to establish the bounds on each route under each condition of dominance.

Impact of Smoke Conditions on Ability to Evacuate

Evacuation Speed in a Smoke-Laden Environment

The emergency movement speeds reported in most sources were derived from experiments and observations conducted in smoke-free environments. While most emergency egress of populations do occur in environments that are smoke free or nearly so, some emergency evacuations involve movement through smoke conditions. Both the density and optic-irritating properties of the smoke can impact movement speed. Jin¹¹ reports the results and analysis of several series of investigations he conducted, involving human subjects moving through a smoke-laden environment. Jin used two types of smoke, a highly irritating smoke produced by burning wood cribs with narrow spacing between the sticks and a less irritating smoke produced by burning kerosene. The graph in Figure 3-14.6 is typical of the results observed. With the less irritating smoke movement speed decreased gradually as the extinction coefficient increased. With the highly irritating smoke, the evacuation movement speed dropped precipitously once the extinction coefficient reached 0.4/m. Where evacuation through smoke is involved, the movement speed of evacuation should be no greater than that appropriate for the expected density and irritation properties of the smoke. Pending further research the adjustment should be made using the values plotted in Figure 3-14.6.

Probability of Movement through Smoke-Obscured Environment

Table 3-14.6 summarizes data compiled in the United Kingdom¹² and in the United States¹³ relating to the visibility distance of smoke and the percentage of building occupants who moved through smoke having the corresponding density. Roughly 40 to 50 percent of occupants

Figure 3-14.6. Walking speed in fire smoke.

Table 3-14.6 *Compilation of Visibility Distance for Populations Moving through Smoke*

Visibility Distance		U.K. Sample Population (%)	U.S. Sample Population (%)
(ft)	(m)		
0-2	0-0.6	12.0	10.2
3-6	0.9-1.8	25.0	17.2
7-12	2.1-3.6	27.0	20.2
13-30	4.0-9.1	11.0	31.7
31-36	9.4-11.0	3.0	2.2
37-45	11.3-13.7	3.0	3.7
46-60	14.0-18.3	3.0	7.4
>60	>18.3	17.0	7.4

moved through smoke at visibility distances of less than 12 ft (3.7 m), while 7 to 17 percent of occupants required visibility distances of greater than 60 ft (18.3 m). This range seems to be the demarcation between those occupants willing to move through smoke to an exit (the majority) and those who are reluctant to travel through smoke (the minority). It should be noted that the data in Table 3-14.6 are subjective and are indicative of visibility to both normal objects and backlit exit signs, as the building occupants interviewed were viewing both types of objects while trying to egress.

Users of the data in Table 3-14.6 need to realize that the data in both of the referenced studies was derived, for the most part, from fires in residential properties housing occupants familiar with the means of egress. Also, in the majority of the cases, travel distance through the smoke was 30 ft or less. Additionally, due to the age of the studies (1972 and 1979) these data should be verified with any available more current data.

EXAMPLE:

Consider an office building (Figure 3-14.7) with the following features:

1. There are nine floors, 300 by 80 ft (91 by 24 m).
2. Floor to floor height is 12 ft (3.7 m).
3. Two stairways are located at the ends of the building (no dead ends).

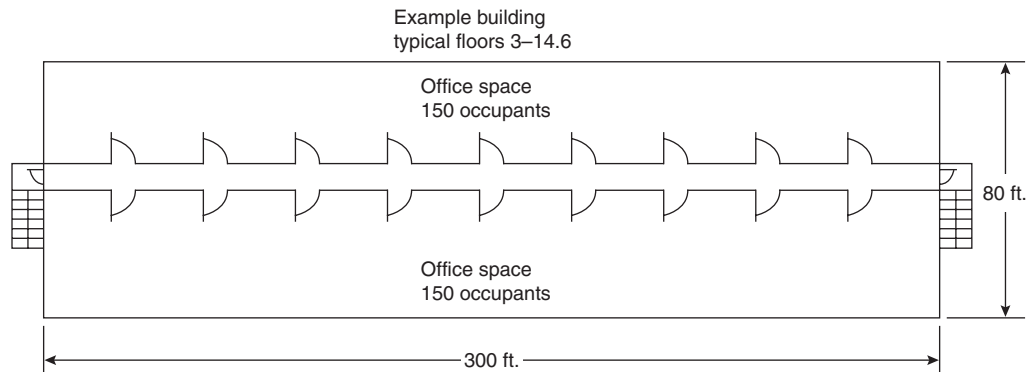

Figure 3-14.7. *Floor plan for example.*

4. Each stair is 44 in. (1.12 m) wide (tread width) with handrails protruding 2.5 in. (63 mm).
5. Stair risers are 7 in. (178 mm) wide and treads are 11 in. (279 mm) high.
6. There are two 4-ft by 8-ft (1.2-m by 2.4-m) landings per floor of stairway travel.
7. There is one, 36-in. (0.91 m) clear width, door at each stairway entrance and exit.
8. The first floor does not exit through stairways.
9. Each floor has a single 8-ft- (2.4-m-) wide corridor extending the full length of each floor. Corridors terminate at stairway entrance doors.
10. There is a population of 300 persons/floor.

SOLUTION A—First Order Approximation:

1. Assumptions.

The prime controlling factor will be either the stairways or the door discharging from them. Queuing will occur; therefore the specific flow, F_s , will be the maximum specific flow, F_{sm} . All occupants start egress at the same time. The population will use all facilities in the optimum balance.

2. Estimate flow capability of a stairway.

From Table 3-14.1, the effective width, W_e , of each stairway is $44 - 12 = 32$ in. (2.66 ft) [813 mm (0.81 m)]. Also, the effective width, W_e , of each door is $36 - 12 = 24$ in. (2 ft) [609 mm (0.61 m)]. The maximum specific flow, F_{sm} , for the stairway (from Table 3-14.5) is 18.5 persons/min/ft (60 persons/min/m) effective width. Specific flow, F_s , equals maximum specific flow, F_{sm} . Therefore, using Equation 6, the flow from each stairway is limited to $18.5 \times 2.66 = 49.2$ persons/min.

3. Estimate flow capacity through a door.

Again from Table 3-14.5, the maximum specific flow through any 36-in. (0.9-m) door is 24 persons/min/ft (78.7 persons/min/m) effective width. Therefore, using Equation 6, the flow through any door is limited to $24 \times 2 = 48$ persons/min. Since the flow capacity of the doors is less than the flow capacity of the stairway served, the flow is controlled by the stairway exit doors (48 persons/stairway exit door/min).

4. Estimate the speed of movement for estimated stairway flow.

From Equation 3 the speed of movement down the stairs is $212 - (2.86 \times 212 \times 0.175) = 105$ ft/min (32 m/min). The travel distance between floors (using the conversion factor from Table 3-14.3) is $12 \times 1.85 = 22.2$ ft (6.8 m) on the stair slope plus 8 ft (2.4 m) travel on each of the two landings, for a total floor-to-floor travel distance of $22.2 + (2 \times 8) = 38.2$ ft (11.6 m). The travel time for a person moving with the flow is $38.2/105 = 0.36$ min/floor.

5. Estimate building evacuation time.

If all of the occupants in the building start evacuation at the same time, each stairway can discharge 48 persons/min. The population of 2400 persons above the first floor will require approximately 25 min to pass through the exit. An additional 0.36 min travel time is required for the movement from the second floor to the exit. The total minimum evacuation time for the 2400 persons located on floors 2 through 9 is estimated at 25.4 min.

SOLUTION B—More Detailed Analysis:

1. Assumptions.

The population will use all exit facilities in the optimum balance; all occupants start egress at the same time.

2. Estimate flow density (D), speed (S), specific flow (F_s), effective width (W_e), and initial calculated flow (F_c) typical for each floor.

Divide each floor in half to produce two exit calculation zones, each 150 ft (45.7 m) long. Determine the density, D , and speed, S , if all occupants try to move through the corridor at the same time, that is, 150 persons moving through 150 ft of an 8-ft- (2.4-m-) wide corridor:

$$D = 150 \text{ persons}/1200 \text{ ft}^2 \text{ corridor area} = 0.125 \text{ persons}/\text{ft}^2.$$

$$\text{From Equation 3, } S = k - akD.$$

$$\text{From Table 3-14.2, } k = 275.$$

$$S = 275 - (2.86 \times 275 \times 0.125) = 177 \text{ ft}/\text{min} (54 \text{ m}/\text{min}).$$

$$\text{From Equation 5, } F_s = (1 - aD)kD.$$

$$F_s = [1 - (2.86 \times 0.125)] \times 275 \times 0.125 = 22 \text{ persons}/\text{ft} (72 \text{ persons}/\text{m}) \text{ effective width}/\text{min}.$$

From Table 3-14.5, F_{sm} is less than the maximum specific flow, F_{sm} ; therefore, F_s is used for the calculation of calculated flow.

From Table 3-14.1, the effective width of the corridor is $8 - (2 \times 0.5) = 7$ ft (2.13 m)

$$\text{From Equation 7, calculated flow, } F_c = (1 - aD)kDW_e.$$

$$F_c = [1 - (2.86 \times 0.125)] \times 275 \times 0.125 \times 7 = 154 \text{ persons}/\text{min}.$$

Note: At this stage in the calculation, calculated flow, F_c , is termed initial calculated flow for the exit route element (i.e., corridors) being evaluated. This term is used because the calculated flow rate can be sustained only if the discharge (transition point) from the route can also accommodate the indicated flow rate.

3. Estimate impact of stairway entry doors on exit flow.

Each door has a 36-in. (0.91 m) clear width. From Table 3-14.1, effective width, W_e , is $36 - 12 = 24$ in. (2 ft) (0.605 m).

From Table 3-14.5, the maximum specific flow, F_{sm} is 24 persons/min/ft effective width.

From Equation 10,

$$\begin{aligned} F_{s(\text{door})} &= [F_{s(\text{corridor})}W_{e(\text{corridor})}]/W_{e(\text{door})}F_{s(\text{door})} \\ &= (22 \times 7)/2 = 77 \text{ persons}/\text{min}/\text{ft} \\ &\quad (25.3 \text{ persons}/\text{min}/\text{m}) \text{ effective width} \end{aligned}$$

Since F_{sm} is less than the calculated F_s , the value of F_{sm} is used. Therefore, the effective value for specific flow is 24.

From Equation 6 the initial calculated flow, $F_c = F_sW_e = 24 \times 2 = 48$ persons/min through a 36-in. (0.91-m) door. Since F_c for the corridor is 154 while F_c for the single exit door is 48, queuing is expected. The calculated rate of queue buildup will be $154 - 48 = 106$ persons/min.

4. Estimate impact of stairway on exit flow.

From Table 3-14.1, effective width, W_e , of the stairway is $44 - 12 = 32$ in. (2.66 ft) (0.81 m).

From Table 3-14.5, the maximum specific flow, F_{sm} is 18.5 persons/ft (60 persons/m) effective width.

From Equation 10, the specific flow for the stairway, $F_{s(\text{stairway})}$, is $24 \times 2/2.66 = 18.0$ persons/ft (59 persons/m) effective width. In this case, F_s is less than F_{sm} and F_s is used.

The value of 18.0 for F_s applies until the flow down the stairway merges with the flow entering from another floor.

Using Figure 3-14.4 or Equation 5 and Table 3-14.2, the density of the initial stairway flow is approximately 0.146 persons/ft² (1.6 person/m²) of stairway exit route.

From Equation 3 the speed of movement during the initial stairway travel is $212 \times (2.86 \times 212 \times 0.146) = 123$ ft/min (37.5 m/min).

From Solution A, the floor-to-floor travel distance is 38.2 ft (11.6 m). The time required for the flow to travel one floor level is $38.2/123 = 0.31$ min (19 s).

Using Equation 6, the calculated flow, F_c , is $18.0 \times 2.66 = 48$ persons/min.

After 0.31 min, 15 (48×0.31) persons will be in the stairway from each floor feeding to it. If floors 2 through 9 exit all at once, there will be $15 \times 8 = 120$ persons in the stairway. After this time the merging of flows between the flow in the stairway and the incoming flows at stairway entrances will control the rate of movement.

5. Estimate impact of merger of stairway flow and stairway entry flow on exit flow.

From Equation 10,

$$\begin{aligned} F_{s(\text{out-stairway})} &= \{[F_{s(\text{door})} \times W_{e(\text{door})}] + \\ &\quad [F_{s(\text{in-stairway})} \times W_{e(\text{in-stairway})}]\}/W_{e(\text{out-stairway})} \\ &= [(24 \times 2) + (18 \times 2.66)]/2.66 \\ &= 36 \text{ persons}/\text{ft effective width} \end{aligned}$$

From Table 3-14.5, F_{sm} for the stairway is 18.5 persons/min/ft effective width. Since F_{sm} is less than the calculated F_s , the value of F_{sm} is used.

6. Track egress flow.

Assume all persons start to evacuate at time zero. Initial flow speed is 177 ft/min. Assume that congested flow

will reach the stairway in 30 s. At 30 s, flow starts through stairway doors. F_c through doors is 48 persons/min for the next 19 s. At 49 s, 120 persons are in each stairway and 135 are waiting in a queue at each stairway entrance door.

Note: Progress from this point on depends on which floors take dominance in entering the stairways. Any sequence of entry may occur. To set a boundary, this example estimates the result of a situation where dominance proceeds from the highest to the lowest floor.

The remaining 135 persons waiting at each stairway entrance on the ninth floor enter through the door at the rate of 48 persons/min. The rate of flow through the stairway is regulated by the 48 persons/min rate of flow of the discharge exit doors. The descent rate of the flow is 19 s/floor.

Thus:

at 218 s (3.6 min)	all persons have evacuated the 9th floor
at 237 s (4.0 min)	the end of the flow reaches the 8th floor
at 401 s (6.7 min)	all persons have evacuated the 8th floor
at 420 s (7.0 min)	the end of the flow reaches the 7th floor
at 584 s (9.7 min)	all persons have evacuated the 7th floor
at 603 s (10.1 min)	the end of the flow reaches the 6th floor
at 767 s (12.8 min)	all persons have evacuated the 6th floor
at 786 s (13.1 min)	the end of the flow reaches the 5th floor
at 950 s (15.8 min)	all persons have evacuated the 5th floor
at 969 s (16.2 min)	the end of the flow reaches the 4th floor
at 1133 s (18.9 min)	all persons have evacuated the 4th floor
at 1152 s (19.2 min)	the end of the flow reaches the 3rd floor
at 1316 s (21.9 min)	all persons have evacuated the 3rd floor
at 1335 s (22.3 min)	the end of the flow reaches the 2nd floor
at 1499 s (25.0 min)	all persons have evacuated the 2nd floor
at 1518 s (25.3 min)	all persons have evacuated the building

Evacuation Efficiency Factors

Decisions

Humans require time to make decisions. In general, people are hesitant to undertake overt actions unless they clearly accept the need for such action.

In group situations, group interaction is extremely important to decision making. Latane and Darley¹⁴ pointed out the tendency of many individuals to defer emergency decision making until action is clearly required. More recently MacLennan⁹ in his experiments in Australia has classified and is now quantifying this as a

factor he and Sime call "associative." MacLennan has noted that persons in groups often delay response to a warning alarm until it is clear that the group accepts the need to take emergency action. Prior training, organization, and real-time fire information can reduce the delay in the time to take emergency action.

Levin,¹⁵ in analyzing data from many sources related to emergency action in residences, has proposed the division of speed of response into four categories. These categories, which Levin terms ambiguity classes, are based on the initial interpretation of the cues by the individual involved. Levin's classes are

- A. Respondent believes that there may be a fire (but is not certain).
- B. Respondent believes that it is likely there is a fire.
- C. Respondent is sure there is a fire and has seen sufficient smoke to believe that it is a dangerous fire.
- D. Respondent has seen flames.

With one major exception, the universal response to ambiguity Class A is to seek information. In the sample studied by Levin, the exception to the general rule occurred with those responsible for persons incapable of taking care of themselves (small children, invalids). These individuals immediately took action to evacuate or otherwise safeguard their charges.

Conversely, in an ambiguity Class D situation emergency action was always taken.

In ambiguity Classes B and C some persons continued to seek information while others undertook other types of emergency action. These actions included attacking the fire, calling the fire department, giving the alarm, and evacuating the building. For the limited number of cases that Levin classified in ambiguity Classes B and C (20 in Class B, and 19 in Class C), the portion of the persons who sought information rather than take emergency action was approximately 50 percent in ambiguity Class B and 35 percent in Class C.

Investigation Time

As noted in the preceding paragraphs, individuals often seek information to clarify the ambiguities inherent in fire situations. This reaction is particularly the case for persons alone or in small groups. Sime⁸ has tracked individuals involved in hotel fires, and his data demonstrate significant amounts of apparently nonproductive movement. This movement is assumed to be prompted by individuals seeking information they feel is necessary to make a proper decision. From an engineering standpoint, this response emphasizes the potential of increasing evacuation efficiency by providing clear information to the occupants of a building about the occurrence and location of the fire, and the condition of the exit routes.

Other Actions

When an individual has decided to take action in response to perceived fire danger, that action may or may not contribute to a speedy evacuation. Figure 3-14.8 diagrammatically shows a variety of the types of actions that are likely to occur. In actual fire situations many individuals undertake actions they believe will mitigate the

Figure 3-14.8. *Types of actions.*

fire, help others, or aid in making decisions. Often these actions do not contribute to their evacuation; these alternative actions may be contributing to safety, detrimental to safety, laudable, or mistaken. All actions, however, impact on evacuation efficiency.

Providing real-time information to building occupants and ensuing rapid response of emergency forces can mitigate delays with a minimum of impact on the desirable effects of nonevacuation actions.

Way Finding

Way finding is most important in situations involving a relatively small number of individuals evacuating a location where they are not familiar with the emergency exit system. This situation typically occurs in hotels, multitenant office buildings, and similar structures where persons seldom use the stairways.

The classic solution to the problem of way finding is the provision of exit signs and exit directional signs. Ozel¹⁶ has summarized the current view of researchers in way-finding problems and related these findings to fire evacuation conditions. A person's ability to find his or her way in an emergency relates to how well that person perceives his or her position and surroundings. The term frequently used is *cognitive mapping*. Most people maintain their cognitive mapping images in simple, regularized forms, such as straight lines and rectangles. In this concept, exit signs are only part of the overall ability of a person to perceive a suitable cognitive map.

Other factors that are rated of high importance to way finding include (1) the complexity of the space as related to common layouts or similar types of buildings (e.g., double-loaded corridors terminating at exits are simple while arrangements involving complex curves or unusual angles are complex); and (2) the presence of distinguishing marks or other indications of points of special attention. Of particular importance are both exit routes

and dead ends or other spaces that should not be entered in exiting the building.

Way finding affects evacuation efficiency in facilities where the population density is low and the occupants are unfamiliar with the evacuation routes. In such facilities the efficiency is greatest when (1) the routes are simple, and (2) the exit points are evident in both their location and assurance (to the evacuee) that they truly lead to safety.

Way-finding efficiency decreases as the layout complexity increases. Some factors increasing complexity are unusual arrangements of corridors, obtuse angles, concentric corridors, undifferentiated enclosures (where one cannot orient oneself with respect to the exterior), and exit access doors that appear the same as every other door.

Conversely, all aspects that tend to simplify and identify the exit route decrease the time involved in way finding.

Merging Conflicts

Modeled evacuation time calculations assume that the flow of people is similar to that of a hydraulic fluid. As such, the merger of two flows (persons entering at a floor into a stairwell that is already flowing with evacuees from higher floors) is assumed to regulate itself according to the capabilities of the stairwell and the amount of flow from each of the sources.

In emergency evacuation drills MacLennan⁹ has observed significant interruption of the continuity of flow when one flow is stopped and another is started at a merger point. The greatest merging flow efficiency occurs when, once a flow uses an exit route to its full capacity, it blocks all other entry until it has cleared past the point of merger. In actual evacuations, however, there is normally a sharing of access at merger points. This situation results in breaks in the egress flow that can have a significant affect on the capacity. MacLennan has seen effects as high as

30 to 50 percent reduction in the stairwell flow from this cause alone.

Wardens

MacLennan's work indicates that the most efficient flow occurs in a situation where all occupants are fully trained and promptly evacuated upon signal without the assistance of wardens.

Where occupants are not so trained it is often necessary to have a trained warden system. While this system is essential, MacLennan's observations indicate that wardens impose a reduction in egress efficiency. The amount of reduction will depend upon the type of organization and the evacuation procedures. The impact on evacuation efficiency is the greatest when wardens hold occupants in a ready position until the wardens are directed from another point to initiate evacuation.

Self-Regulation

In high-density situations (e.g., heavily populated offices, auditoriums, etc.) individuals often withhold themselves from the evacuation procedure until the crowd lessens (i.e., density is reduced). When these persons arrive at critical exit points so that the main crowded path, normally the stairway, is continuously fed by a short queue, their action will have no impact. However, when the self-induced delay reduces the feed of the critical point, a reduction in egress efficiency will occur.

Uneven Use of Exit Facilities

If some exit facilities are used proportionally more than others, the efficiency of the egress system will decrease. Some exit paths will be utilized while others will be overtaxed.

The impact of uneven exit use can be estimated as a function of (1) the distribution of exits relative to the distribution of population, (2) the degree that the exits will be used for either building entry or for common use within the structure, and (3) all of the cognitive mapping factors discussed under "Way Finding."

Evacuation Efficiency Factors—Summary

In his analysis, MacLennan found that large multi-floor office buildings (some high-rise) demonstrated evacuation times in the range of twice the modeled time where a highly organized evacuation system was present; and up to three times the modeled evacuation time when there had been no training and no organization.

It is expected that MacLennan's findings represent reasonable norms but are subject to many variations (e.g., education level, cultural background, age, and gender) that need to be considered in any individual evaluation.

Emergency Movement Models

A number of models have been developed to calculate building emergency movement times. Gwynne and

Galea¹⁷ identified 22 different such models in a review based on available published literature. This includes 16 models that were available at the time of the review and 6 models known to be under development. The 16 available models are as follows:

BGRAF¹⁸
 CRISPII¹⁹
 DONEGAN'S ENTROPY MODEL²⁰
 EGRESS²¹
 E-SCAPE²²
 EVACNET+²³
 EVACSIM²⁴
 EXIT89²⁵
 EXITT²⁶
 EXODUS^{27,28}
 MAGNETMODEL²⁹
 PAXPORT³⁰
 SIMULEX^{31,32}
 TAKAHASHI'S MODEL³³
 VEGAS^{34,35}
 WAYOUT³⁶

Gwynne and Galea¹⁷ critically appraised these evacuation models on the basis of four characteristics.

Nature of the Model Application

Three fundamentally different approaches are used in different evacuation models. These include optimization, simulation, and risk assessment. The optimization models generally assume that occupants evacuate a building in the most efficient manner. The evacuation paths and the flow characteristics of people and exits are considered optimal. The population is considered to be a homogeneous ensemble without individual behavior.

The simulation models attempt to represent the behaviors and movements observed in evacuations to realistically represent the actual paths and decisions taken during an evacuation. The behavioral sophistication employed by these models varies greatly, and consequently so does the accuracy of the results.

Risk assessment models attempt to identify fire hazards associated with evacuation. Repeated runs of the model are made to assess statistically significant variations associated with different design changes, including different fire protection measures.

The Enclosure Representation

The enclosure from which the evacuation takes place must be represented in all evacuation models. Two methods are usually used to represent the enclosure: fine networks and course networks. In each case, the enclosure is subdivided. The resolution of the subdivision distinguishes the fine network from the course network. In the course network models, the geometry is defined in terms of partitions based on the actual structure. Typically, each node represents a room or a corridor. Nodes are connected by arcs representing actual connections within the structure.

In the fine network approaches, the entire floor space of the enclosure is covered by a fairly uniform network of tiles or nodes. Nodes are connected with neighboring nodes, with the number of connections depending on the model. In a fine network, a large space may have thousands of nodes; in this way, the geometry of a space, including internal obstructions, can be accurately represented along with the location of each individual during an evacuation.

The Population Perspective

The population in an enclosure can be represented in one of two perspectives: a global or an individual perspective. Models that use the global perspective treat the population as an homogeneous ensemble without individual characteristics. These models represent evacuation on the basis of the number of occupants who escaped, not on the basis of individuals. With the global perspective, only a distributed or average attribute can be assigned to the population.

Models that use the individual perspective allow for personal attributes to be assigned to individual occupants, either by the user of the model or through a random process, in order to represent a diverse population. These personal attributes are then used in the decision-making and movement process of each individual. This process is typically independent of other individuals, although it does not, preclude group interaction and behavior.

The Behavioral Perspective

To consider the decision-making processes of occupants during an evacuation, a model must have a method of determining behavior. This method will be influenced by the representations used for the population and the enclosure and the broad range of potential behaviors of individuals. Some models do not apply any behavioral rules. These models rely completely on the physical movement of the population and the physical representation of the building according to deterministic equations. For models that do consider behavior, the perspective used can be classified into four categories: implicit, rule-based, functional analogy-based, and artificial intelligence-based. Implicit models do not declare behavioral rules, but rather assume the rules to be implicitly represented through methods and data incorporating psychological and sociological influences.

Rule-based models explicitly recognize the behavioral traits of individual occupants and apply a system that allows occupants to make decisions according to a defined set of rules. In the simpler rule-based methods, the same decisions are triggered by the same stimuli in a deterministic way. Other rule-based methods use either a stochastic approach to apply the rules or a combination of deterministic and stochastic approaches.

Functional analogy-based models apply an equation, or a system of equations, to the entire population, based on a field of study believed to be analogous to some aspect of human behavior. In artificial intelligence-based models, artificial intelligence has been applied to mimic human behavior based on various stimuli.

The behavior of people under fire conditions is influenced by their interactions with other people, with the enclosure and with the fire-induced environment. The decision making of people under fire conditions is influenced and complicated by a number of psychological, sociological, and physiological factors. Because of the behavioral and decision-making factors, some of which are not yet well understood, human behavior is the most complex and difficult aspect of evacuation to simulate.

In addition to the models reviewed by Gwynne and Galea¹⁷ is the model EGRESS TIME, contained in the collection of models and procedures FPETOOL.³⁷ In terms of the characteristics used by Gwynne and Galea,¹⁷ this model would be judged as an optimization model, having a course network, and limited attention to individual population perspectives.

Model Selection Factors

It is beyond the scope of this chapter to review the features, capabilities, uses, limitations, validation, availability, and costs of the evacuation models identified above. Instead, some of the factors that should be considered in the selection of a model for a particular application are presented, based on the foregoing discussion. These factors are presented in the form of a series of questions on a number of topics that a potential user should ask about an evacuation model before deciding to use it for a particular application. These questions are listed by topic.

Evacuation Model Type

- Is the model based on optimization, simulation, or risk assessment?
- Is the type of model suitable for the application?
- What are the limitations of the model with respect to the application?

Enclosure Representation

- Is the model based on a fine network or a course network?
- How are different spaces and areas within spaces represented?
- How are connections between spaces represented?
- How are obstructions within a space represented?
- How do these representations influence the model results?
- How many nodes, connections, and obstructions can the model handle?
- How are the data entered to represent spaces, connections, and obstructions?

Population Perspective

- Does the model use a global or an individual perspective?
- If the perspective is global, what general characteristics of the population are represented?
- If the perspective is individual, what individual characteristics of the population are represented?
- How are the individual or global characteristics of the population entered in the model?

Behavioral Perspective

- What type of behavioral perspective does the model employ—none, implicit, rule-based, functional analogy-based, or artificial intelligence-based?
- How does the model treat people-people interactions and their effects on behavior?
- How does the model treat people-enclosure interactions and their effects on behavior?
- How does the model treat people-environment interactions and their effects on behavior?
- How does the model address physiological factors that influence decision making?
- How does the model address psychological factors that influence decision making?
- How does the model address sociological factors that influence decision making?

Model Validation

- Has the model been validated? If so, how and to what extent?
- How has the model validation been reported?

Model Implementation

- Has the model been implemented on a computer?
- What computer platforms does the model support?

Model Support

- Is the model currently supported by the author(s)?
- Is the model supported by another agency?
- Is the model still being developed? If so, how are users notified of upgrades?

Model Costs

- What is the initial cost of the model?
- What are the ongoing costs for upgrades, support, and maintenances

Appropriateness to Task

- What inputs does the model require of the user? Are these available?
- Does the model consider elements needed for the task at hand, for example,
 speed of movement, impact of density on speed?
 queuing or other congestion?
 merging of flows?
 premovement decisions?
 decisions/actions during movement?
- Does the model produce an output meeting the needs of the task at hand?

Nomenclature

- D* density in persons per unit area
- e* apparent evacuation efficiency

- F* flow
- k* constant from Table 3-14.2
- P* population
- S* speed along the line of travel
- t* time
- W* width

Subscripts

- 1 speed in ft/min and density in persons/ft²
- 2 speed in m/s and density in persons/m²
- ae* actual evacuation
- c* calculated
- (corridor) corridor
- (door) door
- d* delay
- e* effective
- (in - *n*) prior to point *n*
- me* modeled evacuation
- (out - *n*) after point *n*
- p* passage
- s* specific
- sm* maximum specific
- (stairway) stairway

CHAPTER 15**Stochastic Models
of Fire Growth**

G. Ramachandran

Introduction

Apart from changes in environmental conditions, such as wind velocity and direction, humidity, and temperature, the spread of fire in a building is governed by physical and chemical processes evolved from a variety of burning materials arranged in different ways. Multiple interactions among these processes at different times during fire growth cause uncertainties in the pattern of fire development. Although different patterns of fire development can be simulated by varying the input values to the parameters of a deterministic model, there is a need to determine the uncertainty (probability) with which each pattern is likely to occur in a real fire in any type of building considered. The likely pattern of fire spread can only be predicted within limits of confidence expressed in probabilistic terms.

Nondeterministic models¹ (or indeterministic models as defined by Kanury²), rather than deterministic techniques, offer rational methods of evaluating the uncertainties in the pattern of fire growth and are of two types: (1) probabilistic and (2) stochastic. The first type generally deals with a final outcome, such as area damaged, financial loss, or fire severity, and is considered as a continuous random variable reaching various levels in a fire according to a probability distribution.³ Large values of the variable follow an extreme value distribution. (See Section 5, Chapter 8.) A semi-probabilistic approach is provided by a fault tree⁴ in which the probability of occurrence of a top event (e.g., fire spreading beyond the room of origin) is estimated by assigning discrete (not continuous) probabilities

to sub-events leading to the top event. Models of the first type (i.e., probability distributions and fault trees) do not consider in detail the underlying physical processes and their variation over the duration (time) of fire growth. Such "static" models can provide sufficient tools for fire protection and insurance problems concerned with "collective risk" in a group of buildings.

Stochastic models constitute the subject matter of this chapter, and may be regarded as "dynamic," since they are capable of predicting the course of fire development in a particular building. In these models, the various states, realms, or phases occurring sequentially in space and time during fire growth are specified together with the associated probability distributions. Depending on the nature of these distributions, a fire stays in each state for a random length of time and moves randomly from state to state. The sojourn and transition probabilities may be regarded as "noise" terms superimposed over a deterministic pattern of fire growth.

After describing the basic features of stochastic modeling of fire spread, two types of stochastic models are discussed in detail: (1) Markov chains and (2) networks. Attention is also drawn to the application of other stochastic models, such as random walk, diffusion processes, percolation theory, epidemic models, and branching processes. The next-to-last section in this chapter discusses briefly a new type of stochastic model based on the "stochastic differential equation" which is currently being developed in Australia.

The models discussed in this chapter mainly relate to the growth of fire and not to the spread of smoke or other combustion products.

Basic Features**Probability Distributions**

Consider the burning of a particular object in a room as a random (stochastic) process, with $Q(t)$ denoting the

Dr. G. Ramachandran retired in November 1988 as head of the Operations Research Section at the Fire Research Station, United Kingdom. Since then he has been practicing as a consultant in risk evaluation and insurance. He is a visiting professor at the Universities of Manchester, and Leeds. His research has focused on statistical and economic problems in fire protection and actuarial techniques in fire insurance. In October 1998 he published a book on the economics of fire protection.

probability that the object is still burning at time t . In a simple model the process may be assumed to be Poisson,⁵ so that $Q(t)$ has the exponential form

$$Q(t) = \exp(-\mu t) \tag{1}$$

In this model the probability of extinction of fire during the short period $(t, t + \partial t)$ denoted by $\mu(t)$ has been assumed to have the constant value μ independent of t . The function $Q(t)$ can also be interpreted as the probability that the duration of burning of the object considered is greater than t . Then, the (cumulative) probability distribution function

$$F(t) = 1 - Q(t) \tag{2}$$

is the probability that the duration of burning is less than or equal to t . The parameter μ is the "instantaneous probability" of extinction of fire, whereas $\lambda (= 1 - \mu)$ is the "instantaneous probability" of fire surviving.

The value of μ will vary depending on whether it is a free-burning fire or a fire extinguished by fire fighting (e.g., by fire brigade or sprinklers). The value of μ for any object burning under specified conditions can be estimated by carrying out replicated extinction experiments with the object. If \bar{t} is the mean (average) duration of burning of the object

$$\mu = 1/\bar{t} \tag{3}$$

according to the properties of an exponential probability distribution. This distribution was implied in Kida's probabilistic analysis of extinction experiments.⁶

Spread to Another Object

In a simple model, as discussed earlier, it can be assumed that a fire involving one object spreads to another object if it survives (i.e., not extinguished) with the probability λ .

$$\lambda + \mu = 1 \tag{4}$$

The model can be expanded to include an (instantaneous) probability w to denote the event of fire not spreading, even though it is not extinguished, that is, the fire continues to burn without spreading. In this case⁵

$$\lambda + \mu + w = 1 \tag{5}$$

and, following the derivation of Equation 1,

$$Q_1(t) = \exp[-(\lambda + \mu)t] = \exp(-t + wt) \tag{6}$$

where $Q_1(t)$ is the probability that the fire is burning at time t without spreading. The duration of burning in this case follows an exponential probability distribution with mean duration given by the reciprocal of $(\lambda + \mu)$ or of $(1 - w)$.

The length of time a fire involving an object burns affects future fire spread to another object: heat output (fire severity) increases with time. Equation 5 can, therefore, be modified such that, during a short time interval immediately after time t ,

$$\lambda(t) + \mu(t) + w(t) = 1 \tag{7}$$

The instantaneous probabilities $\lambda(t)$, $\mu(t)$, and $w(t)$ are functions of the continuous random variable t . However, in practical problems, one can consider t in minutes and one minute as a short time interval such that the probabilities are denoted by $\lambda(i)$, $\mu(i)$, and $w(i)$ with $i = 1, 2, 3, \dots$. The probability $w(i)$ applies to a single minute and, hence, it is likely to be small. One can, therefore, write

$$Q_1^1(t + 1) = w(1) \cdot w(2) \cdot \dots \cdot w(t) \tag{8}$$

to denote the probability of fire burning during the time period $(t + 1)$ without spreading. Equation 8 follows from Equation 6. If $w(i)$ is a constant w as in Equation 6, it may be seen that

$$Q_1^1(t) = w^t \tag{9}$$

General Model

The probability distribution for duration of burning can have other forms, such as uniform and log-normal, although an exponential distribution has been postulated for the sake of simplicity. Following Ramachandran⁵ and Aoki,⁷ the following probabilities can be defined in the general case for the fire involving the object ignited first:

- $q_1(t + 1)$ = probability of burning at the beginning of the $(t + 1)$ th period or end of the t th period without spreading before that period
- $P_1(t + 1)$ = cumulative probability of becoming extinguished before the end of the $(t + 1)$ th period
- $S_1(t + 1)$ = cumulative probability of spreading before the end of the $(t + 1)$ th period

With subscript 1 denoting the object ignited first, the following equations are easily derived:

$$q_1(t + 1) = q_1(t) \cdot w_1(t) = \prod_{r=1}^t w_1(r)$$

as in Equation 8, since $q_1(1) = 1$.

$$P_1(t + 1) = \sum_{r=1}^{t+1} q_1(r) \cdot \mu_1(r)$$

$$S_1(t + 1) = \sum_{r=1}^{t+1} q_1(r) \cdot \lambda_1(r)$$

The parameters $\lambda_1(r)$, $\mu_1(r)$, and $w_1(r)$ are probabilities of spreading, becoming extinguished, and burning without spreading during the r th period.

The following equations with similar definitions can be derived for the second object to which fire can spread from the object first ignited. (The subscript 2 has been used for the second object.)

$$q_2(t + 1) = q_2(t) \cdot w_2(t) + q_1(t) \cdot \lambda_1(t), q_2(1) = 0$$

$$P_2(t + 1) = \sum_{r=2}^{t+1} q_2(r) \cdot \mu_2(r)$$

$$S_2(t + 1) = \sum_{r=2}^{t+1} q_2(r) \cdot \lambda_2(r)$$

The probabilities $q_2(t + 1)$, $P_2(t + 1)$, $S_2(t + 1)$ and their associated parameters $w_2(t)$, $\lambda_2(t)$, and $\mu_2(t)$ pertain to the second object and are "conditional," given that the fire has spread to the second object.

In the first of the equations mentioned above it has been assumed that the second object starts burning in the second minute after the ignition of the first object in the first minute. The probability of this event is likely to be low such that $q_2(2)$ has a small value. The time of occurrence of sustained or established burning of the second object depends upon the incubation or latent period beyond which the fire involving the first object becomes capable of spreading to the second object.⁸ This time and the spread probability $\lambda_1(r)$ also depend upon the distance between the two objects.⁸ Radiation of heat to an object generally decreases in inverse proportion to the square of the distance of the object from the burning object. Fire spread may not occur if the unignited object is located beyond a "critical distance" from the burning object.⁹

As r varies, $q_1(r)$ gives rise to a discrete or continuous probability distribution for the object first ignited. This distribution can be ascertained by carrying out experiments with the two objects considered by varying the distance between them. In the continuous case, if the instantaneous probabilities are assumed as constants, the average duration of burning of the first object before spreading to the second object is an estimate of $(1/1 - w_1)$, assuming an exponential distribution. Applying this result to the discrete case with constant probabilities, for any specified distance between the two objects,

$$q_1(t + 1) = w_1^t$$

as in Equation 9. An exponential distribution with constant probabilities need not be assumed if the mathematical form of $w_1(t)$ and its variation with the distance between the two objects can be established from an analysis of the experimental data. These data would also provide an estimate of $\lambda_1(t)$ for any distance between the object ignited first and the second object. The value of $\mu_1(t)$ can then be obtained from the equation

$$\mu_1(t) = 1 - \lambda_1(t) - w_1(t)$$

It can be verified that, since $q_1(1) = 1$,

$$\begin{aligned} P_1(t + 1) + S_1(t + 1) &= \sum_{r=1}^{t+1} q_1(r)[\mu_1(r) + \lambda_1(r)] \\ &= \sum_{r=1}^{t+1} q_1(r)[1 - w_1(r)] \\ &= \sum_{r=1}^{t+1} [q_1(r) - q_1(r + 1)] \\ &= 1 - q_1(t + 2) \end{aligned}$$

As t increases, $q_1(t)$ will decrease toward zero such that the sum of the two cumulative probabilities will tend to unity. Hence, as one would have expected, the probability of burning without spreading will tend to zero with the passage of time, and the fire involving the first object would have either been extinguished or spread to the second object.

In the language of stochastic modeling, the spread probability, $\lambda_1(r)$, is the transition probability at time r , and may be redefined as $\lambda_{12}(r)$ to denote the spread from the object first ignited to the second object. Other objects in a room may be considered as the first or second object such that, in the general case, $\lambda_{ij}(r)$ is the probability of spreading from the i^{th} object to the j^{th} object at time r . Based upon the distances between them, the objects can be arranged in order in a diagram to analyze the sequential spread of fire from object to object at any time r . (See Figure 3-15.1.) This simple analysis may be sufficient for all practical purposes, although a fire from one object can spread to another object directly or indirectly through the ignition of another object.

As t increases, $q_i(t)$ will tend to zero and the cumulative probability of extinguishment, $P_i(t + 1)$, to a limiting value E_i . This value, E_i , denotes the probability of fire being extinguished ultimately, with the spread limited to the i^{th} object. Correspondingly, the cumulative probability of spreading, $S_i(t + 1)$, will tend to $(1 - E_i)$. The following equations may be specified in the limiting case:

$$\begin{aligned} E_1 &= \mu_1 & \lambda_1 &= 1 - \mu_1 \\ E_2 &= \lambda_1 \cdot \mu_2 & \lambda_2 &= 1 - \mu_2 \\ E_3 &= \lambda_1 \cdot \lambda_2 \cdot \mu_3 & \lambda_3 &= 1 - \mu_3 \end{aligned}$$

and so on, such that, in general terms

$$E_i = \lambda_1 \cdot \lambda_2 \dots \lambda_{i-1} \cdot \mu_i; \quad \lambda_i = 1 - \mu_i \quad (10)$$

$$P_i = \sum_{j=1}^i E_j \quad (11)$$

The equations aforementioned provide values for μ_i for $i = 1, 2, 3 \dots$ which may be regarded as the limiting probability of extinguishment for the i^{th} object, given (conditional) that the fire has spread to this object. The parameter λ_i is the limiting and conditional probability of spread beyond the i^{th} object.

The model mentioned above for objects in the room of fire origin can be extended to include structural barriers

Figure 3-15.1. Probability diagram for spread of fire from object to object at time γ .

and objects in corridors and other rooms on the same floor or different floors of a building. This procedure involves complex calculations, since a fire in a room can spread to an adjoining room in the same or upper floor; a fire can also spread through several paths. The problem of fire spread throughout a building can be simplified to some extent by applying network models, which are discussed later.

$$P = \begin{bmatrix} \lambda_{11} & \lambda_{12} & \dots & \lambda_{1m} \\ \lambda_{21} & \lambda_{22} & \dots & \lambda_{2m} \\ \cdot & \cdot & \cdot & \cdot \\ \cdot & \cdot & \cdot & \cdot \\ \lambda_{m1} & \lambda_{m2} & \dots & \lambda_{mm} \end{bmatrix}$$

where

$$\sum_{j=1}^m \lambda_{ij} = 1 \quad i = 1, 2, \dots, m$$

The probability distribution of the system at time n can be expressed as the vector

$$P = (q_1 \ q_2 \ q_3 \ \dots \ q_m)$$

where q_i is the probability of the fire burning in the i^{th} state at time n . Since a fire can be in one of the m states at a given time

$$\sum_{i=1}^m q_i = 1$$

The m^{th} state may denote the state of fire having been extinguished if such a state is included in the model considered. The vector given by the product $p \cdot P$ expresses the probabilities of burning in different states one transition (minute) later.

As an example, consider a model of fire growth in a room in which the i^{th} state represents i objects burning. Suppose, with $m = 4$ and no extinguishment, the process

Markov Model

Mathematical Representation

A considerable amount of statistical and experimental data are needed for applying the model for fire spread from object to object. For practical purposes it may be sufficient to consider fire spreading through a number of spatial modules,¹⁰ phases,¹¹ or realms.¹² These stages of fire growth can generally be defined as *states* such that fire spreads, moves, or makes a transition from state to state.

The movement of fire from state to state is governed by a *transition probability*, which is a function of time since the start of the fire. The fire also spends a certain length of time in each state before making the transition; this duration follows a temporal probability distribution. The state occupied by fire at any moment in time is governed by transition probabilities and temporal probability distributions. Represented mathematically, if the fire is in state a_i at the n^{th} minute, it can be in state a_j at the $(n + 1)^{\text{th}}$ minute, according to the transition probability $\lambda_{ij}(n)$. The transition probabilities are most conveniently handled in matrix form. One may write, dropping (n) for convenience, with m states,

stops with the occurrence of flashover when all four objects are ignited. There is no recession in growth and, hence, there is no transition to a lower state from a higher state. With these assumptions, let the transition matrix be

$$P = \begin{bmatrix} 0.4 & 0.3 & 0.2 & 0.1 \\ 0 & 0.5 & 0.3 & 0.2 \\ 0 & 0 & 0.6 & 0.4 \\ 0 & 0 & 0 & 1 \end{bmatrix}$$

If, at time n , the probabilities of fire burning in different states is given by

$$p_n = (0.1 \ 0.2 \ 0.3 \ 0.4)$$

it can be seen by performing the matrix multiplication, that the probability of fire burning in different states at time $(n + 1)$ is given by

$$p_{n+1} = (0.04 \ 0.13 \ 0.26 \ 0.57)$$

Hence, at time $(n + 1)$, the probability of the fire being in the third state, for example, is 0.26, and the probability of flashover (4th state) is 0.57.

Markov Chains

Markov chains are used for repetitive situations in which there is a set of probabilities that define the likelihood of transition from one state to another. A chain comprises a sequence of such transitions. In a Markov chain, the transition probabilities satisfy the following properties:⁴

1. Each state belongs to a finite set of all possible states.
2. The characteristics of any state do not depend upon any other previous state.
3. For each pair of states (i, j) there is a probability λ_{ij} that state j occurs immediately after state i occurs.

The transition probabilities can be specified in a matrix form P as discussed previously, with the aid of a hypothetical example. Berlin⁴ and Watts¹⁰ have illustrated the use of this matrix by modeling a “random walk” among five adjacent spaces.

Markov chains may possess a number of special characteristics, one of which is called an *absorbing state*. The system remains in an absorbing state once it enters this state. A fire burning out (self-termination) and a fire getting extinguished by an extinguishing agent are examples of absorbing states. State i is an absorbing state if row i of the transition matrix has a value of $\lambda_{ij} = 1$ and all other values in the row are zero.

Markov Process

The next step is to consider a slightly more complex model called the *Markov process*, a stochastic or random process where the probability of occurrence of some future state of the system, given its present state, is not altered by information concerning past states. That is, the

history of the process has no influence on its future. This lack of a historical influence is often referred to as a *memoryless* or *Markovian* property of a process.

In a Markov process with stationary transition probabilities, the value of $\lambda_{ij}(n)$ is a constant independent of the time variable n . Following this process Berlin¹² estimated stationary transition probabilities for six realms (states) for residential occupancies: (I) nonfire state, (II) sustained burning, (III) vigorous burning, (IV) interactive burning, (V) remote burning, and (VI) full room involvement. These realms were defined by critical events, such as heat release rate, flame height, and upper room gas temperature. Development of fire over time was considered as a “random walk” through these realms.

Based on data from over a hundred full-scale fire tests, Berlin¹² calculated transition probabilities as in Table 3-15.1. The information in this table indicates that, when a fire is in Realm III, there is a 75 percent chance of growth to Realm IV, and a 25 percent chance of recession to Realm II. Figure 3-15.2 is the transition diagram

Table 3-15.1 Transition Descriptors for a Typical Room in a Residential Occupancy

Fire Type: Smoldering fire in a couch with cotton cushions.

Realm Transition		Transition Probability	Temporal Distribution		
From	To		Type	Mean	Standard Deviation
II	I	0.33	Uniform	2.0	5.0
II	III	0.67	Log-normal	8.45	0.78
III	II	0.25	Uniform	1.0	2.0
III	IV	0.75	Normal	5.55	3.22
IV	III	0.25	Uniform	1.5	9.0
IV	V	0.75	Uniform	0.5	3.5
V	IV	0.08	Uniform	0.6	6.0
V	VI	0.92	Log-normal	5.18	4.18

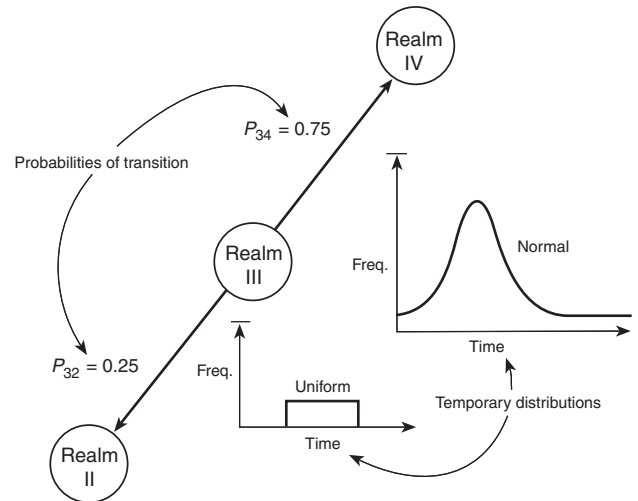

Figure 3-15.2. Realm transition descriptors.

defined by the transition probabilities in Table 3-15.1. Realm I, no fire, is an absorbing state, since all fires eventually terminate in this state. The process also ends when Realm VI (full room involvement) is reached; for this reason, this state also is an absorbing state. Berlin¹² used uniform, normal, and log-normal distributions to describe temporal probability distributions for the different states.

Among many questions asked about fire development using the Markov model is what maximum extent of fire growth represents the most extreme condition. The portion of fires that does not grow beyond Realm II is the probability (0.33) of transition from Realm II to I. If M_3 is the long-run (limiting) probability of fire reaching Realm III, but not growing beyond, then¹²

$$M_3 = \frac{\lambda_{21} + \lambda_{23} \cdot \lambda_{31}}{1 - \lambda_{23} \cdot \lambda_{32}} - \lambda_{21} \quad (12)$$

Using the figures in Table 3-15.1 and noting that $\lambda_{31} = 0$, it may be seen that $M_3 = 0.07$. Beyond Realm III is more difficult, as described by Berlin.¹² Probabilities of maximum extent of flame development as estimated by Berlin are given in Table 3-15.2. Berlin has also discussed other fire effects, such as probability of self-termination and distribution of fire intensity.

One of the major weaknesses of the Markov model regards the "stationary" nature of the transition probabilities. It is assumed that these probabilities remain unchanged regardless of the number of transitions representing the passage of time. The length of time a fire burns in a given state affects future fire spread. For example, the probability of a wall burn-through increases with fire severity which is a function of time. The time spent by fire in a particular state may also depend on how that state was reached (i.e., whether the fire was growing or receding). Some fires may grow quickly and some grow slowly, depending on high or low heat release. In a Markov model with stationary transition probabilities no distinction is made between a growing fire and a dying fire.

Berlin¹² has estimated that 99 percent of all fires will terminate within twelve transitions. This result is based on the assumption of stationary transition probabilities that may be nearly true for a few fluctuations between the same realms where different materials would be contributing to the burning process. However, the fire will eventually consume all fuels, in which case the probabilities of termination from all realms will be equal to one. Therefore, Berlin's approach represents a worst-case analysis.

Table 3-15.2 Maximum Extent of Flame Development

Maximum Flame Extent	Probability of Flame Extent
Realm II	0.33
Realm III	0.07
Realm IV	0.02
Realm V	0.58

State Transition Model

According to Berlin's Markov model, a fire in a particular realm can either grow to a higher realm or recede to a lower realm. There is no transition to the nonfire (absorbing) state (Realm I) from any realm higher than Realm II, except Realm VI (full room involvement) which is also an absorbing state. Receding to a lower state may be true to some extent when describing fire growth in terms of flame spread, but such an assumption is not possible in the case of spatial spread of fire in which, as discussed previously, fire spreads sequentially from one object to another. According to this model, if fire spreads to an object it cannot spread backwards to the object from which it spread. The fire involving an object either spreads forward to other objects, gets extinguished, or stays with the object without spreading.

Complex computational procedures would be involved in a stochastic model for fire spread from object to object in a room or to different rooms. Hence, consistent with the fire statistics available, particularly in the United Kingdom and United States, a simplified model based on the following three main states can be considered for fire development in a room:

- S₁ Fire confined to the object first ignited
- S₂ Fire spreading beyond the object first ignited but confined to the contents of the room
- S₃ Fire spreading beyond room of origin but confined to the building

A fourth state may be added to denote extinguishment or burning out (self-termination) of fire; this is an absorbing state, since a fire process cannot leave this state after entering it. The third state, S₃, is also an absorbing state, since a spreading fire will eventually terminate within the building of origin; spreading beyond the building is not considered.

The three states ($i = 1, 2, 3$) mentioned above generate a state transition model, distinct from Berlin's Markov model. This model was used by Ramachandran⁵ for evaluating the transition (spread) probabilities $\lambda_i(t)$ and the probabilities $\mu_i(t)$ for extinguishment or transition to the fourth state. The value of $\lambda_3(t)$ was taken as zero, since fire spread beyond the building was not considered. The probability of burning in a state without spreading was also considered with the aid of the parameter $w_i(t) [= 1 - \lambda_i(t) - \mu_i(t)]$. The duration of burning was divided into subperiods, each of a fixed length of five minutes.

Statistics furnished by fire brigades in the United Kingdom related to fires that were extinguished during each time period since ignition. Hence, Ramachandran⁵ used the extreme value technique, with some assumptions, to estimate the number of fires that were burning in a particular stage at the beginning of each subperiod. With the aid of these estimates and the actual numbers of fires that were extinguished, approximate values were obtained for the extinguishment and spread probabilities (as functions of time) and probability distributions of duration of burning in each state. The equations given previously for the general model were utilized for this purpose. Four materials ignited first in the bedroom of a

dwelling were considered for illustrating the application. Tables 3-15.3 and 3-15.4 and Figures 3-15.3 and 3-15.4 are examples extracted from this study. Aoki⁷ described fire growth with similar states based on the spatial extent of spread; his analysis was similar to that of Ramachandran⁵

Table 3-15.3 Bedroom Bedding (Probabilities)

and Morishita¹¹ and considered eight phases of spatial spread of fire, including spread to the ceiling.

In a later study, Ramachandran³ added another state between S_2 and S_3 to denote the event of fire involving the structural barriers of a room, assumed to occur after fire has spread beyond S_1 and S_2 but still confined to the room. This intermediate state was considered as generally consecutive to S_2 , although a fire can spread directly from S_1 and involve the structural boundaries. Fire statistics available in the United Kingdom permit the incorporation of this additional state into a state transition model. As shown in Figure 3-15.5, only the limiting probabilities λ_i and μ_i specified in Equation 10 were estimated.

Fire statistics provided estimates for $E_i (i = 1 \text{ to } 4)$, the proportion of fires extinguished in the i^{th} state. The condition that

$$\sum_{j=1}^4 E_j = 1$$

- E_1 = Probability of confinement to items first ignited = μ_1
- E_2 = Probability of spreading beyond item first ignited but confinement to contents of room of fire origin = $\lambda_1 \cdot \mu_2$
- E_3 = Probability of spreading beyond item first ignited and other contents but confinement to room of fire origin and involvement of structure = $\lambda_1 \cdot \lambda_2 \cdot \mu_3$
- E_4 = Probability of spreading beyond room of fire origin but confinement in the building = $\lambda_1 \cdot \lambda_2 \cdot \lambda_3 \cdot \mu_4$ ($\mu_4 = 1$)

Figure 3-15.5. Probability tree—textile industry.

follows from the assumption that $\mu_4 = 1$ and, hence, $\lambda_4 = 0$; fire spread beyond the building of origin was not considered.

The parameter μ_1 is the same as λ_{21} in Berlin’s model in which the first state (Realm I) is the nonfire state and the second state and above are fire states (Realms II through VI). Also λ_1 is the same as Berlin’s λ_{23} , and μ_2 corresponds to λ_{31} . With these changes and the assumption that there is no recession of fire growth ($\lambda_{32} = 0$), the value of M_3 in Equation 12 is equal to

$$E_2 = \lambda_1 \cdot \mu_2$$

as derived from Equation 10.

In Figure 3-15.5, the product $\lambda_1 \cdot \lambda_2 (= E_3 + E_4)$ may be regarded as the probability of flashover, and λ_3 as the probability of failure of the structural boundaries of the room.¹³ For the following reasons fire statistics do not provide a valid estimate of λ_3 . Figures for the number of fires that spread beyond the room of origin include: (1) fires that spread by destruction of barrier elements (wall, floor, ceiling) as well as (2) those that spread by convection through a door or window left open or through some other opening. In the latter case, the barrier elements would still be structurally sound. A “room,” as recorded in fire brigade reports, is not necessarily a “fire compartment.” Using a probabilistic model¹³ or other methods, the value of λ_3 for any compartment of given fire resistance can be estimated and multiplied by the probability of flashover to provide an estimate of probability of spread beyond the compartment of origin.

The probabilities provided by a stochastic model can be regarded as “noise” terms superimposed over a deterministic trend in fire growth over space and time. The trend can be predicted by a deterministic model, such as an exponential model.³ Table 3-15.5 is an example based on such a model and fire incidence statistics.¹³ The estimates of time in this table have been measured from the time of occurrence of established burning at the end of the first state, denoting confinement of fire to object first ignited. The percentage figures in Table 3-15.5 have provided the probabilities for constructing the probability tree in Figure 3-15.5.

To represent the interaction between human behavior and fire dynamics, Beck¹⁴ developed a series of stochastic

state transition models and interrelated deterministic models. His sequential fire growth model was based on the six realms defined by Berlin,¹² with the remote burning state denoting flashover. His results, reproduced in Table 3-15.6, are applicable to office buildings. P_I in this table is the same as E_i in Equation 10. Adopting a different notation and starting with $P_I = \mu_1$, the conditional probabilities of extinguishment, μ_i , and conditional probabilities of spread, $\lambda_i (= 1 - \mu_i)$, were calculated according to Equation 10. The probability of a fully developed fire, given a fire defined by P_{FDF}/F , is given by the product $\lambda_1 \cdot \lambda_2 \cdot \lambda_3 \cdot \lambda_4$. The probability of spread beyond the compartment of fire origin, P_{Vl} , is given by the product of P_{FDF}/F and λ_5 or by $\lambda_1 \cdot \lambda_2 \cdot \lambda_3 \cdot \lambda_4 \cdot \lambda_5$.

Beard¹⁵ proposed a state transition model by considering a number of "critical events" with directional characteristics that a fire may pass through and the times between critical events. For example, critical heat event CHE2U referred to "fire passing through 2 kW on the way up," whereas CHE2D referred to "fire passing through 2 kW on the way down." The time between two critical events was assumed to have a temporal probability distribution independent of the time between earlier critical events. A particular succession of critical events formed a chain; specific times between critical events were referred to as a *sequence* within the chain. Based on assumed forms for transition probabilities and temporal probability distributions, Monte Carlo simulation was employed to generate randomly particular chains and sequences. A generated sequence to smoke and toxic gases was related to the corresponding sequence for the burning rate. Based on the concentration of carbon monoxide, Beard employed the concept of "fraction of fatality," with fatality resulting at a unit value for this fraction. He applied the model to a particular case involving flaming ignition on a bed in a hospital ward. He concluded that there would be a very large (greater than 80 percent) likelihood of having multiple fatalities if a fire exceeds 50 kW. One of the several assumptions used by him was that the fire did not spread beyond the ward.

Williamson¹⁶ introduced a state transition model for analyzing and reporting the results of fire growth experiments performed under conditions resembling actual fire conditions. Three preflashover states were defined as follows:

- J The period of time from the beginning of the experiment to ignition of the specimen
- K The period of time from ignition of the specimen until flames touch the ceiling
- L The period of time from when the flames first touch the ceiling until full involvement (flashover) occurs

Histograms and cumulative distribution functions of the state durations provided a graphical representation of fire performance. Examples were chosen to illustrate the method. Traditional cellulosic and cementitious walls and ceilings were compared to plastic materials in the same configuration.

Networks

State Transition Model

There is a probability p_f for flashover occurring in a room or compartment which depends on the objects in the room and their spatial arrangement apart from ventilation and other factors. Given flashover, the fire can breach the structural boundaries of the room with a probability p_b and spread beyond the room with a probability $p_s (= p_f \cdot p_b)$. The value of p_b depends on the level of fire severity attained after flashover and the fire resistance of the structural elements, such as walls, ceilings, and floors. The probability of failure of a room or compartment of given fire resistance, p_{br} , can be estimated from the joint probability distribution of fire severity and fire resistance expressed in units of time.¹³ Fire resistance of a compartment will be reduced and the failure probability p_b increased by weakness caused by penetrations, such as piping or cables through walls, doors, windows, or other openings in the structural barriers.

Each room or corridor in a building has, therefore, an independent probability p_s of fire spreading beyond its boundaries. Using these probabilities for different rooms and corridors, fire spread in a building can be considered as a discrete propagation process of burning among points that abstractly express the rooms, spaces, or elements of a building. In a simple analysis, states classified by the burning situation of individual points can be incorporated in a state transition model.¹⁷

Consider, for example, three adjoining rooms, R_1 , R_2 , and R_3 , that provide the following four states with the fire commencing with the ignition of objects in R_1 .

1. Only R_1 is burning.
2. R_1 and R_2 are burning (and not R_3).
3. R_1 and R_3 are burning (and not R_2).
4. All three rooms are burning.

There is no transition from the

1. First to the fourth state
2. Second to the third state
3. Third to the second state
4. Second or third or fourth to the first state (recession of fire growth).

Table 3-15.6 Probabilities of Extinguishment: Fire-Growth and Suppression Model

System Configuration	P_I	P_{II}	P_{III}	P_{IV}	P_V	P_{VI}	P_{FDF}/F
No sprinkler	0.5673	0.0038	0.0017	0.3282	0.0666	0.0324	0.0990
Sprinkler	0.5673	0.3827	0.0201	0.0232	0.0045	0.0022	0.0067

A transition from the second to the fourth state involves the spread of fire to R_3 from R_1 or R_2 . The probability for this transition is, therefore, the sum of probabilities for spread from R_1 to R_3 and R_2 to R_3 . Likewise, the probability of transition from the third to the fourth state is the sum of probabilities for spread from R_1 to R_2 and R_3 to R_2 . A fire can burn in the same state without transition to another state. The process terminates when the fourth state is reached.

With the assumptions mentioned above, the following transition matrix can be formed with p_{ij} denoting the probability, p_s , of fire spread from room i to room j per unit time.¹⁷ The unit may be longer than one minute, say, five minutes since one is considering spread from room to room after the occurrence of flashover. The values of p_{ij} may be considered as constants in a state transition model with stationary transition probabilities.

$$P = \begin{bmatrix} 1 - p_{12} - p_{13} & p_{12} & p_{13} & 0 \\ 0 & 1 - p_{13} - p_{23} & 0 & p_{13} + p_{23} \\ 0 & 0 & 1 - p_{12} - p_{32} & p_{12} + p_{32} \\ 0 & 0 & 0 & 1 \end{bmatrix}$$

During the initial period, since only R_1 is burning, the probability of burning in different states is given by the probability distribution of the system

$$p_0 = (1 \ 0 \ 0 \ 0)$$

The probability distribution of the system after one unit of time is given by

$$p_1 = p_0 \cdot P = (1 - p_{12} - p_{13} \ p_{12} \ p_{13} \ 0)$$

and after two units of time by the following row vector which, for convenience, has been written as a column vector

$$p_2 = p_1 \cdot P = \begin{bmatrix} (1 - p_{12} - p_{13})^2 \\ 2p_{12}(1 - p_{13}) - p_{12}^2 - p_{12} \cdot p_{23} \\ 2p_{13}(1 - p_{12}) - p_{13}^2 - p_{13} \cdot p_{32} \\ p_{12} \cdot p_{23} + 2p_{12} \cdot p_{13} + p_{13} \cdot p_{32} \end{bmatrix}$$

The probability distributions of the system for later periods can be obtained by repeating the matrix multiplication as described above. This process will generate for each state a probability distribution for burning in that state as a function of time. For the first state (only R_1 burning), for example, the probability after n units of time is $(1 - p_{12} - p_{13})^n$. The probability distributions for the other three states can be obtained by performing the calculations on a computer. The distribution for any state will provide an estimate of average transition time to that state. For estimating the average transition time to the fourth state, denoting the burning of all three rooms, Morishita¹⁷ has proposed a method based on partitioning the matrix P . He has also discussed the stochastic process for a system in which extinguishment is attempted. For pur-

poses of illustration he has applied the model to a hypothetical small house.

By carrying out further calculations and adding the corresponding probabilities, cumulative probabilities over time can be estimated for burning in the four states. The cumulative probabilities would generally tend to some limits as the value of n denoting time increases. The limiting value of the cumulative probability for the fourth state (all three rooms burning) and the corresponding time would be of special interest. This probability can be reduced and the associated time increased by (1) increasing the structural fire resistance of the rooms to reduce the probability of barrier failure, p_b , and (2) installing sprinklers to reduce the probability of flashover, p_f . With these safety measures probability of fire spread from room to room, p_s , will be reduced. Consequently the cumulative probability of fire being confined to the room of origin, R_1 , will increase; this probability for a duration of t minutes is given by

$$\sum_{n=1}^t (1 - p_{12} - p_{13})^n$$

where p_{12} and p_{13} are the probabilities of spreading from R_1 to R_2 and R_3 per unit time.

Network Models

The model described above can be extended to provide cumulative probabilities, at time n or limiting, for the burning of more than three rooms, but this will involve tedious and complex calculations. It would be simpler to consider fire spread between two given rooms through intermediate rooms and corridors in terms of discrete values attached to the probability p_s of spread beyond a room. This probability may be the limiting value for the cumulative probability given by, say, $E_4 (= \lambda_1 \cdot \lambda_2 \cdot \lambda_3)$ in Figure 3-15.5. Alternatively, the time taken by fire to breach the boundaries of a room may be ascertained from deterministic (scientific) models and a probability assigned to this time, t_s , used for p_s in the stochastic model. The duration t_s is the sum of t_f representing the time to the occurrence of flashover after the start of established burning and t_b representing the time for which the barriers of the room can withstand fire severity after flashover. The latter time may be the endurance of barrier elements as measured by a standard fire resistance test, such as ASTM E119, *Standard Test Methods for Fire Tests of Building Construction and Materials*. As mentioned earlier $p_s = p_f \cdot p_b$.

Consider, as an example, the simple layout of Figure 3-15.6(a), relating to four rooms, and the corresponding graph shown in part (b), which also shows the probability (p_{ij}) of fire spread between each pair of rooms (i, j). The probability p_{ij} refers to p_s as defined herein, whereas Dusing et al.¹⁸ and Elms and Buchanan¹⁹ have considered only the barrier failure probabilities denoted by p_b , ignoring the probability of flashover denoted by p_f . The specific problem considered by these authors was to compute the probability of fire spread from room 1 to 4, which might follow any of the four paths, that is, (1) → (2) → (4); (1) → (3) → (4); (1) → (2) → (3) → (4); and (1) → (3) → (2) → (4).

Figure 3-15.6. Simple diagram for fire spread.

Using the event space method, Elms and Buchanan¹⁹ considered first all possible “events” or combinations of fire spreading or not spreading along various links. If a_{ij} represents spread of fire along link ij , and \bar{a}_{ij} represents fire not spreading along the link, then one event might be

$$[a_{12}, \bar{a}_{13}, a_{23}, \bar{a}_{32}, \bar{a}_{24}, a_{34}]$$

There will be $2^6 = 64$ events that will be all-exclusive, as any pair of events will contain at least one link for which fire spreads in one event and does not spread in the other. The probability of each event occurring is the product of the probabilities of its elements, assuming that the elements are independent. Thus, for the example given above, the event probability will be

$$p_{12}(1 - p_{13})p_{23}(1 - p_{32})(1 - p_{24})p_{34}$$

and the overall probability is the sum of all 64 event probabilities.

The complete event space can be represented as a tree with 64 branches. The probability of fire spread for each event (branch) is obtained by multiplying all the link probabilities in a branch. However, not all branches have to be computed in full. The computation can be curtailed, while still allowing for all cases. For this purpose, Elms and Buchanan¹⁹ have described a method of constructing the tree and its ordering to identify or search possible paths of links leading to node (room) 4 from node 1. This procedure is known as a “depth-first search” of a graph. In this algorithm, a path is a series of nodes or rooms in a building; the construction of a branch, which is part of a particular event, is based on an underlying path. Each branch allowing fire spread must contain at least one path. Figure 3-15.7 shows the actual tree as it would be computed by the algorithm. The total probability of spread from node 1 to node 4 is given by the sum of all the branch probabilities. The calculation is carried out for each pair of rooms,

Figure 3-15.7. Modified event space tree.

and the results assembled in a “fire spread matrix.” The diagonal elements of the matrix are unity.

Various means have been employed to curtail the algorithm to prevent the computer developing excessively lengthy branches that would, as the branch probability decreases with branch length, have little effect on the result. The first means is to restrict the length of a fire spread path to a maximum number of compartments. The second approach is to terminate development of a branch if the cumulative branch probability drops below a certain fraction of the running total of the branch-spread probabilities calculated up to that point. The third means is to terminate development of a branch if the underlying path length becomes greater than a specified amount more than the length of the shortest possible path between the two rooms being considered.

In the computer-based technique of Elms and Buchanan¹⁹ as described above, a building is represented as a network by defining compartments as nodes and the links between these nodes as possible paths for fire spread from compartment to compartment in a multi-compartment building. The core of this model is a probabilistic network analysis to compute the probability of fire spreading to any compartment within the building. A series of further refinements were added when the model was applied to analyze the effects of fire resistance ratings on the likely fire damage to buildings.²⁰

Time Dimension

Elms and Buchanan¹⁹ did not consider the dimension of time explicitly, although it was implicit in many of their functions. The probability of fire spreading from one compartment to another was considered irrespective of how long it might take. As a result, the analysis did not take into account any intervention (e.g., the fire service). In this respect the model represented a worst-case scenario and assumed that the fire would eventually burn itself out.

The model of Elms and Buchanan¹⁹ was not concerned with the process of fire growth and assumed that the spread was solely a function of the probable effects of a fully developed fire. The probability of flashover was not considered in this model. Platt²¹ has proposed a new network model in which fire resistance and severity are

related to real time instead of equating these two parameters to the time based on the ISO standard fire which is not necessarily representative of the real time. The model computes the probability that fire will have spread to any part of a building after an elapsed time t . The essential features of Platt's model²¹ are described in the following paragraphs.

The spread of fire to an adjacent compartment may be via the following paths:

1. Through an open doorway
2. Vertical spread via windows
3. Through a barrier, such as a wall, closed door, or ceiling

Two models are considered for estimating fire growth as a function of time. The first model is based on the exponential relationship between fire area and growth time as suggested by Ramachandran.²² The second model uses the parabolic relationship between rate of heat release and growth time as proposed by Heskestad.²³ This model is used in conjunction with the relationship between compartment temperature and rate of heat flow to provide an estimate of flashover time, which is taken as the time when ceiling temperature reaches 600°C. The temperature is a function of the ventilation characteristics of the compartment, the type of fuel material, its configuration, and the thermal properties of the structural boundaries.

A figure of 49 percent is used to represent the probability that the initial fire will not result in flashover. Subsequent ignitions caused by fire spread are given a 100 percent probability of reaching flashover. This assumption may overestimate the spread of fire, since a barrier may fail in the very latter stages of a fully developed fire, which may not then have the momentum to initiate further ignition.

The real time of the fire duration, t , representing fire severity, s , is estimated by the ratio of fuel load to rate of combustion which is a function of ventilation and dimensional characteristics of the compartment. A formula suggested by CIB²⁴ is used to estimate the equivalent time, t_e involving the real parameters of the compartment. The approved fire resistance rating (FRR) of a barrier element, modified for weakness and another factor, is multiplied by the ratio (t/t_e) to yield an equivalent FRR denoted by R . R and fire severity, s , are not independent but quite rightly they have been assumed to be independent random variables with log-normal probability distributions. Under this assumption, the probability of fire spread through a barrier is estimated through the safety factor (R/s) which is also a log-normal variate. The probability of fire spread via an open door is assumed to be 100 percent. The probability of fire spreading vertically up the facade of a building via windows is equated to the probability that the height of the external flames is greater than or equal to the height of the spandrel.

A comparison is then made between these values and the design values of the barrier and door fire resistance and the spandrel heights. The output from these comparisons is a series of probabilities that fire will spread via each of the three possible paths described earlier. Combining these individual probabilities gives an overall probability of fire spreading to an adjacent compartment. Repeated for each compartment within the building,

these values collectively form the adjacency fire spread matrix whose values represent the probability that fire will spread from compartment i to an adjacent compartment j . The expected time for fire to spread to an adjacent compartment, given that fire does spread, provides values for the adjacency fire spread time matrix.

By combining the two matrices providing probabilities and expected times for fire spread between adjacent compartments, the analysis computes the probability of fire spreading from an initial compartment i to any compartment j . The fire may spread along any path, but is conditional on having arrived at compartment j in a given time. The resulting matrix (i.e., global fire spread matrix) may be considered as a three-dimensional matrix with each layer being evaluated at a different time. Once the fire spread matrix has been formed, Platt's model²¹ is very similar to that of Elms and Buchanan²⁰ except that, in the former model, the probability of spread is dependent on time, whereas, in the latter model the probability of fire spreading is irrespective of the time taken.

Ling and Williamson²⁵ have proposed a model in which a floor plan is first transformed into a network similar to the process described by Dusing et al.¹⁸ and Elms and Buchanan.¹⁹ Each link in their network represents a possible route of fire spread, and those links between nodes corresponding to spaces separated by walls with doors are possible exit paths similar to those developed by Berlin et al.²⁶ The space network is then transformed into a probabilistic fire spread network as in the example in Figure 3-15.8 with four rooms, Rm 1 to Rm 4, and two corridor segments C_1 and C_2 . In this figure, Rm 1 has been assumed as the room of fire origin, but it would be a simple modification to reformulate the problem for another room of origin. With Rm 1 and Rm 1', with a "prime" denoting the preflashover and post-flashover stages, the first link is represented by

$$\text{Rm 1} \rightarrow \text{Rm 1}' \\ (p_f, t_f)$$

where p_f represents the probability of flashover and t_f represents the time to flashover. The nodes denoted by a prime represent a fully developed (i.e., post-flashover) fire in the compartment.

Figure 3-15.8. Probabilistic network of fire spread of Rm 1 to C_2 .

In Figure 3-15.8, three different types of links are identified. The first corresponds to the fire growth in a compartment, the second to the fire breaching a barrier element, and the third to fire spread along the corridors. To each link i , a pair of numbers (p_i, t_i) is assigned, with p_i representing the distributed probability that a fire will go through link i , and t_i representing the time distribution that it will take for such a fire to go through link i . The section of the corridor, C_1 , opposite Rm 1, is treated as a separate fire compartment and is assigned a (p_f, t_f) for the link from C_1 to C_1' . The number pair (p_s, t_s) represents the probability and time for the preflashover spread of fire along the corridor from C_1 to C_2 . As a first approximation, p_s may be considered to be governed by the flame spread classification of the corridor's finish materials on the walls and ceiling, as measured by a test method such as the tunnel test in ASTM E84, *Standard Test Method for Surface Burning Characteristics of Building Materials*.

Once full involvement occurs in the section C_1 of the corridor outside Rm 1 (i.e., node C_1' is reached) the fire spread in the corridor is influenced more by the ventilation in the corridor and by the contribution of Rm 1 than by the material properties of the corridor itself. Thus there is a separate link, C_1' to C_2 , that has its own (p_s, t_s) . The number pair (p_b, t_b) represents the probability of failure of the barrier element, with t_b representing the endurance of the barrier element.

Once one has constructed the probabilistic network, the next step is to solve it by obtaining a listing of possible paths of fire spread with quantitative probabilities and times associated with each path. For this purpose, Ling and Williamson²⁵ have adopted a method based on "emergency equivalent network," developed by Mirchandani²⁷ to compute the expected shortest distance through a network. (The word *shortest* has been used instead of *fastest* to be consistent with the literature.) This new equivalent network would yield the same probability of connectivity and the same expected shortest time as the original probabilistic network. In this method, each link has a Bernoulli probability of success and the link delay time is deterministic.

It must be noted that there are multiple links between nodes in the equivalent fire spread network. For example,

the door between Rm 1 and the corridor could be either open or closed at the time the fire flashed over in Rm 1. Ling and Williamson²⁵ assumed, as an example, that there is a 50 percent chance of the door being open and that an open door has zero fire resistance. Furthermore, they assumed that the door, if closed, would have a 5-min fire rating. With further assumptions they constructed the equivalent fire spread network (Figure 3-15.9) with twelve possible paths for the example in Figure 3-15.8 to find the expected shortest time for the fire in Rm 1 to spread to the portion of corridor C_2 . This network changes to Figure 3-15.10 with ten possible paths if self-closing 20-min fire-rated doors had been installed in the corridor, assuming that the reliability of the self-closures is perfect and that doorstops had not been allowed. Note that the links have been renumbered for Figure 3-15.10.

For the two equivalent networks shown in Figures 3-15.9 and 3-15.10, all of the possible paths are listed in Tables 3-15.7 and 3-15.8 with increasing time and with all the component links identified. Each of these paths can be described by a fire scenario; for instance, path 1 in Table 3-15.7 consisting of links ℓ_1, ℓ_2 , and ℓ_4 , would be

"The fire flashes over, escapes from Rm 1 through an open door into the corridor C_1 and spreads along the corridor to C_2 ."

The probability of that scenario (0.13) is strongly dependent on the probability (0.5) for the occurrence of flashover in Rm 1 and of the probability (0.5) that the door will be open. The time of 17.5 min is composed of the times of 10 min for flashover and 7.5 minutes for fire to spread in the corridor from C_1 to C_2 .

Ling and Williamson²⁵ have derived a formula for calculating from the figures in Tables 3-15.7 and 3-15.8, the probability of connectivity R , which is 0.5 for both the networks (Figures 3-15.9 and 3-15.10). This probability is a direct result of the assumed probability of 0.5 for flashover in the room of fire origin and the occurrence of unity probabilities in the remaining links that make up certain paths through the network. According to another formula, the expected shortest time is 29.6 min for Figure 3-15.9, and increases to 47.1 min for Figure 3-15.10 due to the presence of the 20-min fire-rated door. The equivalent

Figure 3-15.9. Equivalent fire spread network with 5-min unrated doors.

Figure 3-15.10. Equivalent fire spread network with self-closing 20-min fire-rated doors.

Table 3-15.7 Pathways through the Example Fire Spread Equivalent Network Assuming 5-Min Unrated Corridor Doors, as Shown in Figure 3-15.9

Paths	Component Links	Probability p_i	Time t_i (min)
1	1-2-4	1/8 = 0.13	17.5
2	1-2-5	1/16 = 0.06	22.5
3	1-3-4	1/4 = 0.25	22.5
4	1-6-10-11	1/44 = 0.02	25.0
5	1-3-5	1/8 = 0.13	27.5
7	1-6-10-12	1/22 = 0.05	30.0
8	1-7-10-12	3/40 = 0.08	35.0
9	1-8-10-11	3/14 = 0.21	40.0
10	1-8-10-12	3/7 = 0.43	50.0
11	1-9-10-11	1/4 = 0.25	55.0
12	1-9-10-12	1/2 = 0.50	60.0

Table 3-15.8 Pathways through the Example Fire Spread Equivalent Network Assuming Self-Closing 20-Min Fire-Rated Corridor Doors, as Shown in Figure 3-15.10

Paths	Component Links	Probability p_i	Time t_i (min)
1	1-2-3	1/4 = 0.25	37.5
2	1-2-4	1/8 = 0.13	42.5
3	1-5-9-10	1/22 = 0.5	45
4	1-6-9-10	3/20 = 0.15	55
5	1-7-9-10	3/7 = 0.43	65
6	1-8-9-10	1/2 = 0.50	75

fire spread network thus facilitates an evaluation of design changes and affords ready comparison of different strategies to effect such changes.

Random Walk

In a simple stochastic representation, the fire process involving any single material or number of materials can be regarded as a random walk. The fire takes a random step every short period either to spread with a probability λ or to get extinguished (or burnout) with a probability $\mu (= 1 - \lambda)$. The parameter λ denotes the success probability of the fire, whereas μ denotes the success probability of an extinguishing agent. The problem is similar to two gamblers, A (fire) and B (extinguishing agent), playing a sequence of games, the probability of A winning any particular game being λ . If A wins a game he or she acquires a unit stake by destroying, say, a unit of the floor area; if he or she loses the game, no stake is gained. In the latter case, A does not lose his or her own stake to B; an already burned out area is a loss that cannot be regained. Extinguishment can also be considered as an absorbing boundary to the random walk, just as it is an absorbing state in a state transition model.

A random walk will lead to an exponential model described in Equations 1 through 3. In these equations, if one writes $c = \mu - \lambda$ such that $\mu = (1 + c)/2$, since $\mu + \lambda = 1$

$$Q(t) = \exp\left[\frac{-(1 + c)t}{2}\right] \tag{13}$$

The fire-fighting effort is adequate if c is positive with μ greater than λ and, hence, greater than $1/2$; it is inadequate if c is negative with μ less than λ and, hence, less than $1/2$. If $c = 0$, such that $\mu = \lambda = 1/2$, there is an equal balance between fire-fighting efforts and the propensity of fire to spread.

Associated with the random variable t denoting time, there is another random variable x denoting damage which may be expressed in terms of, say, area destroyed. Damage in fire has an exponential relationship with duration of burning,²² such that the logarithm of x is directly proportional to t as a first approximation. This assumption would lead to Pareto distribution

$$\phi(x) = x^{-w}, \quad x > 1 \tag{14}$$

denoting the probability of damage exceeding the value x . This distribution is used in economic problems concerned with, for example, income distribution to describe the fact that there are a large number of people with low incomes and a small number of people with high incomes. The damage is small in most of the fires, with high levels of damage occurring only in a small number of fires.

The use of Pareto distribution for fire damage originally proposed by Benckert and Sternberg²⁸ was later supported by Mandelbrot²⁹ who derived this distribution following a random walk process. For all classes of Swedish houses outside Stockholm, the value of the exponent w was found to vary between 0.45 and 0.55. A value of $w = 0.5$ in Equation 14 would imply, as discussed with reference to Equation 13, an equal balance between fire-fighting efforts and the propensity of fire to spread and cause damage.

The parameter μ in Equations 1 and 2 is known as the *hazard* or *failure rate* given by the ratio

$$\frac{f(t)}{Q(t)}$$

where $f(t)$ is the probability density function obtained as the derivative of $F(t)$ in Equation 2. A constant value for μ would denote a random failure. For a Pareto distribution in Equation 14, the failure rate is w/x , such that, with a constant value for w , the failure rate would decrease as x increases, indicating that, in terms of damage, a fire can burn forever without getting extinguished. A constant value for μ or w is somewhat unrealistic, particularly for a fire that is fought and extinguished at some stage. A fire will also burn out when all the available fuel is consumed or when it stops spreading due to the arrangement of objects in a room or building. For the reasons mentioned above, although the failure rate can decrease in the early stages of fire development denoting a success for fire spread, it would eventually increase ("wear out failure"), since fire extinguishing efforts would succeed ultimately.³⁰ There may be a long intermediate stage of steady growth of fire with μ remaining as a constant. The failure rate as a function of time would, hence, resemble a "bathtub" whose cross-section is composed of two curves sloping downwards representing the early and final stages of fire growth, connected at the bottom by a long straight line representing the intermediate stage.

Erving et al.³¹ presented an approach to the theory of burning velocity in which a flame front moves forward at a rate determined by the random walk of chemical energy. The flame velocity is estimated by the value of a parameter which is a "collision rate" divided by a "reaction rate," both determined at the point of maximum reaction velocity. Empirical activation energies were given by the authors for certain hydrocarbon flames.

In the context of fire spread, random walk is a one-dimensional process describing the damage by random functions of time rather than by a random function of time and space. The random walk indicates the position of the fire (i.e., damage at any time). At every unit of time, there is a change in position indicated by an increment to the damage or no change due to absorption (extinguishment or burning out). Generally the walk is considered in discrete time. If the walk is continuous in time such that the increments are Gaussian, this leads to a diffusion process.³² (A diffusion process is an approximation to Brownian motion, a phenomenon well known in many branches of science and technology.) The normal, or diffusion, term is one of two possible components of a general additive stochastic process, the other component being a

discontinuous or transition term arising from occurrences of events at random times. The Markov chains discussed earlier belong to the second type of component. A linear superposition of the two components provides a solution to an equation governing a general additive process.

Percolation Process

In random walk and diffusion models, randomness is a property of the moving object, whereas in a percolation process, randomness is a property of the space in which the object moves.³³ Thus the transition the object suffers when at a particular point is random but, if the object ever returns to this point, it would suffer the same transition as before. The process is described by a stochastic field on the space (i.e., a vector field of transition numbers). Percolation process deals with deterministic flow in a random medium, in contrast with random walk and diffusion models which are concerned with random flow in a deterministic medium.

Broadbent and Hammersley³⁴ considered the walk as taking place on a graph consisting of a number of sites, connected by directed bonds, passage being possible only along such a "bond." If such a graph obeys certain connectivity requirements, it is termed a *crystal*. In a randomized version, each bond of the crystal has an independent probability of being blocked, and it is desired to know what effect this has on the probability of communication from one site A to another site B; this is not the same as from B to A, since communication has a direction.

If fire is considered as the moving object, the movement takes place in a space or medium that has a certain random property although the object (fire) itself has some randomness associated with it. Buildings in an area, for example, are somewhat randomly distributed. Buildings are also connected by directed bonds, with spread (flow) of fire being possible only along the bonds. Each bond has an independent probability of blocking or preventing fire spread; this depends on the nature of a building and its contents, wind conditions, and the distances between buildings. A percolation problem also arises when one considers a network some of whose links, chosen at random, may be blocked, and one wishes to know the effect of this random blockage on flow through the network. Such a problem would be encountered in predicting fire spread in a forest or from building to building in an urban area.

Apparently for the reasons mentioned above, Hori³⁵ considered percolation process for the modeling of fire spread from building to building. Sasaki and Jin³⁶ were concerned with the actual application of this model and estimation of probabilities of fire spread. By using the data contained in the fire incidence reports for Tokyo, urban fires were simulated and the average number of burnt buildings per fire estimated. Apart from distances between buildings and wind velocity, the following factors were also regarded as having some effect on the probability of fire spread: building construction, building size and shape, window area, number of windows, indoor construction materials, furniture, walls, fences, gardens, and trees.

For the model, the first factor was classified into three groups: (1) wood construction, (2) mortar (slow burning) construction, and (3) concrete (fireproof) construction. The wind velocity was classified into two groups: (1) 0 to 2.5 m/s and (2) 2.5 to 5.0 m/s. In the former case, fire spread was assumed to be unidirectional (isotropic) whereas, in the latter case, the data were subdivided into smaller groups according to the directions of fire spread: the windward direction, the leeward direction, or direction perpendicular to that of the wind (the sideward direction). Fire incidents in which wind velocity was larger than 5.1 m/s were excluded due to their small number. If the number of burnt buildings was i and that of unburnt ones was j , the probability of fire spread was expressed as $i/(i + j)$.

The data were divided by every meter of the distance between buildings, or every 2 m or more in case the data were few. The exponential function $\exp(-cd)$ was used for estimating the probability of spread between two buildings as a function of distance d between them. Using the least square method, the values of c were obtained for different building construction and wind velocity categories. The analysis revealed that building construction was the main factor responsible for fire spread. The simulations did not evaluate the changes in the pattern of spread according to time.

In a recent study, Nahmias et al.³⁷ have examined the feasibility of applying percolation theory to the spread of fires in forests. For studying the effect of randomness on the propagation of fire the authors have built a square network model containing combustible and noncombustible blocks randomly distributed, with a variable concentration, the parameter q denoting the fraction of noncombustible elements. In the absence of wind, the propagation was found to be consistent with a model of invasion percolation on a square site lattice with nearest neighbor interaction leading to a threshold not far from the theoretical value $q = 0.39$. The threshold was larger with wind blowing on the model. The largest threshold value obtained was $q = 0.65$. The final state of the model after combustion was represented for different values of wind velocity and fraction values q . The observation of this state can bring out the directed, nonlocal, and correlated characters of the contagion.

Epidemic Theory

For predicting fire spread in a large urban area, Albin and Rand³⁸ have proposed a model that has some similarity with chain-binomial models of Reed and Frost³⁹ for the spread of an epidemic. The authors envisaged fires in "locales," which may be single buildings or blocks of buildings. A number of these are presumed to be alight initially and randomly distributed and to stay alight for a time T in the absence of fire fighting. At time T , this generation of fires can spread fire and then die out, leaving a second generation to burn for a second period T , and so on.

Fire spread is assumed to take place only at the end of each fire interval. For the $(n + 1)$ th interval, the *a priori* probability that any locale is burning is P_n and that it has not yet been burnt is A_n . It follows that

$$A_n = (1 - P_0)(1 - P_1) \dots (1 - P_n)$$

$$P_{(n+1)} = A_n \cdot B_n$$

where B_n is the probability that during the $(n + 1)$ th interval, fire spreads into a "locale" previously unburnt. To obtain B_n , Albin and Rand³⁸ introduced parameters defining the following three probabilities:

1. Probability that during the $(n + 1)$ th interval there are just m locales burning out of N possible locales adjacent to a given locale
2. Probability that at least one of the m burning locales spreads fire
3. *A priori* probability that fire will spread during any interval of duration T from a burning locale to an unburnt neighbor

Based on the aforementioned parameters the authors obtained an upper and lower approximation for B_n and narrow limits for $(1 - A_n)$, the probability of a locale being burnt.

The Albin and Rand³⁸ model allowing for fire fighting was based on a number of idealizations. First, fire-fighting effort was assumed to be constant. The authors introduced a parameter M for the fraction of burning locales wherein all fire fighters in a city could extinguish that fraction during the given time interval out of all possible burning locales. Fire fighting was assumed to be continuous throughout the time interval. A fire not extinguished may or may not spread; if extinguished it cannot spread. Under the assumptions mentioned above, the authors have derived an expression for the probability $P_{(n+1)}$ defined earlier. Albin and Rand considered directional spread of fire assuming that from an isolated locale the probability of spread forward and backward was the same and the directional element in the spread arose only from the initial condition. Spatial variation was included in the model by connecting the probability of spread to the probability that any building was itself burning and separated from any of its neighbors not yet burning by less than the appropriate "safe" distance for radiation or brand transfer.

Thomas⁴⁰ drew attention to the possible relevance of epidemic theory to fire spread in a building, and compared the model of Albin and Rand³⁸ with a deterministic epidemic model based on a continuous propensity of fire to spread. He found the results of both models to be in reasonable agreement as to their basic features, but concluded that neither would be appropriate for addressing spread in a single building where the number of "locales" is not large. For such a situation a stochastic treatment is necessary to allow for the finite chance that the initiating fires can burn out before spreading, a chance that is negligible when the number of initial fires is large.

Stochastic Differential Equation

Introduction

Most of the models developed to date use statistical data provided by real fires for quantifying, in terms of

probabilities, uncertainties caused by factors which cannot be controlled. These models do not explicitly consider the underlying physical processes. On the other hand, models such as zone, field, and others involving computational fluid dynamics (CFD) are based on physico-chemical and thermodynamic theories supported by experimental data. These models are essentially deterministic since they do not explicitly consider the uncertainties or randomness affecting the spread of a real fire. In order to avoid complex calculations which cannot be performed even with the aid of advanced computer programs, deterministic models use simplified equations which treat as fixed values parameters which are clearly variables. Exclusion of parameters that can affect fire spread is another source of uncertainty generally ignored by a deterministic model. For these reasons, the development of a real fire is unlikely to follow exactly the pattern predicted by a deterministic model even for the early stage involving the material or object first ignited. More uncertainties are involved when a fire spreads from object to object in a room.

For the reasons mentioned above, there is a need to develop models which couple deterministic and stochastic processes governing the spread of a real fire in a room or building. Ramachandran⁴¹ suggested one such model in which heat output and area damage in a real fire are considered as correlated variables for predicting the rate of fire growth (and "doubling time") according to an exponential model.²² This method, in conjunction with the probability distribution of area damage, can provide estimates for the time of flashover in a compartment and for the probability of flashover. Another method is to introduce additional parameters in a deterministic model to take account of uncertainties and derive the stochastic version of the deterministic model. One such method, based on the stochastic differential equation,⁴² is currently being developed in Australia and has the following basic features.

The Deterministic Model

The deterministic version of the stochastic model derived by Hasofer and Beck⁴² for compartment fires is a one-zone model consisting of three variables: the gas temperature T (°C), the rate of fuel burning R (g/min), and the oxygen mass fraction in the compartment x . Eventually x is converted into the percentage oxygen deficiency $D = 23 - 100x$. The initial temperature is $T_0 = 20^\circ\text{C}$ and the time t is measured in min. The basic laws used to derive the equations are discussed by Dysdale,⁴³ section 10.3.2.

The following parameters have been used in the model:

Variable parameters

$$\begin{aligned} V \text{ (volume of compartment)} &= 21.6 \text{ m}^3 \\ S \text{ (inside surface area of compartment)} &= 46.88 \text{ m}^2 \\ A \text{ (area of opening)} &= 1.6 \text{ m}^2 \\ B_{\max} \text{ (total fuel mass)} &= 172.8 \text{ kg} \\ R_0 \text{ (initial burning rate)} &= 8.38 \text{ g/min} \\ h \text{ (height of opening)} &= 2 \text{ m} \end{aligned}$$

Fixed Parameters

$$\begin{aligned} \rho \text{ (gas specific gravity)} &= 490 \text{ g/m}^3 \text{ at } 500^\circ\text{C} \\ &= 1300 \text{ g/m}^3 \text{ at } 20^\circ\text{C} \\ C_p \text{ (specific heat of gas)} &= 0.001 \text{ kJ/gK} \\ \sigma \text{ (Stefan Boltzmann constant)} &= 3.4 \times 10^{-9} \text{ kJ/min}\cdot\text{m}^2\text{K}^4 \\ \varepsilon \text{ (gas emissivity)} &= 0.015 \\ \nu \text{ (mass of oxygen used up by 1 g of fuel)} &= 1.36 \text{ g} \end{aligned}$$

The values of the variable parameters refer to a flashover fire.

With Q_L denoting the net rate of heat loss from the enclosure, the heat balance equation is

$$C_p \rho V \frac{dT}{dt} = H_B R - Q_L \quad (15)$$

where H_B is the net combustion heat per gram of fuel, R is the fuel-burning rate, and ρ is taken to be some average gas specific gravity. Rewriting Equation 15

$$\frac{dT}{dt} = \beta R - q(T) \quad (16)$$

where $\beta = H_B/C_p \rho V$ and $q(T) = Q_L/C_p \rho V$. By expressing the total heat loss rate Q_L as the sum of radiation loss rate and convection loss rate, the following equation has been derived under some assumptions:

$$q(T) = \sum [(T + 273)^4 - (T_0 + 273)^4] + \Phi(T - T_0) \quad (17)$$

for some values of the calibration parameters Σ and Φ .

Let the oxygen fraction in the incoming air be y ($= 0.23$). Then, assuming homogenous mixing, the following differential equation is derived for oxygen mass balance:

$$\frac{dD}{dt} = \delta(k_1 - D)R - \mu D \quad (18)$$

where

$$D = 100y - 100x = 23 - 100x$$

$$\delta = 1/\rho V$$

$$k_1 = 100(y + \nu)$$

$$\mu = m_a/\rho V$$

The new symbol m_a denotes the ventilation rate in g/min. Equation 18 applies only as long as the oxygen concentration is above 7 percent. When that value is reached, it remains steady at that value until the burning rate starts diminishing.

For the burning rate R , the differential equation

$$\frac{dR}{dt} = \alpha(k - D)z \quad (19)$$

has been derived under the assumptions that R is an increasing function of the gas temperature T , and R stops increasing when the oxygen fraction falls below 0.126. R rises only slowly for low temperatures. For z , which is

slowly increasing for small T , the following calibration formula has been used:

$$z = 22T \left(1 - \frac{1}{1 + (0.001T)^2} \right) \quad (20)$$

Equation 19 is applicable as long as there is still some fuel not burning. When most of the combustible material has been consumed, the burning rate quickly decreases exponentially. Equations 16, 18, and 19 require the specification of the initial burning rate, R_0 .

The three-variable model described above was calibrated to the output of the National Research Council of Canada (NRCC) model⁴⁴ with the particular set of values of the variable and fixed parameters listed earlier, by choosing appropriate values for the calibration parameters. These values were chosen as follows. A discrete version of the NRCC model, at intervals of 0.02 min. was obtained. Denoting the values of the gas temperature, the burning rate, and the oxygen deficiency by T_N , R_N , and D_N , respectively, discrete versions of the model were run with varying values of the parameters. An optimization algorithm was used to obtain the values of the parameters that minimized the distance function

$$\Delta = \sum C_1^2 (T_N - T)^2 + C_2^2 (R_N - R)^2 + C_3^2 (D_N - D)^2 \quad (21)$$

where $C_1 = 0.001$, $C_2 = 0.008$, and $C_3 = 23$. These values of the C s were chosen so as to obtain comparable fits for the three variables at their maximum values.

The values of the calibration parameters obtained were as follows:

$$\begin{aligned} \alpha &= 2.5; \quad \beta = 0.1125 & \Phi &= 0.399 & \Sigma &= 1.875 \times 10^{-10} \\ \delta &= 1.5 \times 10^{-5} & \mu &= 0.58 & k &= 10.4 & k_1 &= 158 \\ R_0 &= 280 \text{ g/min} & B_{\max} &= 82.5 \text{ kg} \end{aligned} \quad (22)$$

The Stochastic Model

The set of three deterministic equations derived in Equations 16, 18, and 19 have been turned into a set of stochastic differential equations by adding on the right hand side forcing functions, which are white noise multiplied by some function of the variables. The purpose of these forcing functions is to model the intrinsic variability of the fire phenomenon due, for example, to the turbulent behavior of the hot gases. The forcing function adopted is a standard Brownian motion differential $d\mathbf{W}$ with independent components (each with mean zero and variance dt) multiplied by an appropriate function of the variables. The standard form for describing the behaviour of a set of n coupled variables is

$$d\mathbf{X} + \boldsymbol{\alpha}(\mathbf{X}, t) dt = \boldsymbol{\beta}(\mathbf{X}, t) d\mathbf{W} \quad (23)$$

where \mathbf{X} , $\boldsymbol{\alpha}$, and $d\mathbf{W}$ are vectors of length n and $\boldsymbol{\beta}$ is an $n \times n$ matrix. Since the future behavior of the vector \mathbf{x} is independent of its past values, given its present value, it is a Markov vector.

The model does not make $\boldsymbol{\alpha}$ and $\boldsymbol{\beta}$ depend explicitly on the time; they are functions of \mathbf{x} only. It is further assumed that the forcing functions for each of T , D , and R are independent, such that the matrix $\boldsymbol{\beta}$ is diagonal. An-

other assumption is that the randomness of the fire will increase with increasing temperature. Bearing in mind that the variance of a scalar forcing function differential βdw is $\beta^2 dt$, the following set of stochastic differential equations have been obtained:

$$\begin{aligned} dT - \beta R dt + q(T) dt &= f_1(T) d\mathbf{W}_1 \\ dD - \delta(k_1 - D)R dt + \mu D dt &= f_2(T) d\mathbf{W}_2 \\ dR - \boldsymbol{\alpha}(k - D)z dt &= f_3(T) d\mathbf{W}_3 \end{aligned} \quad (24)$$

where $q(T)$ is given by Equation 17 and $z(T)$ by Equation 20. The functions $f_1(T)$, $f_2(T)$, and $f_3(T)$ are appropriately chosen increasing functions of T .

Due to a great paucity of information about the intrinsic variability of enclosure fires, it is presently difficult to determine precise formulas for the functions f_1 , f_2 , and f_3 . Experiments specifically designed to provide data for identifying these functions have been planned to be carried out at the Centre for Environmental Safety and Engineering Risk, Victoria University of Technology, Australia. Statistical variability is another problem whose source is lack of knowledge of the parameters governing the fire. The most important unknown parameter is the initial burning rate which is a nonnegative quantity and, hence, can be assumed to have a lognormal probability distribution. Other parameters affecting the fire are the geometry of the compartment, the size of the openings and whether they are open or shut, and the nature, amount, and position of the fuel load. If these parameters are also unknown, further parameters of the model must be allocated a probability distribution to cater for the added uncertainty. With additional reasonable assumptions regarding the variability of the phenomenon, the probability of extreme values of the fire load can be estimated by a Monte Carlo simulation and used as an input to the probabilistic fire risk analysis of the building under consideration.

Simulation-Illustration

To illustrate the capacity of the model to simulate the intrinsic variability of a fire, a Monte Carlo simulation was performed, using Equation 24 and the parameter values in Equation 22. The functions f_i were chosen as follows:

$$f_1(T) = \frac{\Phi T}{1000} \quad (25)$$

$$f_2(T) = \frac{15\Phi T}{1000} \quad (26)$$

$$f_3(T) = \frac{12\Phi T}{10^6} \quad (27)$$

By varying the parameter Φ , varying degrees of stochasticity may be achieved. Figure 3-15.11 ($\Phi = 50$) and Figure 3-15.12 ($\Phi = 100$) illustrate the type of fire curve obtained.

Since (T, D, R) is a Markov vector and initially all three components increased monotonically, any decrease in the initial burning rate R_0 will just shift the fire curves in Figures 3-15.11 and 3-15.12 to the right. This is illustrated in Figure 3-15.13 for $R_0 = 150$. Thus, choosing a random value for R_0 and a nonzero value for Φ will produce curves similar to Figures 3-15.11 and 3-15.12, but shifted either to the right or to the left.

Figure 3-15.11. Stochastic model. Gas temperature. $\phi = 50$.

Figure 3-15.13. Deterministic model. Effect of reducing R_0 to 150.

Figure 3-15.12. Stochastic model. Gas temperature. $\phi = 100$.

The main projected use of the stochastic fire curves such as Figures 3-15.11 and 3-15.12 is as an input to modules which will calculate the effect of the fire on fire barriers and subsequently trace the possible spread of fire to adjacent compartments. As an illustration of the kind of results obtainable, Hasofer and Beck⁴² studied one particular measure of fire severity, normalized heat load, H , proposed by Harmathy and Mehaffy.⁴⁵ They obtained histograms of the values of H based on 1500 simulations of the fire curves with $\Phi = 100$ for two cases. In the first case, both the initial burning rate, R_0 , and the total fuel mass, B_{max} , were considered as fixed quantities. In this case, in degrees Celsius, the mean of H was 8063.5 and the standard deviation was 849.8. In the second case, R_0 and B_{max} were considered as independent random variables with lognormal distributions. The parameters mean and coefficient of variation had the values of 280 and 0.3 for R_0 and 82.5 and 0.3 for B_{max} . The mean of H increased only slightly to 8222.2, but the standard deviation almost tripled to 2471.6.

A histogram was drawn for the maximum temperature reached, based on 1500 simulations with $\Phi = 100$ and R_0 and B_{max} as independent random variables. This exercise revealed values of 1181.1 and 176.6 for the mean and standard deviation, respectively, of the maximum temperature.

The stochastic model discussed above only takes account of uncertainties governing certain parameters in a deterministic model of fire spread relating to a single material or object. The model does not take account of uncertainties governing the spread of fire from object to object.

However, it may be possible to use the outputs of this model for different objects to construct the matrix of transition probabilities required for a Markov model, discussed earlier, for fire spread from object to object in a room or compartment. Further research in bridging the gap between deterministic fire growth models and stochastic fire growth models is currently being carried out at Victoria University of Technology in Australia.

Other Models

Branching processes⁴⁶ can be relevant for fire spread in a building in which a material first ignited (first generation) ignites one or more other materials (second generation), which ignite other materials (third generation), and so on, leading to the spread of fire throughout the building. The number of offsprings (burning materials) vary randomly from one generation to another, depending on the distances between ignited and unignited materials, ventilation, and other factors affecting fire spread. Hence, there is a need to develop a branching process model applicable to random environment.⁴⁷

For predicting the damage to buildings and other properties resulting from incendiary or nuclear attacks, Phung and Willoughby⁴⁸ considered two types of stochastic models. In the first model, the entire fire front was regarded as a random walker moving along a linear row of cells or small square areas. In each short time interval the front may be in one of three states: (1) die or stop permanently, (2) spread or move one cell forward, or (3) pause or stay where it is. Simple probability considerations provide an estimate of the probability P_n that, at time t , the fire will be n cell units long after an initial condition of being lit at time zero

$$P_n = \exp[-(\lambda + \mu)t] \lambda^n \mu^n$$

The parameters λ and μ are, respectively, the probabilities for forward spread and burnout during a short time interval. The fire will stay where it is, with probability $[1 - (\mu + \lambda)]$.

The second stochastic model of Phung and Willoughby was called *fuel-state* model, because it dealt explicitly with the state of the fuel in each cell. In the burning process, the fuel changes from the unignited to the burnout state passing through the flaming state. A cell will be in one of these three states at any time with probabilities U , F , and B for unignited, flaming, and burnout states, respectively. In a two-dimensional array of cells, the cell dimension can be so chosen that a burning cell can ignite the immediate neighbor cells but not those that are farther away. Under this assumption, an unignited cell can be ignited by one or more of its eight (8) immediate burning neighbors with probability

$$P = 1 - (1 - P_1)(1 - P_2) \dots (1 - P_8)$$

where $P_1, P_2 \dots P_8$ denotes the chances of ignition by the neighbors. These eight spread probabilities are not necessarily symmetrical, due to factors such as wind and topography. Using the formulation described, differential

equations are derived for U , F , and B for each cell with the condition $(U + F + B) = 1$, solutions of which can be obtained by numerical calculations using computers, if necessary.

CHAPTER 16

Explosion Protection

Robert Zalosh

Introduction

Combustible gases, vapors, and dusts/powders represent explosion hazards when and if they are mixed with air (or some other oxidant) in proportions between the lower and upper flammable limits. The explosion hazard is associated with the premixing of fuel and oxidant in a confined environment prior to the introduction of an ignition source. Upon ignition, flame propagates through the fuel-oxidant mixture, and the confinement prevents the unrestrained expansion of the combustion products. The result is the rapid development of a potentially damaging pressure increase.

Explosion hazard evaluations usually entail (1) recognizing the potential formation of a flammable fuel-air mixture, (2) identifying potential ignition sources present after fuel-air mixture formation, and (3) determining the resulting explosion pressures and their implications with regard to structural damage potential. Explosion protection measures interrupt this sequence of explosion events either by (1) preventing fuel-air mixture formation (e.g., by ventilation or inerting), (2) eliminating potential ignition sources (e.g., by grounding equipment to prevent electrostatic discharges), or (3) limiting pressure buildup (e.g., by explosion venting or explosion suppression). This chapter provides an engineering framework for performing this type of explosion hazard and protection measure evaluation.

Flammability, Explosibility, and Inerting

Gases and Vapors

Flammable limit concentrations for gases and vapors are traditionally determined in a glass test vessel that al-

lows observation of any flame propagation. In some cases, the test vessel is a 5- to 10-cm-diameter, 1.5-m-long, glass tube,¹ while in other cases a 5-liter-capacity (22-cm-diameter) flask is used.² A spark situated either at the open lower end of the tube, or near the center of the flask is triggered to determine the flammability of a gas-air mixture of known concentration. If ignition results in flame propagation to the top of the tube, or upward and outward from the center of the flask,² the mixture is deemed flammable. The lower flammable limit is the average value of (1) the lowest gas/vapor concentration capable of supporting flame propagation and (2) the largest concentration that does not result in flame propagation. Similarly, the upper flammable limit is average value of (1) the highest gas/vapor concentration for which flame propagation is observed and (2) the lowest concentration at which there is no propagation. The chapter in this handbook entitled "Flammability Limits of Premixed and Diffusion Flames" (Section 2, Chapter 7) has tabulated values of the lower and upper flammable limits reported previously by Zabetakis.¹

Flammability limit testing is also sometimes performed in pressure vessels that allow pressure increases to indicate flame propagation. Since this type of test is a more direct measure of explosion hazards, the data are usually called explosion limits. In some cases (e.g., methane lower limit and hydrogen upper limit) the flammability limits and explosibility limits are virtually the same, but in other cases (e.g., methane upper limit and hydrogen lower limit) there can be substantial differences. In practice, flammability limits are used when the criterion is the prevention of flame propagation, and explosibility limits are used either when the criterion is the avoidance of a significant overpressure, or when flammability limits are needed at elevated temperatures or pressures.³ Upper flammable limits are more sensitive to pressure variations than lower limits, except at very low pressures (typically less than one-tenth of an atmosphere) where the two limits suddenly narrow and the gas or vapor becomes nonflammable.⁴

The maximum safe oxygen concentration for explosion prevention via inerting is called the limiting oxidant

Dr. Robert Zalosh is a professor of fire protection engineering at Worcester Polytechnic Institute. He previously worked for Factory Mutual Research Corporation where he initiated the explosion research group and was manager of the applied research department. Professor Zalosh has been a member of the NFPA Committee on Explosion Protection Systems for more than 20 years.

concentration (LOC) in NFPA 69, *Standard on Explosion Prevention Systems*, 1997 edition.⁵ Representative values for the limiting oxygen concentration for nitrogen inerting and carbon dioxide inerting are listed in Table 3-16.1. The LOC for carbon dioxide inerting of all of the flammable vapors/gases in Table 3-16.1 except hydrogen is in the range 11.5 to 14.5 volume percent, whereas the corresponding range for nitrogen inerting is 9.5 to 12 volume percent.

The volume percent of inert gas needed to reduce the oxygen concentration to the LOC values shown in Table 3-16.1 is

$$\% \text{ Inert} = 100 - 4.76(\text{LOC})[1 + (F/A)] \quad (1)$$

where F/A is the fuel/air volumetric ratio for the most challenging gas-air mixture for inerting. Values of F/A can be determined if the complete fuel-air-inert flammability diagram is available. Flammability diagrams for methane and for n -hexane are given in the chapter "Flammability Limits of Premixed and Diffusion Flames." The F/A corresponding to the nose of the methane flammability diagram is the stoichiometric ratio of 0.105. The F/A corresponding to the nose of the n -hexane flammability diagram is approximately 0.03, which is somewhat greater than the stoichiometric ratio for hexane-air. Since

Table 3-16.1 Limiting Oxygen Concentrations for Fuel-Air Mixtures with Added N_2 or CO_2 ⁵

Fuel	Limiting Oxygen Concentration for Nitrogen Inerting	Limiting Oxygen Concentration for Carbon Dioxide Inerting
Gases and vapors		
Acetone	11.5	14
<i>n</i> -Butane	12	14.5
Ethanol	10.5	13

Polycarbonate	—	15
Silicon	11	12
Stearic Acid and Metal Stearates	10.6	13
Sulfur	—	12
Zinc	9	10
Zirconium	0	0

the worst-case F/A value is $\ll 1$ for most flammable gases and vapors, a reasonably conservative approximation for use in the absence of the complete flammability diagram would be to set $F/A = 0$ in evaluating the volume of inert gas needed via Equation 1.

It is important to recognize that practical applications of flammability/explosibility data for explosion hazard evaluations should account for nonuniform or stratified vapor-air mixtures. The accuracy, response-time, and reliability of the oxygen monitoring instrumentation is another important consideration. Based on these considerations, the guidelines for inerting systems given in NFPA 69 state that the maximum allowable oxygen concentration should be at least 2 volume percent below the LOC when the concentration is continuously monitored. If the oxygen concentration is not continuously monitored, a greater margin of safety is needed.

Combustible Dusts and Powders

Combustible dusts and powders pose a potential explosion hazard when their characteristic particle size is smaller than 100 to 400 micrometers (depending on material combustibility) and they are suspended in air at a concentration between the lower and upper explosive limits. Typical lower explosive limits for dusts with characteristic particle sizes less than about 100 micrometers are in the 30- to 60-g/m³ range, which is roughly equal to the range for many flammable gases and vapors when expressed in these units. The upper explosive limit for dusts is typically⁴ between 2000 and 6000 g/m³, but it is a difficult measurement to make and an even more difficult measurement to apply as a practical explosion prevention measure.

Contemporary laboratory testing to determine dust explosibility is conducted with a near-spherical vessel of 20- to 30-liter volume. Figure 3-16.1 is a schematic drawing of a typical 20-l spherical apparatus. The weighed dust sample is placed into an auxiliary dust chamber and is air-injected into the sphere via a perforated dispersion

Figure 3-16.1. Twenty-liter spherical dust explosion apparatus.

ring. An electrical spark or pyrotechnic igniter located in the center of the sphere ignites the dust cloud after a suitable time delay for dispersion. ASTM E1515,⁶ the American standard for determining the minimum explosible concentration (MEC), specifies using either a 2500 J or 5000 J pyrotechnic igniter in a 20-l test vessel. Results are sensitive to the ignition source used and the level of turbulence in the test vessel at the time of ignition. In some cases, MEC results are so sensitive to the igniter energy that tests are needed in a 1-m³ vessel to minimize ignition energy effects.

Minimum explosible dust concentrations, as determined in a 1-m³ vessel, are shown in Table 3-16.2 for representative industrial and agricultural dusts. More comprehensive tabulations are available.^{7,8} The MEC for a given material generally decreases with decreasing particle size, until a limiting size is reached, below which there is no further reduction of the MEC. Apparently, the combustion reaction is limited by the rate of devolatilization (which is dependent on particle surface area) at particle diameters above this limiting size, whereas the flame propagation rate is limited by vapor phase thermochemistry below this limiting size. This explanation is consistent with the equivalence of flammable gas and small-particle combustible dust lower limit concentrations for generically similar materials. For a given material and particle size, the MEC decreases linearly with increasing temperature.⁹

One inherent difficulty in using minimum explosible concentration data is the unknown or deceptively minimal dust concentrations in many industrial facilities. An

example might be a situation in which there is concern about possible explosive dust concentrations in a plastic powder silo. Even if suspended dust concentrations were measured during normal loading and unloading operations, considerably higher concentrations can be generated during upset conditions such as the use of vibrations or air blasts to dislodge powder flow obstructions.

One dust explosion prevention measure for equipment in which dust concentrations cannot be maintained below the MEC, is to use an inert gas to reduce the oxygen concentration. Limiting oxygen concentration data for several dusts are shown in Table 3-16.1. The data for carbon dioxide inerting of organic dusts are in the range 11 volume percent to 15 volume percent, but the LOC values for some of the metals are significantly lower. In fact, the zero LOC for zirconium is indicative of its pyrophoric behavior as a powder. As with the MEC, the LOC for a given dust decreases linearly with increasing temperature, according to the correlations presented by Siwek.⁹

The minimum ignition temperature (MIT) for a dust cloud is usually determined in an apparatus known as the Godbert-Greenwald furnace. A dust sample is air-injected into the top of the preheated vertical tube, and thermocouple measurements indicate whether the dust is ignited before it exits the bottom of the tube. Most of the dusts listed in Table 3-16.2, and in the more extensive tabulation by Eckhoff,⁷ have cloud MIT values in the range 440°C to 750°C.

Dust layer ignition temperatures are usually measured using a 5-mm-thick layer of dust deposited on a hot plate with a temperature control. The temperature is in-

Table 3-16.2 Explosibility Data for Representative Powders and Dusts⁷

Material	Median Particle Size (μm)	Minimum Explosive Concentration (g/m ³)	Minimum Cloud Ignition Temp (°C)	Minimum Layer Ignition Temp (°C)	Minimum Ignition Energy (mJ)	P _{max} (bar-g)	K _{ST} (bar-m/s)

^aThis MEC for polyethylene was determined in a 1.2 liter cylinder.

creased slowly until the dust layer begins to glow. As is evident from the data in Table 3-16.2, the dust layer ignition temperature is often significantly lower than the dust cloud minimum ignition temperature. This is a ramification of the increased heat dissipation rates in a dust cloud compared to the interior of a dust layer.

An important consideration in applying the dust cloud and dust layer ignition temperature data is the frequent occurrence of nonuniform hot wall temperatures. An example is the situation in which a small hot spot is created by mechanical friction, perhaps in a blender or a pulverizer. Data presented by Siwek and Cesana¹⁰ suggest that the small spot (with a temperature of at least 900°C) in a mill or similar process equipment can ignite a dust cloud if the MIT < 600°C as determined in furnace tests.

The minimum ignition energy (MIE) for an electrical spark discharge within a combustible dust cloud is measured via a standardized test conducted in a 1.2-l cylindrical tube, sometimes called a modified Hartmann tube. The International Electrotechnical Commission (IEC) test method described by Siwek and Cesana¹⁰ allows for spark energies in the range from 1 mJ to several hundred mJ. MIE data for the dust samples in Table 3-16.2 range from less than 1 mJ to more than 2000 mJ. For a given material, the MIE is known to be influenced by the following parameters:

- The MIE decreases as the spark duration increases, due to the presence of either inductance or resistance in the capacitive discharge circuit. For example, adding a series inductance in the range 0.1 to 1.0 H, or a series resistance in the range 10^4 to $10^5 \Omega$, decreases the MIE by an order of magnitude. The practical significance of this is that it takes more spark energy for an electrostatic (capacitive) discharge to ignite a dust cloud than for a spark in electrical equipment due perhaps to actuation of an electromechanical switch. The MIE data in Table 3-16.2 were obtained with long duration inductive discharges.
- The MIE decreases as the dust median particle size increases; Siwek and Cesana¹⁰ show that the variation is to the -2.5 power of particle diameter.
- The MIE varies with dust concentration, but the most sensitive concentration depends on the particular material. The data in Table 3-16.2 are for the most sensitive concentration.
- The MIE decreases with increasing air-dust temperature.
- The MIE and the MIT increase with increasing velocity of the dust-air mixture.

The theoretical spark energy can be calculated for simple electrical discharges. For example, the energy (J) in a purely capacitive discharge is $1/2CV^2$, where C is the capacitance (F), and V is the stored voltage prior to discharge. In the case of a purely inductive circuit, the theoretical spark energy is $1/2Li^2$, where L is the circuit inductance, and i is the current (A). The inductance spark energy can be compared directly to the MIE for a particular dust to assess the likelihood of ignition; the capacitive spark energy comparison should account for the higher ignition energies associated with short duration capacitive discharges. The energy associated with mechanical fric-

tion and impact sparks is much more difficult to determine. Siwek and Cesana¹⁰ state that such sparks will only ignite dusts with MIE values < 10 mJ and MIT values < 500°C.

EXAMPLE 1:

Coal feed rates and airflow rates at two coal pulverizers are as follows. At Pulverizer A the bituminous coal feed rate is 1.9 kg/s and the airflow rate is 7.1 m³/s. At Pulverizer B the coal feed rate is 13.9 kg/s and the airflow rate is 7.1 m³/s.

Are the pulverizer outlet coal dust concentrations within the explosive range? If both coals have a Godbert-Greenwald furnace ignition temperature of 510°C, would you expect a dust explosion to occur if there is a frictional hot spot or a frictional spark in the pulverizer?

SOLUTION:

The pulverizer outlet coal dust concentration during steady-state operation is equal to the coal feed rate divided by the airflow rate. The concentrations for these two pulverizers are 0.27 kg/m³ for Pulverizer A and 1.96 kg/m³ for Pulverizer B. The Pulverizer A concentration is well within the explosive limits for typical bituminous coals. The Pulverizer B concentration is close to the reported upper explosive limit for coal (2 to 4 kg/m³). Since the MIT of both coals is in the range 500 to 600°C, we would expect them to be ignitable by sustained mechanical friction that produces wall temperatures in the range 600 to 900°C depending on the size of the heated area; we would not expect ignition by short-duration mechanical impact sparks because the cloud MIT is greater than 500°C. This suggests that a temperature monitor in the pulverizer could be used to shut down the pulverizer well before the wall temperature approaches 600°C, either from mechanical friction or smoldering coal.

EXAMPLE 2:

An elevated silo with an electrical capacitance of 500 picofarads is used to store a pharmaceutical powder with a minimum ignition energy of 10 mJ for inductive sparks and 50 mJ for capacitive sparks. If the silo is not adequately grounded, what would its minimum voltage have to be in order for an electrostatic spark to ignite the cloud of powder in the silo, or being discharged from the silo?

SOLUTION:

The voltage needed to generate an electrostatic spark of capacitive energy E is equal to $\sqrt{2E/C}$, which in this case is equal to

$$\sqrt{\frac{2(50 \times 10^{-3} \text{ J})}{500 \times 10^{-12} \text{ F}}} = 1.4 \times 10^4 \text{ V} = 14 \text{ kV}$$

A very high voltage of this magnitude may indeed be generated from the continuous impact/friction of the powder during filling and unloading. Although grounding of the silo would prevent high voltage from accumulating on the silo itself, there is also a hazard associated with electrostatic charge accumulation on ungrounded

objects and equipment in the silo, and possibly on the powder itself if it has a high electrical resistivity.

Closed Vessel Deflagrations

Ignition of either a gas-air mixture or a dust cloud in an unvented enclosure will usually result in a deflagration (i.e., flame propagation at subsonic speed away from the ignition site). The pressure developed in the enclosure is dependent on the extent of flame propagation, and the temperature and composition of the burned gas. If the flame has propagated throughout the enclosure, the ratio of the deflagration pressure to the initial pressure in the enclosure can be obtained from the ideal gas equation as it applies to the postdeflagration and predeflagration gas-air mixtures, both of which occupy the same enclosure volume. Thus

$$\frac{P_m}{P_0} = \frac{n_b T_b}{n_0 T_0} \quad (2)$$

where

P_m = pressure developed at the completion of a closed vessel deflagration

P_0 = initial pressure in the enclosure

n_b = number of moles of burned gas at the completion of the deflagration

n_0 = number of moles of gas-air mixture initially in the enclosure

T_b = temperature of the burned gas at the completion of the deflagration

T_0 = initial temperature of the gas-air mixture

Equation 2 is applicable to both gas deflagrations and dust deflagrations. However, in the case of dust deflagrations, the effect of the dust does not appear explicitly in the equation because only the gas temperature and composition determine the deflagration pressure. Conservative estimates of burned gas temperature and composition can be obtained using the assumption that combustion occurs adiabatically at constant volume. Thus, the calculation of deflagration pressures becomes an exercise in thermochemical equilibrium in which the initial fuel-oxidant mixture is specified to react adiabatically at constant volume. Various computer codes can be used to do these calculations.

Calculated results obtained with the STANJAN code (written and distributed by Professor William Reynolds of Stanford University) are shown in Figure 3-16.2(a) for the adiabatic, constant-volume flame temperature, for methane-air, propane-air, and hydrogen-air mixtures of varying concentration. The fuel concentration used in Figure 3-16.2 is the equivalence ratio, defined as the fuel-to-air ratio divided by the stoichiometric fuel-to-air ratio. In terms of fuel volume fraction, x , the equivalence ratio is equal to $[x(1 - x_{st})]/[x_{st}(1 - x)]$, where x_{st} is the stoichiometric volume fraction of fuel. The stoichiometric fuel volume fraction for methane-air is 0.095, for propane-air is 0.040, and for hydrogen-air is 0.296. The calculated adiabatic constant-volume flame temperatures shown in Figure 3-16.2(a) are generally 200°C to 400°C higher than the

corresponding adiabatic, isobaric flame temperatures for the same fuel-air concentrations.

Calculated adiabatic constant-volume deflagration pressures for the same fuel-air mixtures are shown in Figure 3-16.2(b). The maximum pressures for each flammable gas occur at fuel equivalence ratios in the range 1.1 to 1.2 (i.e., at slightly richer than stoichiometric concentrations). These worst-case deflagration pressures are in the range 8 to 9.6 atm abs. Theoretical values of P_m at an equivalence ratio of 0.5, which corresponds to the lower flammable limit for methane and propane, are in the range 6 to 6.5 atm abs. Experimental measurements of closed vessel deflagration pressures agree well with the theoretical values of P_m at near-stoichiometric concentrations, but are significantly less than the theoretical values at concentrations near the lower and upper flammable limits. The reasons

Figure 3-16.2(a). Calculated adiabatic, constant-volume flame temperatures as a function of equivalence ratio.

Figure 3-16.2(b). Flammable gas-air deflagration pressures as a function of fuel equivalence ratio.

for the deviation at near-limit concentrations are 1) incomplete combustion due to flame propagation through only a portion of the enclosure and 2) slow flame propagation allowing time for heat losses from the burned gas mixture to the enclosure walls. As an example of the incomplete combustion, extensive deflagration testing of lean hydrogen-air mixtures has shown that the fraction of hydrogen burned ranges from zero to one as the hydrogen concentration increases from its lower limit of 4 volume percent to 8 volume percent, and remains equal to approximately one (complete combustion) as the hydrogen concentration ranges from 8 volume percent to about 40 volume percent (equivalence ratio of 1.6).

Measured values of P_{\max} (worst-case P_m) are shown in Table 3-16.3 for twelve flammable gases and vapors. All but two values are in the range 6.8 bar g to 8.1 bar g. The two exceptions are acetylene ($P_{\max} = 10.6$ bar g) and ammonia ($P_{\max} = 5.4$ bar g).

Theoretical values of P_m can also be calculated for combustible dusts using a thermochemical equilibrium computer code, such as the NASA code CET89, that contains extensive properties for condensed phase materials. Experimental values of P_m depend on particle size as well as dust concentration. The effect of particle size is illustrated by the data in Figure 3-16.3. The value of P_{\max} for three of the four dusts is invariant with particle size providing the median particle diameter is no greater than 100 μm . However, for polyvinylchloride (which is significantly less combustible than the other three materials), P_{\max} decreases with increasing median particle size for all particles greater than 20 μm , and cannot be ignited at all at particle sizes of 150 μm and larger. The effect of dust concentration on P_{\max} is such that the worst-case concentration often occurs at a concentration of about 500 g/m³, which for many organic materials is roughly twice the stoichiometric concentration, and five to ten times the minimum explosible concentration. Values of P_{\max} for the twenty dust samples listed in Table 3-16.2 are in the range 6.7 bar g to 11.2 bar g (i.e., about the same range as the values of P_{\max} for flammable gases and vapors).

Table 3-16.3 Deflagration Parameters for Flammable Gases and Vapors in Air^a

Gas or Vapor	P_{\max} (bar g)	Laminar Burning Velocity (cm/s)	K_G (bar·m/s)
Acetylene	10.6	166	1415
Ammonia	5.4	—	10
<i>n</i> -Butane	8.0	45	92
Diethyl ether	8.1	47	115
Ethane	7.8	47	106
Hydrogen	6.8	312	550
Isopropyl alcohol	7.8	41	83
Methane	7.1	40	55
Methyl alcohol	7.5	56	75
<i>n</i> -Pentane	7.8	46	104
Propane	7.9	46	100
Toluene	7.8	41	94

Figure 3-16.3. Effect of particle size on deflagration pressure and rate-of-pressure rise.^b

The rate of pressure rise during a deflagration is primarily dependent on the rate of flame propagation and the vessel size, as well as the flame temperature. Theoretical calculations are usually based on the following assumptions. First, it is assumed that the flame speed is small in comparison to sound speed so that the pressures in the enclosure are spatially uniform at any given time during the deflagration. The rate of flame propagation relative to the unburned gas ahead of the flame front is called the burning velocity, S_u . The mass burning rate is

$$\frac{dm_b}{dt} = -\frac{dm_u}{dt} = \rho_u \chi S_u A_f \quad (3)$$

where

m_b = mass of burned gas in enclosure at time t

m_u = mass of unburned gas in enclosure at time t

ρ_u = density of unburned gas at time t

A_f = surface area of flame front at time t

χ = ratio of turbulent burning velocity to laminar burning velocity

Flame propagation into a near-stoichiometric gas-air mixture will occur as an expanding spherical flame until the flame approaches the walls of the enclosure. Laminar burning velocities have been measured for worst-case concentrations of many gases and vapors. Values are listed for the twelve gases/vapors in Table 3-16.3. Representative

values for the alkanes and many other hydrocarbons are 40 to 47 cm/s. Expansion of the burned gas, and the corresponding motion of the unburned gas away from the ignition site as the flame propagates, causes the actual flame velocity relative to a fixed observer (i.e., the flame speed) to be significantly larger than the burning velocity. Before any compression occurs, the flame speed is $(T_b/T_0)S_u$, which is equal to 350 to 440 cm/s for many hydrocarbons at near-stoichiometric concentrations. Turbulent motion of the unburned gas can further increase the burning velocity and flame speed, as represented either by the augmentation factor χ , or by generating wrinkled or distorted flames with corresponding larger flame surface areas, A_f .

A second key assumption invoked in most theoretical models of closed vessel deflagrations is that the fractional pressure rise at any time during the deflagration is equal to the fraction of the total mass burned, that is,

$$\frac{P - P_0}{P_m - P_0} = \frac{m_b}{m_0} \quad (4)$$

where

P = deflagration pressure at time t

m_0 = total mass in the enclosure

The justification for Equation 4 is that it has been verified by more complicated models, such as the Complete Computer Solution described by Bradley and Mitcheson,¹¹ as well as by experimental data reported in that paper and in Lewis and von Elbe.¹² Equation 4 can also be used to calculate the maximum pressure developed in enclosures that are partially with fuel-air mixtures (i.e., partial volume deflagrations).

The third assumption needed for a closed vessel deflagration model is the type of thermodynamic process undergone by the unburned gas as it is compressed. The most common assumption is that the unburned gas is compressed isentropically [i.e., $P/P_0 = (\rho/\rho_u)^\gamma$], where γ is the ratio of specific heats of the unburned gas (1.4 for most flammable hydrocarbon-air mixtures). Although it is not necessary, it is also common to assume the flame continues to propagate spherically such that its radius at any time t is r_b in a vessel of radius a . The resulting equations for $P(t)$ and $r_b(t)$ are

$$\frac{dP}{dt} = \frac{3\chi S_u}{a} \left(\frac{P}{P_0}\right)^{1/\gamma} (P_m - P_0) \left(\frac{r_b}{a}\right)^2 \quad (5)$$

$$\left(\frac{r_b}{a}\right)^2 = \left[1 - \left(\frac{P_0}{P}\right)^{1/\gamma} \left(\frac{P_m - P}{P_m - P_0}\right) \right]^{2/3} \quad (6)$$

Equations 5 and 6 can be solved simultaneously starting from the initial condition that $r_b/a = \varepsilon$ at $t = 0$, where ε is some small number $\ll 1$ representing the kernel of flame at ignition. An example solution for $P(t)$ and $r_b/a(t)$ for the case $S_u = 45.5$ cm/s, $\chi = 1$, $P_m = 640$ kPa g, $a = 7.15$ m is shown in Figures 3-16.4(a) and 3-16.4(b). The curve in Figure 3-16.4(a) labeled *numerical solution* refers to the numerical integration of Equation 5. The curve labeled *analytical*

Figure 3-16.4(a). Pressure versus time for a closed vessel deflagration with $S_u = 45.5$ cm/s, $a = 7.15$ m, and $P_m = 640$ kPa g.

Figure 3-16.4(b). Calculated nondimensional flame radius during deflagration.

approximation refers to the following simplified solution for $P(t)$ early in the deflagration when $(P - P_0)/P_0 \ll 1$.

$$\frac{P - P_0}{P_0} = \left(\frac{1}{\gamma} + \frac{P_0}{P_m - P_0} \right)^2 \left(\frac{P_m - P_0}{P_0} \right)^3 \left(\frac{\chi S_u t}{a} \right)^3 \ll 1 \quad (7)$$

The analytical approximation in Figure 3-16.4(a) is virtually identical to the numerical solution when $P < 2$ psig, and only differs by about 20 percent up to $P = 8$ psig. The flame radius at the time $P = 2$ psig is equal to half the enclosure vessel radius, and it is equal to 80 percent of the vessel radius when $P = 16$ psig. Since the pressure ultimately increases to 93 psig in this particular deflagration, it is clear that most of the pressure increase occurs when

the flame has propagated very close to the enclosure wall, such that the entire enclosure is almost filled with flame.

The continued integration of Equation 5 up to $P = P_m$ would require an empirical correlation to account for the variation of S_u with increased pressure and temperature of the unburned gas as it is compressed. Bradley and Mitcheson¹¹ have carried out nondimensionalized solutions using such correlations. Their results indicate that the time, t_m , at which P reaches P_m can be approximated as

$$t_m = \frac{a}{0.3S_u}$$

where the burning velocity is the mean value of the burning velocities at the beginning and end of the deflagration (i.e., when $P = P_0$ and $P = P_m$). In other words, the mean flame speed, a/t_m , during the deflagration is equal to 3.3 times the mean burning velocity.

Experimental measurements of the rate-of-pressure-rise in a closed vessel explosion are often characterized in terms of the parameter, K_G , defined as

$$K_G = \left(\frac{dP}{dt} \right)_{\max} V^{1/3} \quad (8)$$

where V is the vessel volume, and the maximum rate of pressure rise is measured at the inflection point in the P -versus-time curve. Theoretically, there is no inflection point (because there is no heat loss or other mechanism to decelerate the flame), and $(dP/dt)_{\max}$ occurs when $P = P_m$. Based on Equation 5, the theoretical relationship between K_G and S_u is

$$K_G = 4.84\chi S_u \left(\frac{P_m}{P_0} \right)^{1/\gamma} (P_m - P_0) \quad (9)$$

Experimentally determined values of K_G listed in Table 3-16.3 for the various gases and vapors indicate that they generally increase as S_u increases, but that they are not necessarily linearly proportional to S_u . This is a manifestation of the fact that the turbulence factor, χ , varies among the individual gases and vapors in a manner that cannot be predicted a priori.

The effect of turbulence on the rate-of-pressure-rise is even more important in the case of dust explosions. There is inherently some level of turbulence in every dust explosion because some type of disturbance or initial motion is needed to generate the dust cloud. One convenient, albeit indirect, measure of the turbulence level is the time delay between the beginning of dust injection and ignition actuation. The turbulent motion in the vessel is a maximum when the dust is first injected, and decays significantly by the time the entire dust cloud has entered the vessel. Figure 3-16.5 shows how the ignition delay time influences the values of P_{\max} and $(dP/dt)_{\max}$ measured in a 1-m³ vessel with coal dust and with aluminum dust. In view of the importance of this effect, a standardized test method has been developed¹³ in the interest of obtaining reproducible results in different test vessels and laboratories. Values of $K_{ST} = [(dP/dt)_{\max}]V^{1/3}$ obtained for various dusts using this standardized injection and ig-

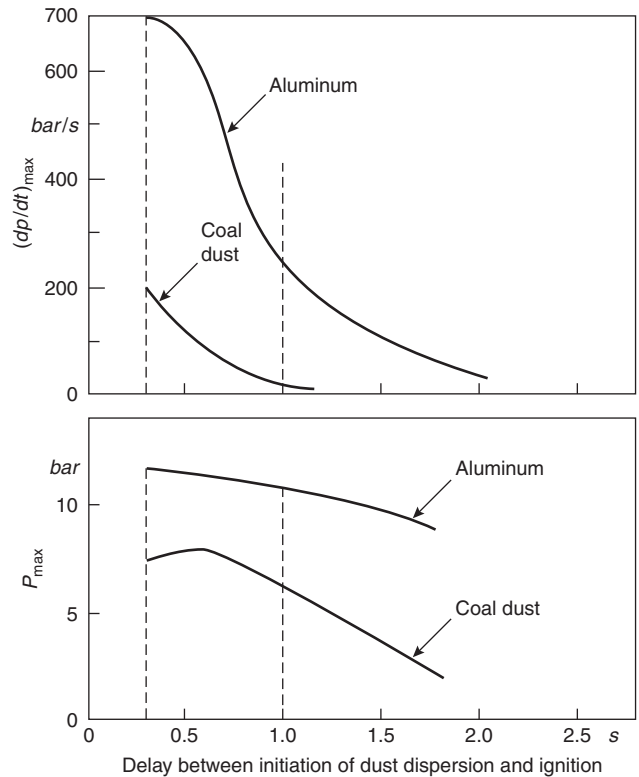

Figure 3-16.5. Effect of ignition delay time on deflagration pressure and rate-of-pressure-rise.⁷

nition delay methodology are listed in Table 3-16.2. Except for aluminum, all of the dusts listed have K_{ST} values no greater than 208 bar·m/s. A more direct measure of turbulence level is the root-mean-square fluctuating air velocity in the vessel. Measurements of this rms velocity as a function of time following the initiation of dust injection have been carried out by several researchers and their results are summarized in Eckhoff's textbook.⁷ Eckhoff also provides a summary of some theoretical models for closed vessel dust deflagrations that are analogous to the one described for gas explosions, but account for the finite particle burn time and corresponding finite flame thickness in dust explosions.

One special consideration in dust explosions is the propensity for damaging secondary explosions. These secondary dust explosions arise when a gas or dust deflagration in some process equipment causes the equipment to fail (because it cannot withstand the closed vessel deflagration pressure, P_{\max}), and produce a strong disturbance in the form of a blast wave and associated air motion. This disturbance often causes the dust that has settled on walls and floors to be put into suspension and form a combustible dust cloud. Even if the subsequent cloud occupies only a small fraction of the building, it is often ignited by the flame that has also emerged from the breached process equipment. If the secondary explosion occurs in an occupied building, it can produce numerous

casualties as well as building structural damage. The quantities of dust needed to generate a particular pressure rise can be estimated using Equation 4.

EXAMPLE 3:

Approximately 200 g of *n*-butane are released into an aerosol can-filling room due to a valve misalignment on one large deodorant can. Suppose the butane mixes in stoichiometric proportions with a portion of the air in the $4 \times 4 \times 3$ m room and is subsequently ignited. What will the peak pressure be in the absence of any explosion venting?

SOLUTION:

Equation 4 can be used to solve this problem if we first calculate the mass of butane needed to fill the entire room with a stoichiometric butane-air mixture. We can do this calculation in terms of the mixture density, ρ_0 , and the butane mass fraction as follows:

$$m_0 = \left(\frac{x_{\text{but}} M_{\text{but}}}{M_{\text{mix}}} \right) \rho_0 V$$

where the mixture molecular weight, M_{mix} , is calculated based on the stoichiometric concentration of butane (3.1 volume percent).

$$\begin{aligned} M_{\text{mix}} &= x_{\text{but}} M_{\text{but}} + (1 - x_{\text{but}}) M_{\text{air}} \\ &= (0.031)(58) + (1 - 0.031)(28.8) = 29.7 \end{aligned}$$

The mixture density (which is not much different than air density) is calculated from the ideal gas equation:

$$\begin{aligned} \rho_0 &= \frac{M_{\text{mix}} P_0}{RT_0} = \frac{(29.7 \text{ kg/kmol})(101 \times 10^3 \text{ Pa})}{(8314 \text{ J/kmol} \cdot \text{K})(298 \text{ K})} \\ &= 1.21 \text{ kg/m}^3 \end{aligned}$$

$$\begin{aligned} \text{Therefore, } m_0 &= \left[\frac{(0.031)(58)}{29.7} \right] (1.21 \text{ kg/m}^3)(48 \text{ m}^3) \\ &= 3.52 \text{ kg.} \end{aligned}$$

$$\text{and } m_b/m_0 = (0.20 \text{ kg})/(3.52 \text{ kg}) = 0.057.$$

Using the value for $P_m - P_0$ for *n*-butane in Table 3-16.3,

$$P - P_0 = (8.0 \text{ bar g})(0.057) = 0.456 \text{ bar g} = 6.6 \text{ psig.}$$

We note that since this pressure is greater than the strength of rooms in industrial facilities, some form of explosion venting and explosion suppression would be needed. We also note that this scenario is entirely possible even though the 200 g of *n*-butane released would be too small to form a flammable mixture if it was dispersed uniformly throughout the 48 m^3 enclosure.

EXAMPLE 4:

Determine the value of χ , the ratio of turbulent-to-laminar burning velocity, corresponding to the K_G value listed in Table 3-16.3 for *n*-butane.

SOLUTION:

The value of χ can be calculated using Equation 9 as follows:

$$\begin{aligned} \chi &= \frac{K_G}{4.84 S_u \left(\frac{P_m}{P_0} \right)^{1/\gamma} (P_m - P_0)} \\ &= \frac{92 \text{ bar} \cdot \text{m/s}}{4.84(0.45 \text{ m/s})(9.0)^{1/1.4}(8 \text{ bar})} = 1.10 \end{aligned}$$

This suggests that the flame speed in the test used to determine K_G was not significantly faster than the speed corresponding to the laminar burning velocity for a worst-case butane-air mixture.

EXAMPLE 5:

A coal-fired power plant has bituminous coal dust layers with a mass-per-floor-area of 1000 g/m^2 in an enclosure with a 4-m ceiling height. Assume the coal dust layer is dispersed by a primary explosion such that it forms a worst-case dust cloud with a concentration of 500 g/m^3 in the lower portion of the enclosure. What would the pressure increase due to a secondary explosion in the enclosure without any explosion venting be?

SOLUTION:

Equation 4 can be used to solve this problem if we use both m_b and m_0 on a per-unit-floor-area basis. Thus, $m_0/A = (500 \text{ g/m}^3)(4 \text{ m}) = 2000 \text{ g/m}^2$, and we are given $m_b/A = 1000 \text{ g/m}^2$. Using the value of $P_m - P_0$ for bituminous coal in Table 3-16.2,

$$P - P_0 = (9.1 \text{ bar g})(1/2) = 4.55 \text{ bar g} = 66 \text{ psig}$$

If the volumetric bulk density of the coal dust layer is equal to a typical value of 500 kg/m^3 , the corresponding coal dust layer thickness would be

$$\frac{1.00 \text{ kg/m}^2}{500 \text{ kg/m}^3} = 2 \times 10^{-3} \text{ m} = 2 \text{ mm}$$

Detonations

A detonation is an explosion in which the combustion wave (i.e., flame) propagates at supersonic speeds through the unburned fuel. Detonations are fundamentally different than the closed vessel deflagrations described in the previous section of this chapter. Since flames in a deflagration propagate at speeds well below the speed of sound (which is about 340 m/s in room temperature air), the pressure increase during a deflagration occurs virtually uniformly throughout the enclosure as the explosion evolves. In contrast, the pressure rise during a detonation is highly nonuniform and occurs virtually instantaneously as the shock wave propagates through the gas-air mixture. If the flame speed is slightly less than the speed of sound, such that the pressure rise is nonuniform but shock waves do not occur, the explosion is called a quasi-detonation.

The practical significance of this fundamental difference between detonations and deflagrations is that they require different approaches to explosion protection. The sudden, spatially nonuniform pressure rise during a detonation or quasi-detonation precludes the use of explosion venting or explosion suppression systems. Furthermore, the high-peak, short-duration detonative pressure loads warrant special considerations in the evaluation of structural resistance.

The peak pressure during a detonation can be calculated from the classical Chapman-Jouguet theory, which is a combination of thermochemical equilibrium and gas dynamic conservation equations across the detonation front.^{12,14} Figure 3-16.6 shows calculated detonation pressures as a function of fuel concentration for seven different flammable gases. Chapman-Jouguet calculations for these and other mixtures can be conducted with both the STANJAN and CET89 computer codes mentioned previously for deflagration calculations. Burgess et al.¹⁴ and others have suggested that a good approximation to the Chapman-Jouguet detonation pressure, P_{CJ} , is $P_{CJ} = 2P_m$ (i.e., twice the closed vessel deflagration pressure). This approximation represents a much simpler alternative to the Chapman-Jouguet theory of calculating detonation pressures. As indicated in Figure 3-16.6, P_{CJ} for a near-stoichiometric gas-air mixture initially at atmospheric pressure is in the range 16 to 20 atmospheres.

The pressure distribution behind the C-J detonation front is shown in Figure 3-16.7 for the case of a detonation wave propagating in both directions away from the initiation site in a tube. Behind the propagating detonation front the pressure decreases to a plateau value equal to about 0.35 P_{CJ} . The speed of propagation is equal to the C-J Mach number times the speed of sound in the unburned gas-air mixture. If the tube has one or more closed ends, the detonation wave will be reflected and propagate in the reverse direction with increased amplitude. If the

Figure 3-16.6. Calculated Chapman-Jouguet detonation pressures.

Figure 3-16.7. Pressure distribution in C-J detonation wave propagating through a tube.

end wall is rigid, the reflected shock wave for many gas-air mixtures is equal to 2.76 P_{CJ} . If the end wall is open, the detonation wave will be reflected as a rarefaction wave propagating back toward the detonation initiation site.

The structural load associated with a detonation wave depends on the impulse, I_D , per unit area, where

$$I_D(x, t) = \int_{t_a}^t [p(x, t) - p_a] dt \quad (10)$$

The detonation front arrival time, t_a , is equal to $x/(M_D a_1)$, where x is the distance from the detonation initiation site, M_D is the detonation Mach number, and a_1 is the speed of sound in the unburned gas-air mixture.

Neglecting any reflected waves, Sichel¹⁵ has shown that a good approximation for I_D is

$$I_D = \frac{0.35 \rho_1 a_1 M_D x}{(\gamma_2 + 1)} \quad (11)$$

where γ_2 is the ratio of specific heats in the burned gas; in many cases γ_2 is equal to 1.2. The C-J detonation Mach numbers for several stoichiometric gas-air mixtures are listed in Table 3-16.4. They are in the relatively narrow range 4.9 to 5.5. The unburned gas sound speed for most stoichiometric hydrocarbon-air gas mixtures is in the narrow range 330 m/s to 350 m/s, while for hydrogen it is 403 m/s.

An interesting aspect of Equation 11 is that the specific impulse is linearly proportional to the distance from detonation initiation site. Burgess et al.¹⁶ note that pipeline detonations often cause periodic ruptures along the pipeline length, with each break serving as a pressure relief expansion, requiring the pressure duration/impulse to rebuild to the structural failure threshold again by propagating over another length of pipe. Methods to assess the structural damage potential from these impulsive loads generated during detonations are described by Baker et al.¹⁷ One after-the-fact indication of

Table 3-16.4 Detonation Mach Numbers and Cell Sizes for Stoichiometric Gas-Air Mixtures

Gas	C-J Mach Number	Cell Width (cm) ¹⁹
Acetylene	5.46	0.98
<i>n</i> -Butane	—	5.0–6.2
Ethane	—	5.4–6.2
Ethylene	—	2.8
Hydrogen	4.89	1.5
Hydrogen sulfide	—	10
Methane	5.17	28
Propane	5.38	6.9
Propylene	—	5.4

C-J Mach numbers were calculated with the STANJAN computer code.

structural failure due to detonative loads is the occurrence of fragmented structural debris associated with brittle failure, as opposed to the bulging and more ductile failure of structural steel subjected to deflagration pressures beyond the yield point.

In view of the drastically different explosion protection considerations for detonations, it is important to assess the potential for a detonation to occur as opposed to a deflagration. Some guidance, as described below, can be offered for this assessment, but there are no exact criteria to provide an unequivocal answer.

The detonability length scale is the detonation cell width, S_c , shown in Figure 3-16.8. As indicated in Figure 3-16.8, the detonation front consists of a complicated network of curved shock segments that propagate transversely to the detonation propagation direction. The transverse wave structure includes curvilinear triangles with a width S_c . If a smoke foil is inserted on the inner wall of a detonation tube, the detonation cells create a diamond- or fish-scale-shaped pattern on the smoke foil. Detonation cell widths are measured from the traces deposited on these smoke foils as described, for example, by Gelfand et al.¹⁸ The same is true for chemical induction length as a qualitative measure of detonability.

Detonation cell widths can also be correlated with the detonation reaction zone length in a one-dimensional representation of the shock wave initiated chemically reacting flow behind the leading edge of a detonation. This model, which is called a ZND model (the initials stand for three original model developers), requires some chemical kinetics data as well as an assumption about heat losses and drag associated with the tube wall. The calculations and their relationship to cell size are described by Gelfand et al.,¹⁸ by Shepherd,²⁰ and by Stamps et al.²¹

Detonation cell widths measured or calculated for nine different stoichiometric gas-air mixtures are listed in Table 3-16.4. Values range from about 1 cm for acetylene to about 28 cm for methane. These values were obtained at atmospheric pressure and room temperature. Higher initial pressures and temperatures would result in smaller cell widths. Furthermore, some of the gases listed in Table 3-16.4 have smaller cell widths at some fuel-rich concentrations, with minimum values for a given fuel being as much as 40 percent smaller than the values shown in the table.

**Figure 3-16.8. Detonation cell structure.¹⁸**

A sustained detonation can only occur if the characteristic length scale of the gas-air mixture is greater than some multiple of the detonation cell width. The value of the multiplication factor depends on the geometry. In the case of a pipe, the detonation will not propagate down the pipe if the pipe diameter is less than about $S_c/3$. The detonation will not propagate from open end of the pipe into the surrounding gas mixture if the pipe diameter is less than $13 S_c$.

What is the likelihood of a detonation occurring in an enclosure or cloud larger than the critical size indicated by the detonation cell size? The answer depends on the strength of the ignition source and the presence of either a highly elongated geometry or an exceptionally high level of turbulence for promoting flame acceleration. The minimum ignition source energy required for the direct initiation of a detonation ranges from a low of about 5 kJ for acetylene and hydrogen in air to a high estimated to be 93,000 kJ for methane. Since these initiation energies are many orders of magnitude larger than the energies associated with accidental ignition sources, direct initiation can be precluded from almost all accident initiation scenarios.

In the case of a weak (typically accidental) ignition source in a pipe or some other elongated enclosure, the deflagration-to-detonation transition (DDT) distance depends upon the following parameters.

Mixture reactivity. The more reactive the mixture, the more rapid is the flame acceleration to DDT.

Enclosure or pipe wall roughness and the presence of obstruction. The rougher the pipe interior surface or the more obstructions present, the shorter is the transition length to DDT.

Enclosure or pipe diameter. The larger the pipe or enclosure diameter, the shorter is the transition to DDT.

Initial pressure and temperature. The higher the initial temperature and pressure, the shorter is the transition length to DDT.

Initial turbulence level. The more turbulence or initial gas velocity in the enclosure, the shorter is the DDT transition length.

Figure 3-16.9 illustrates how mixture reactivity influences the DDT length/diameter ratio for the case of a smooth walled 2-inch (5-cm) diameter pipe.²² The ratio of DDT transition length to pipe diameter is plotted as a function of the ratio of nitrogen/oxygen concentration for methane, for ethane, and for propane at near-worst-case fuel/oxygen ratios that produce stoichiometric combustion with CO formation instead of CO₂. The L_{DDT} /diameter ratio increases rapidly as the nitrogen/oxygen ratio increases for all three alkanes, with the transition length being shortest for propane and longest for methane. In these experiments, the largest N₂/O₂ ratio at which transition occurred (last data point on each curve), was less than the 3.76 ratio corresponding to air. In other words, the L_{DDT} /diameter ratio for these alkanes in air (at a 2-inch pipe diameter) is larger than the largest ratio (120) measurable in these experiments. The three arrows in the graph represent the absence of transition at the indicated N₂/O₂ ratio. These data are consistent with the experimental observations of Flessner and Bjorkland,²³ who did *not* see DDT with gasoline-air mixtures in a 15-cm-diameter, 16-m-long smooth wall pipe, but saw DDT at a distance of 74 pipe diameters when they inserted an expanded metal liner in the pipe entrance to simulate a rough wall section.

Sherman and Berman²⁴ have developed a semiquantitative methodology to categorize the probability of detonations occurring in specific industrial accident scenarios by subjectively extrapolating the experimental data on the various effects mentioned above. They categorize gas mixture reactivities on the basis of detonation cell size, and they categorize enclosure geometries on the basis of size,

Figure 3-16.9. Deflagration-to-detonation transition length data.²³

confinement, level of obstructions, amount of venting, and so on. They have applied their methodology to the case of a possible hydrogen detonation during hypothesized severe accident scenarios in one particular nuclear plant containment building.

Although most accidental explosions are deflagrations, there are some occasional well-documented accounts of detonation incidents. One excellent example is the Jacobs et al.²⁵ description of a particularly destructive detonation in a section of a petroleum refinery in which a gas mixture of 3 percent naphtha, 19 percent oxygen, and 78 percent inert gas at 105 psig was accidentally allowed to enter several large pieces of process equipment connected by over 1000 ft of piping. Their account of the incident includes a description of the flame propagation path and associated pressures (3000–4000 psi in some locations) developed.

EXAMPLE 6:

A large process oven is heated with a burner utilizing a 1-cm-diameter, 5-m-long fuel line containing a stoichiometric propane-air mixture. What is the likelihood of a detonation occurring in the oven and the fuel line as a result of a delayed ignition after the oven has been inadvertently filled with a fuel-air mixture? How would the situation change if a stoichiometric hydrogen-air mixture replaced the propane-air mixture in the fuel line?

SOLUTION:

From Table 3-16.4, $S_c = 6.9$ cm for a stoichiometric propane-air mixture. Thus, the minimum pipe diameter for detonation propagation in this case is $S_c/3 = 2.3$ cm. Therefore, a sustained propane-air detonation will not propagate through the 1-cm fuel line. If the propane is replaced by hydrogen, $S_c/3 = 0.50$ cm, and a fuel line detonation would be possible, particularly in view of the 500:1 length to diameter ratio.

In order for the detonation to be transmitted into the oven, the fuel line would have to be larger than $13 S_c = 20$ cm for hydrogen. Thus, the oven should not experience a detonation. Explosion venting could be a viable form of explosion protection for the oven.

EXAMPLE 7:

If a detonation did propagate through a stoichiometric hydrogen-air mixture in the fuel line, what would the specific impulse be on the pipe wall? Neglect any reflected shock wave effects, and use a sound speed of 400 m/s for the unburned stoichiometric hydrogen-air mixture.

SOLUTION:

Before using Equation 11 to evaluate the specific impulse, we need to calculate the molecular weight and density of the stoichiometric hydrogen-air mixture.

$$\begin{aligned} \rho_{\text{mix}} &= \frac{M_{\text{mix}}}{M_{\text{air}}} \rho_{\text{air}} \\ &= \frac{(0.295)(2) + (1 - 0.295)(28.8)}{28.8} (1.2 \text{ kg/m}^3) \\ &= 0.87 \text{ kg/m}^3 \end{aligned}$$

Using the C-J detonation Mach number for stoichiometric hydrogen-air listed in Table 3-16.4,

$$I = \frac{0.35(0.87 \text{ kg/m}^3)(400 \text{ m/s})(4.89)(5 \text{ m})}{(1.2 + 1)}$$

$$= 1354 \text{ Pa}\cdot\text{s}$$

If we assume the pressure is effectively relieved when the detonation reaches the open end of the tube, the detonation duration in the 5 m long pipe is

$$\frac{5 \text{ m}}{4.89(400 \text{ m/s})} = 2.56 \text{ m}\cdot\text{s}$$

The average pressure exerted on the pipe wall is $I/t_{\text{dur}} = 530 \text{ kPa} = 77 \text{ psig}$. This value is about one-third of the C-J detonation pressure. Structural analysts familiar with dynamic loadings can use these values and the pipe wall properties to determine whether the fuel line should survive the detonation.

Explosion Venting

Explosion venting is the discharge of combustion gases during a deflagration to maintain pressures below the enclosure damage threshold. The enclosure can be a room, a building, or a piece of process equipment. The fuel may be a combustible gas, dust, mist, or hybrid dust-gas mixture. The discharge vent opening is usually covered initially by one or more blowoff panels, rupture discs, or other engineered vent devices. Since explosion vents usually open after the explosion is initiated to limit the pressure rise, they cannot be used for detonations because the maximum pressure occurs instantaneously when the shock front reaches a given location.

The most effective explosion venting systems are those that deploy early in the deflagration, have as large a vent area as possible, and allow unrestricted venting of combustion gases. Early vent deployment requires that the vent release at the lowest possible pressure without interfering with normal operations and pressure fluctuations in the enclosure. In the case of vents on exterior walls and roofs of buildings, the minimum feasible vent release pressure is usually slightly larger than the highest expected differential pressure associated with wind loads (typically 0.14 to 0.21 psig; i.e., 0.96 to 1.44 kPa).

The amount of vent area needed for effective explosion venting depends on the size of the enclosure and the rate of pressure rise within it. According to Equation 5, the rate of pressure rise in an unvented enclosure is proportional to the product of the mixture effective burning velocity and flame surface area, and varies inversely with the enclosure volume. The rate of pressure reduction due to venting is proportional to the product of vent area and gas velocity through the vent. The vent velocity is dependent on the instantaneous pressure in the enclosure and the composition of the vented gas (i.e., the relative proportions of burned and unburned gas). These considerations have been implemented in the formulation of theoretical models, scaling correlations for test

data, and guidelines for determining the required vent area.

Theoretical Models

Most of the theoretical models are for vented gas explosions because their effective burning velocities and flame surface areas are more amenable to modeling than those of dust explosions. The two categories of gas explosion models are (1) two-fluid models and (2) computational fluid dynamics (CFD) models. The two-fluid models are conceptually similar to the closed vessel model described previously, but include provisions for modeling the vented flow and various types of flame accelerations and turbulent combustion with possible highly wrinkled flame surface areas. Zalosh²⁶ has reviewed the status of these models through 1995.

Computational fluid dynamics models are much more sophisticated and complicated than the relatively simple two-fluid models. They solve for the spatial distribution of gas velocities, gas composition, and thermodynamic variables throughout a computational grid that can be either fixed or adaptive to the instantaneous flow and combustion field. Two distinguishing features of each of these models are their formulations for turbulence generation and for turbulent combustion rates. Although they are too complicated and computationally burdensome for routine deflagration vent design, several of these models are being used now for special applications such as offshore platform modules with highly congested equipment. Popat et al.²⁷ have provided a comparative review of four popular CFD models used in Europe, including their success in pre-test predictions.

Although dust explosions are more difficult to model than gas explosions, there have been several noteworthy efforts summarized by Eckhoff.⁷ Some of these explicitly utilize the gas explosion parameters (burning velocity and flame surface area) and provide prescriptions to evaluate them from experimental data. Others use the closed vessel K_{ST} parameter as a representation of the effective burning rate. One recent burning velocity type model developed by Tamanini²⁸ at FMRC has been utilized to correlate dust-explosion-venting test data.

Test Data and Correlations

Crucial aspects of both vented gas explosion and vented-dust-explosion testing and data correlations are (1) mixture reactivity, (2) turbulence sources (both initial turbulence and obstacle-flame interaction turbulence), (3) vessel volume (scale) effects, and (4) vessel geometry (primarily length/diameter ratio), as well as the vent parameters: vent area, vent release pressure, and vent panel inertia. Vented-gas-explosion testing has the additional complication of various flame instabilities, some of which are dependent on ignition location, enclosure wall lining, and the presence of equipment within the enclosure. Dust-explosion testing has the additional complications of ignition source strength and dust cloud uniformity, as well as the time delay between dust dispersion and ignition.

Rather than attempt to review the numerous vented-explosion test programs, we will briefly focus on the testing that seems to have had the greatest influence on the development of data correlations and our current understanding of vented-explosion phenomenology. In this regard, perhaps the most influential and most extensive testing has been the large-scale testing conducted by Bartknecht and his protégés at the Ciba-Geigy Test Center in Basel, Switzerland. Their test vessels ranged in size from 2.4 m³ to 250 m³, and had a pressure rating of 10 bar so they could be used for both vented and unvented tests.²⁹ Most of their testing has been with dusts using energetic igniters and worst-case dust concentrations. Their data have been correlated in the various versions of the VDI Guideline for Dust Explosion Venting.³⁰

Recent efforts in explosion venting data correlations have utilized nondimensional parameters that lend themselves to data interpolation and extrapolation. The nondimensional pressure parameter is

$$\pi = \frac{\Delta P_{\text{red}}}{\Delta P_{\text{max}}}$$

and the nondimensional vent parameter is

$$\Gamma = \frac{a_{CD} \cdot A_v \cdot P_0}{V^{2/3} \cdot K_{ST}}$$

where

A_v = vent area (m²)

V = enclosure volume (m³)

K_{ST} = ASTM E1226 (20-l vessel) dust reactivity (bar·m/s)

P_{red} = reduced pressure in vented explosion (bar·ga)

P_{max} = unvented explosion pressure (bar·ga)

P_{stat} = vent deployment pressure (bar·ga)

P_0 = initial pressure (= 1 bar·abs)

a_{CD} = vent discharge coefficient \times sound speed = $C_D a_1 = 230$ m/s

The current FMRC correlation³¹ uses the π parameter and a modified form of the Γ parameter in which a volume-adjusted K_{ST} parameter is used, and P_{max} replaces P_0 in the numerator. The particular correlation of π (Γ) was developed to provide a best fit to the Bartknecht data.

Gas explosion venting correlations relate the pressure parameter, π , to one of two alternate forms of the nondimensional vent parameter.

1. The Swift-Epstein³² form of the vent parameter is

$$\Gamma_{S-E} = \frac{\chi S_u A_s}{C_D A_v} \sqrt{\frac{P_1}{P_{\text{red}}}}$$

where A_s is the interior surface area of the enclosure, that is, the maximum flame surface area at the time the enclosure is completely filled with flame.

2. The Bradley-Mitcheson³³ form of the vent parameter is

$$\Gamma_{B-M} = \frac{A_v a_1}{V^{2/3} S_u} \left(\frac{M_1 T_f}{M_b T_u} \right)$$

where T_f is the adiabatic isobaric flame temperature and M_b is the burned gas molecular weight. Molkov³⁴ has subsequently modified the Bradley-Mitcheson vent parameter to include the ratio χ/C_D , and has developed correlations for this ratio that account for turbulent flame stretch.

The turbulence parameter, χ , is particularly difficult to estimate and correlate for the vented gas explosions that produce flame instabilities. These flame instabilities produce complicated pressure-versus-time traces with multiple pressure peaks and oscillations such as shown in Figure 3-16.10. Depending on conditions (as described by Cooper et al.³⁵), the maximum pressure during a vented explosion can correspond to any one of the four types of pressure peaks shown in Figure 3-16.10.

Explosion Venting Guidelines

The following vent area guidelines are based on data obtained from numerous tests in relatively large-scale enclosures with near worst-case gas-air or dust-air mixture compositions. The specific test programs are referenced in NFPA 68.⁸ In some cases, the data was correlated using the parameters described previously. In other cases (particularly for gas explosions), the data were enveloped rather than correlated. Separate guidelines are offered for low-strength and high-strength enclosures, with the nominal demarcation between the two corresponding to a damage threshold pressure of 1.5 psig (0.1 bar ga). The reason for this demarcation is that the high-strength guidelines were primarily developed from European test programs, which did not include low-pressure tests, while many of the U.S. test programs featured large, low-strength structures.

Low-strength enclosures: The low-strength enclosure guidelines are currently based on the Swift-Epstein correlation parameter described previously. Thus the required vent area required to maintain pressures below the damage threshold, P_{red} , is proportional to the internal surface

Figure 3-16.10. Pressure-time profile typical of an explosion in a near-cubic vessel with a low failure pressure explosion relief.³⁵

area of the enclosure. The general form of this venting equation is

$$A_v = \frac{CA_s}{\sqrt{P_{\text{red}}}} \quad (12)$$

where

A_v = vent area (ft² or m²)

C = fuel characteristic constant (psig^{1/2} or kPa^{1/2}) specified in Table 3-16.5

A_s = internal surface area of enclosure (ft² or m²)

P_{red} = overpressure damage threshold (psig or kPa)

The intended range of applicability of Equation 12 is

- $0.35 \text{ psig} < P_{\text{red}} < 1.5 \text{ psig}$
- $P_{\text{red}} - P_{\text{stat}} > 0.35 \text{ psi}$, where P_{stat} = vent opening pressure
- enclosure length/diameter (hydraulic) < 3

The recommended values of C in Table 3-16.5 represent the highest values inferred on the basis of test data presented in 18 references cited in NFPA 68.⁸ Test conditions encompassed both quiescent and initially turbulent fuel-air mixtures in enclosures with volumes ranging from 0.18 to 82.3 m³.

For a given fuel, most of the data correspond to C values well below those given in Table 3-16.5. For example, the most likely value of C for propane is about one-third of the recommended value of 0.17. On the other hand, it is entirely possible for the recommended C value as used in Equation 12 to underestimate the pressure developed in a vented explosion with an extremely high level of turbulence, such as might occur in a hammermill, for example.

Values of C for other gases should be based on test data. In lieu of such data, a reasonable guess that is consistent with the Swift-Epstein correlation could be made by multiplying the 0.17 psig^{1/2} value for propane (for which the most data are available) by the ratio of the burning velocity of the other gas to that for propane.

High-strength enclosures: The vent area recommended in NFPA 68 for compact ($L/D \leq 2$) high-strength enclosures subject to gas explosions is

$$A_v = [(0.127 \log_{10} K_G - 0.0567)P_{\text{red}}^{-0.582} + 0.175P_{\text{red}}^{-0.572}(P_{\text{stat}} - 0.1)]V^{2/3} \quad (13)$$

where $P_{\text{stat}} \leq 0.5 \text{ bar}$ and $P_{\text{red}} \leq 2 \text{ bar}$.

Table 3-16.5 C Values in Swift-Epstein Equation⁸

Fuel	English Unit C (psig) ^{1/2}	Metric Unit C (bar) ^{1/2}
Anhydrous ammonia	0.05	0.013
Methane	0.14	0.037
Gases with S_u values < 60 cm/s	0.17	0.045
Dusts with $K_{ST} < 200 \text{ bar}\cdot\text{m/s}$	0.10	0.026
Dusts with $K_{ST} > 200$ and < 300 bar·m/s	0.12	0.030
Dusts with $K_{ST} > 300 \text{ bar}\cdot\text{m/s}$	0.20	0.051

For enclosures with $L/D > 2$, there is an equation for an incremental vent area to cope with the higher rates of pressure rise in elongated enclosures subject to flame acceleration.

The current (1998) version of NFPA 68 has the same equation for dust explosions in high-strength enclosures as is in VDI 3673. However, the committee has proposed the following new equation for dust explosions in compact enclosures for the 2002 Edition of NFPA 68.

$$A_v = (8.535 \times 10^{-5})(1 + 1.75P_{\text{stat}})K_{ST}V^{0.75}\sqrt{\frac{(1 - \Pi)}{\Pi}} \quad (14)$$

where $\Pi = P_{\text{red}}/P_{\text{max}}$ as in the general correlations, V is in m³ and A_v is in m².

An equation for an incremental vent area for enclosures with $L/D > 2$ is also being proposed as of this writing. If approved by NFPA in the fall of 2001, Equation 14 and the auxiliary L/D equation will appear in the next version of NFPA 68, and will be recommended for low-strength as well as high-strength enclosures.

One limitation of all the explosion-vent guidelines as they are currently formulated, is that they do not account for application-specific turbulence levels and equipment obstruction levels. In other words, the implication in using the guidelines is that either the turbulence and equipment levels in the application are comparable to those used in the test data from which the guidelines were based, or else the vent designer is inherently accepting a certain ill-defined level of conservatism by assuming that the application turbulence and equipment obstruction levels are significantly lower than those used in the testing. By the same token, most of the guidelines do not account for the extent of the enclosure filled with combustible mixture. Current research, such as that described by Tamanini^{36,37} is providing a basis for overcoming these limitations.

EXAMPLE 8:

Suppose the $4 \times 4 \times 3$ in room of Example 3 has a damage threshold pressure of 1.0 psig. What would be the minimum vent area to maintain pressures under this value for a worst-case butane-air mixture explosion? Assume the gas mixture is initially at rest and the vent release pressure is 0.2 psig.

SOLUTION:

For this room,

$$A_s = 2[4(4) + 4(3) + 4(3)] = 80 \text{ m}^2$$

Since butane has a burning velocity similar to that for propane, from Table 3-16.5, $C = 0.17$. Therefore, using Equation 9,

$$A_v = 80(0.17)/1.0 = 13.6 \text{ m}^2 \text{ (146 ft}^2\text{)}$$

EXAMPLE 9:

A 400-m³ electrostatic precipitator used in a power plant firing bituminous coal is to be equipped with lightweight explosion vents. If the damage threshold pressure for the precipitator is 1.2 bar (17.4 psig), its L/D ratio is 1.5, and the vent static release pressure is 0.4 bar (5.8 psig), what is the minimum vent area needed? Assume the bitu-

minous coal has the explosibility parameters listed in Table 3-16.2.

SOLUTION:

From the Table 3-16.2 listing for bituminous coal, $K_{ST} = 59 \text{ bar}\cdot\text{m/s}$ and $P_{\max} = 9.1 \text{ bar g}$. Therefore, $\pi = 1.2/9.1 = 0.132$. Substituting into Equation 14,

$$A_v = (8.535 \times 10^{-5})[1 + 1.75(0.40)](59)(400)^{0.75} \sqrt{\frac{1 - 0.132}{0.132}}$$

$$= 1.96 \text{ m}^2$$

We note that since the vent area is linearly proportional to K_{ST} , which can vary substantially among various coals (and other generic materials for that matter), it is important to base the calculated vent area on data for site-specific samples. Note also that the calculated vent area does not account for the weight (inertia) of the vent panel. A procedure to determine the additional vent area required for heavy vent panels will appear in the next edition of NFPA 68.

Explosion Suppression Systems

An explosion suppression system is designed to detect and suppress an incipient explosion before the pressure rises to the enclosure damage threshold. Suppression is achieved by the rapid discharge of an extinguishing agent from pressurized containers mounted on the protected enclosure. The sequence of events is pictured in Figure 3-16.11. A pressure or flame radiation detector senses the incipient explosion while only a small fraction of the flammable gas or dust has burned. The sensor signal triggers the discharge of suppression agent into the enclosure. When the agent reaches the expanding flame front, it quenches the flame and thereby suppresses the explosion.

One important advantage of explosion suppression systems versus explosion venting is that there is no discharge of flame or fuel. Thus suppression systems can often be used more readily on indoor equipment and on equipment containing toxic materials. One major disadvantage of the system is the high cost associated with both the installation of a complex system and the refilling and resetting of the system after a discharge.

The basic components of an explosion suppression system include detectors, an electrical power supply and control system, and a set of rapid action extinguishing units. Pressure sensing detectors are usually used in applications involving dust explosion hazards, while gas explosion applications can employ either pressure sensors or ultraviolet radiation detectors, depending on the required response time (UV detectors provide the fastest response time) and concerns for spurious activation and/or optical shielding of the detectors. Electrical power supplies and control systems include appropriate interlocks for self-monitoring and for shutting down processes and triggering alarms at system activation. Extinguishing agents traditionally used in explosion suppression systems have been either halogenated hydrocarbons (halons) or chemical powders. Dry chemicals, such as monoammonium phosphate and sodium bicarbonate, are still

Figure 3-16.11. (a) Explosion suppression system. (b) Pressure versus time diagram of a normal and a suppressed explosion.⁴

being used to protect many unoccupied facilities and equipment. However, the recent phaseout of halon production, because of ozone depletion concern, has triggered an ongoing search for new liquid and gaseous

agents (primarily perfluorocarbons and hydrofluorocarbons), and has generated renewed interest in water and aqueous salt solutions for explosion suppression of potentially occupied facilities, such as aerosol propellant filling rooms and gas compressor stations.

Several test programs have provided data on the quantity of agent, activation times and pressures, and method of agent dispersal needed for effective suppression. These programs have encompassed a variety of flammable gases and dusts, have ranged in scale from laboratory vessels³⁸ to a 500-m³ tanker pump room,³⁹ and include many tests in the 250-m³ Ciba-Geigy test vessel mentioned previously.⁴⁰ The ISO and Factory Mutual standards^{41,42} specify that testing should be conducted in a vessel of at least 1-m³ volume, and should include tests with and without suppression agents.

Bartknecht⁴³ has systematically investigated the effect of enclosure size on the quantity of dry chemical agent needed for effective suppression. His data indicate that the required quantity of agent is proportional to the enclosure volume (i.e., there is a certain critical agent concentration) for volumes under about 5 m³, but that the required amount of agent is proportional to the two-thirds power of the enclosure volume beyond 9 m³. This change in scaling suggests that the dry chemical suppression mechanism changes from advance inerting of unburned fuel ahead of the flame front in small vessels, to actual quenching of the flame front in large vessels. Chatrathi and Going⁴⁴ have recently reported on testing using dry chemical suppression agents in both modes: inerted (injected into the vessel with combustible dust) and post-ignition suppression. His inerted test results were used to determine minimum inerting concentrations for monoammonium phosphate and sodium bicarbonate.

Recent fundamental research with various suppression agents has elucidated the suppression mechanisms associated with various agents and fuel combinations. Many agents provide the thermal heat sink effect that is the most clearly understood mechanism. Some agents also provide a chemical inhibition effect (via free-radical scavenging), but the magnitude of this effect is dependent upon the flame speed as well as the chemical compositions of the fuel and agent.^{45,46}

The importance of the flame speed in assessing suppression agent and system effectiveness can best be appreciated in terms of the components contributing to what Chatrathi and Going⁴⁴ call the *total suppressed pressure* (TSP). These components can be expressed in the following equation:

$$\text{TSP} = P_A + \Delta P_{\text{inj}} + \Delta P_{\text{comb}} \quad (15)$$

where

P_A = deflagration pressure at the time of agent discharge actuation

ΔP_{inj} = incremental pressure associated with the discharge of propellant gas and any gaseous agent into the enclosure

ΔP_{comb} = incremental pressure associated with the combustion that occurs as the agent travels to the flame front and actually suppresses the deflagration

The first term in Equation 15 can be minimized through the selection of fast-acting detectors and the use of very fast opening suppression agent containers. The second term is usually only an important consideration in small enclosures (Chatrathi and Going report that $\Delta P_{\text{inj}} = 1.4$ psig when one 2.5 l container, pressurized to 900 psig with nitrogen is injected into a 1-m³ closed vessel). The third term is the most difficult to characterize because it includes consideration of agent dispersal as well as the chemically reacting interaction of the agent with the expanding flame front. In terms of minimizing agent travel time to the flame front, it is clear that the use of a large number of well distributed small agent containers would be preferable to use of fewer large containers. Moore's testing⁴⁷ has verified this conjecture. If the agent travel time can be calculated, and the agent is assumed to be instantly effective once it reaches the flame front, the value of ΔP_{comb} can be estimated using Equations 6 and 7.

The ΔP_{comb} term in Equation 15 will inevitably increase with increasing fuel K_{ST} or K_G , as well as with the increasing turbulence level associated with the application explosion scenario. The highest challenge K_{ST} material subjected to explosion suppression tests has been aluminum dust. Early results described by Bartknecht⁴³ showed the limitations of the first generation suppression systems and agents in suppressing aluminum dust explosions. The recent results of Chatrathi and Going suggest that the TSP of aluminum dust can now be reduced to 10–20 percent of P_{max} . This is significantly larger than the TSP achieved with organic fuels, which is usually less than 5 percent of P_{max} .

The choice of a suitable suppression agent and number/location of agent containers involves some very practical considerations as well as consideration of the maximum pressure developed in the suppressed explosion. Some of these considerations include agent compatibility with process materials, agent toxicity, environmental impact, and agent retention time for applications in which there is a threat of repeated ignitions.

Blast Waves

If explosion prevention and explosion suppression measures are not successful, a blast wave will emanate from the breached enclosure. The blast wave will propagate into the surrounding atmosphere and will decay with distance from the enclosure. One of the most common questions with regard to explosion protection is whether or not the blast wave at a particular location will be sufficiently strong to cause damage or injury. Simplified methodology to address this question is presented here along with reference citations for more thorough and extensive analyses.

If we confine our attention to distances that are large in comparison to the characteristic diameter of the breached enclosure, we can deal with relatively simple far-field blast wave scaling correlations. The characteristic shape of the far-field blast wave is shown in Figure 3-16.12. It consists of a shock wave with a pressure rise, P_s , followed immediately by a rarefaction wave in which the pressure decays to some value below atmo-

Figure 3-16.12. Far-field blast wave.⁴⁹

spheric pressure, and then a gradual recovery to atmospheric pressure, P_0 . Sometimes the final pressure recovery occurs in the form of a second shock, and the shape takes the form of a slightly deformed letter *N*, thus leading to the term *N wave*.

Blast wave correlations are often in the form of a nondimensional pressure $(P_s - P_0)/P_0$ and a nondimensional distance from the blast source. The nondimensional distance, \bar{R} , is defined as

$$\bar{R} = R \left(\frac{P_0}{E} \right)^{1/3} \quad (16)$$

where R is the actual distance from the blast source (m), E is the blast wave energy (J), and P_0 is in Pa.

The correlation for nondimensional pressure versus \bar{R} is shown in Figure 3-16.13. The curve labeled PS in Figure 3-16.13 refers to the incident overpressure, while the curve labeled PR refers to the reflected blast wave pressure resulting from a blast wave being reflected head-on from a rigid wall. Neither curve in Figure 3-16.13 accounts for the reflection of the shockwave off the ground surface. The usual procedure for including ground surface reflection is to use twice the calculated blastwave energy when using the correlations in Figure 3-16.13.

The implication in this type of blast wave scaling correlation is that the blast wave is characterized by only one parameter, the blast energy, E . In theoretical models of blast wave pressure, the energy is assumed to be released instantaneously, at a single point. This approach is called ideal blast wave theory. The correlations for ideal blast waves are based on a combination of theory and test data from condensed phase, compact explosives. Baker^{17,48} describes the development of these correlations, which include nondimensional blast wave impulses, positive-phase durations, and many other parameters. The impulse is particularly important for doing dynamic structural response analyses, such as those described by Kinney and Graham.⁴⁹

Figure 3-16.13. Blast wave pressure versus scaled distance.

Can the blast waves from various accidental explosions be predicted from these ideal blast wave correlations? In some cases the answer is unequivocally yes. A good example is the blast wave from a ruptured pressure vessel containing a gas that is not ignited upon release. The energy associated from this type of physical explosion is the energy of expansion of the gas as it goes from an initial pressure, P_1 , to atmospheric pressure. A perfect gas isentropic expansion representation of this energy is

$$E = \frac{(P_1 - P_0)V}{\gamma - 1} \quad (17)$$

where V is the vessel volume and γ is the gas ratio of specific heats. Other approaches to this problem, including the assessment of vessel fragment shrapnel effects, are described in the AIChE Consequence Analysis Guidelines.⁵⁰

If the breached vessel fails as a result of an internal combustion explosion, or if the vessel is vented per explosion venting guidelines, the blast wave analysis is considerably more complicated because there is a combustion energy contribution to the total blast wave energy. Correlations to predict blast waves from vented explosions are contained in NFPA 68, and more recent developments, including two-dimensional considerations, are described by Forcier and Zalosh.⁵¹

Another special consideration in breached vessel blast waves is the blast wave and fragment shrapnel released when a liquefied gas undergoes a boiling liquid expanding vapor explosion (BLEVE) as a result of severe fire exposure. Correlations for BLEVEs are described in *Guidelines for Evaluating the Characteristics of Vapor Cloud Explosions, Flash Fires, and BLEVEs*,⁵² and some of the research leading to these correlations are described in Baurer et al.,⁵³ Hasegawa and Sato,^{54,55} and Fay and Lewis.⁵⁶ These publications include correlations for the size and radiation emitted from the rising fireball that occurs in most BLEVEs.

One final special consideration is the blast wave associated with vapor cloud explosions. These explosions occur when a very large cloud of flammable gas or vapor is ignited in a highly obstructed environment such as a chemical or petrochemical plant with a high density of process equipment and storage vessels. The strength of the blast wave that occurs in a vapor cloud explosion is dependent on the flame speed that develops and the degree of confinement in and around the vapor cloud.

Early assessments of vapor cloud explosion blast waves were conducted using the idealized blast wave type correlations described here, along with some rough guess at the energy yield (i.e., the fraction of the available combustion energy actually contributing to the blast wave). However, these early efforts were not very successful because 1) most of the interest is in the near-field rather than the far-field, and 2) even the far field assessments were not accurate because the blast wave strength and impulse decays far less rapidly than that of an ideal blast wave. Two other types of blast wave models are utilized now for vapor cloud explosions. The simpler current approach involves an empirical estimate for the flame speed in different applications, along with results of one-dimensional flame propagation (or piston propagation) nonideal blast wave calculations. This approach, which is still evolving, is described in *Guidelines for Evaluating the Characteristics of Vapor Cloud Explosions, Flash Fires, and BLEVEs*,⁵² Strehlow,⁵⁷ and van den Berg.⁵⁸ The second current approach is to utilize CFD models of the actual two-dimensional or three-dimensional flame propagation, in which the flame speed and acceleration are calculated as part of the solution. The models used for this approach are essentially the same models referenced earlier for CFD calculations of vented gas explosions.²⁷ Which of these two approaches will see more widespread use in the future depends, in large part, on the availability of faster and more powerful computers, along with the education of potential users of these sophisticated models. In a sense, this issue is only a microcosm of the more general question of what level of modeling will be utilized for performance based explosion hazard assessments.

CHAPTER 1

Design of Detection Systems

Robert P. Schifiliti, Brian J. Meacham, and Richard L. P. Custer

Introduction

Fire detection and alarm systems are recognized as key features of a building's fire prevention and protection strategy. This chapter presents a systematic technique to be used by fire protection engineers in the design and analysis of detection and alarm systems. The majority of discussion is directed toward systems used in buildings. However, many of the techniques and procedures also apply to systems used to protect planes, ships, outside storage yards, and other nonbuilding environments.

Scientific research on fire growth and the movement of smoke and heat within buildings provides fire protection engineers with information and tools that are useful in the design of fire detection systems. Also, studies of sound production and transmission allow communication systems to be engineered, thus eliminating the uncertainty in locating fire alarm sounders. All of this information allows engineers and designers to design systems that meet specific, identifiable goals.

Sections 1, 2, and 3 of this handbook introduced and discussed a series of concepts and tools for use by fire protection engineers. This chapter shows how some of these tools can be used collectively to design and evaluate detection and alarm systems.

Robert P. Schifiliti, P.E., is a fire protection consultant based in Reading, Massachusetts, and an adjunct associate professor of fire protection engineering at Worcester Polytechnic Institute. He specializes in fire detection and fire alarm system design and analysis.

Brian J. Meacham, Ph.D., P.E., is Principal Risk Consultant and Principal Fire Protection Consult for Arup Fire, located in Massachusetts. Dr. Meacham is a fellow of the Society of Fire Protection Engineers.

Richard Custer, M.Sc., is Technical Director and Principal Fire Analyst for Arup Fire. Mr. Custer is a fellow of the Society of Fire Protection Engineers.

A Note about Precision

When solving multiple equations with numerous variables from many sources, it is often easy to overlook the importance of precision and confidence in the final answer. This acknowledgment is particularly true since engineers have progressed from slide rulers to calculators to computers in a relatively short span of time. Most calculations in this chapter have been done using a computer—most often with a simple spreadsheet. The generally accepted practice for these types of tools is to round off only the final answer to the correct number of significant digits.

The standard and most widely taught rule for rounding is to round off using the same number of significant digits as the least precisely known number used in the calculation. An alternate rule suggests using one more significant figure than suggested by the standard rule. It has been shown that the alternate rule is more accurate and does not lead to loss of data as does the standard rule.^{1,2} The alternate rule for rounding has been used in this chapter. For more information or to refresh your knowledge of precision, rounding, and significant figures, consult the references or a standard text on engineering and scientific measurements.

Overview of Design and Analysis

To design a fire detection and alarm system, it is first necessary to establish the system's goals. These goals are established by model codes, the property owner, risk manager, insurance carriers, and/or the authority having jurisdiction. Ultimately, the goals of the system can be put in four basic categories:

1. Life safety
2. Property protection
3. Business protection
4. Environmental concerns

Some designers include heritage conservation in the list of goals. However, the protection of historic property is really another form of property and mission protection, although the methodology and extent for protection may vary.

When designing for life safety, it is necessary to provide early warning of a fire condition. The fire detection and alarm system must provide a warning early enough to allow complete evacuation of the danger zone before conditions become untenable. The fire detectors or fire alarm system may be used to activate other fire protection systems, such as special extinguishing systems and smoke control systems, that are used to help maintain a safe environment during a fire.

In some situations, the life safety mission of a detection system is enhanced by providing information to occupants. This situation is often the case in *stay-in-place* or *defend-in-place* strategies or partial evacuation/relocation strategies. The detection system is used to provide information about the location and extent of the fire. Instructions are then given to the target audience.

Property protection goals are principally economic. The objective is to limit damage to the building structure and contents. Maximum acceptable losses are established by the property owner or risk manager. The goal of the system is to detect a fire soon enough to allow manual or automatic extinguishment before the fire exceeds acceptable damage levels.

Goals for the protection of a mission or business are determined in a manner similar to that used in property protection. Here, fire damages are limited to prevent undesirable effects on the business or mission. Some items that need to be considered are the effects of loss of raw or finished goods, loss of key operations and processes, and loss of business to competitors during downtime. Other concerns include the availability and lead time for obtaining replacement parts. If the equipment to be protected is no longer available or requires several months for replacement, the ability to stay in business during and after an extended period of downtime may be jeopardized.

Protection of the environment is also a fire protection concern. Two examples are (1) toxicity of products of combustion and (2) contamination by fire protection runoff water. Should large quantities of contaminants be expected from a large fire, the goal of the system may well be to detect a fire and initiate appropriate response prior to reaching a predetermined mass loss from burning materials or quantity of fire suppression agent discharged.

Once the overall goals have been set, specific performance and design objectives for a performance-based design can be established.³⁻⁵ Performance-based fire protection design requires that specific performance objectives, rather than generic prescriptive requirements, be met. A typical prescriptive requirement would be to provide a smoke detector for every 84 m² (900 ft²) or 9-m (30-ft) spacing. In prescriptive design, speed of detection and the fire size at detection for such an installation are not known or considered explicitly. In addition, if some action must be taken in response to the alarm in order to control the fire, the expected damage is also unknown.

Implementation of a fire safety performance objective requires that the objective be stated first by the client

in terms of acceptable loss. The client loss objectives must then be (1) expressed in engineering terms that can be quantified using fire dynamics, and (2) related to design fires, design fire environments, and the performance characteristics of fire suppression equipment. For example, the client loss objective may be to prevent damage to essential electronic equipment in the compartment of origin. To meet this objective, one must first define what *damage* is. This damage could be expressed in terms of the thickness of the smoke layer. Other criteria, such as temperature or concentration of corrosive combustion products, or a combination of criteria, could also be used.

Based on a study of the likelihood of ignition and fire growth scenarios, a design fire needs to be established. The design fire is characterized by its heat release rate, \dot{Q} , at any moment in time; its growth rate, dq/dt ; a combustion product rate dcp/dt , such as smoke particulate, toxic or corrosive species, and so forth; and production rate, dp/dt . The design fire may be determined by (1) a combination of small- and large-scale testing specific to the application or (2) analysis of data taken from studies reported in the literature.

For a given fire safety design objective, there will be a point, \dot{Q}_{dor} , on the design fire curve where the energy and product release rates will produce conditions representative of the design objective. Given that there will be delays in detecting the fire, notifying the occupants, accomplishing evacuation, or initiating suppression actions, the fire will need to be detected at some time in advance of \dot{Q}_{dor} . In order to account for these delays, a critical fire size, \dot{Q}_{cr} , can be defined as the point on the design fire curve at which the fire must be detected in order to meet the design objectives for a given spacing or radial distance from the fire.

There are two types of delays that influence the size of the fire at detection: (1) those that are variable and (2) those that are fixed. Variable delays represent transport lag and are related to radial distance of the detector from the fire, ceiling height, and the convective heat release rate of the fire. Fixed delays are associated with system characteristics, such as alarm verification time. Adding the fixed delays to \dot{Q}_{cr} defines another point on the design fire curve: \dot{Q}_i or the *ideal* fire; that is, the fire that would be detected with no transport delay.

The design fire, \dot{Q}_{dor} , has been defined as the fire size (in terms of peak heat release and given growth rate history) that corresponds to the maximum acceptable loss fire, and the critical fire, \dot{Q}_{cr} , as the maximum fire size at time of detection that allows actions to be taken to limit the continually growing fire to the design fire limit. The time needed to take the limiting actions is the response lag. The total system response time, then, is the amount of time required between the critical fire and the design fire for all the actions to take place before \dot{Q}_{dor} is reached, and is the sum of the fixed and variable delays and the response lag. The various design and evaluation points on a design fire curve are shown in Figure 4-1.1.

For example, if the design fire is determined to be 1500 kW and manual suppression will be employed, the critical fire can be selected at a moment in time that permits detection, notification, and response before the 1500 kW fire size is reached. If the total system response

Figure 4-1.1. Design fire curve.

time is estimated to be 3 min, the critical fire would be at the size determined at 3 min prior to reaching 1500 kW using the estimated fire growth rate.

Expressing fire size or fire load as an energy release and growth rate may be thought of in the same way that structural engineers use earthquake zone maps to design for potential earthquakes. Electrical engineers might compare fire loads to fault currents used in designing over-current protection devices. At the present time, design fire, critical fire, and total system response time requirements are not established by any building codes. It is the job of the design engineer to work with the building owner and local code officials to establish the performance requirements for a given system application.

Once the goals of a system have been established, several probable fire scenarios should be outlined. The occupancy of the building and the expected fuels should be analyzed to establish an expected fire growth rate and an expected maximum heat release rate. Fire loss reports and fire test data can be used to help estimate heat release rates and the production of smoke and fire gases. It is important that different fire scenarios be evaluated to establish how the system design or response might change as a result of varying fire conditions. Several possible fire scenarios should be outlined using the techniques presented elsewhere in this handbook.

When designing a system, select the most likely fire scenario as the basis of the design. Once the design requirements for spacing and detector type are established, the system's response can be analyzed using the other possible fire scenarios. If the alternate fire scenarios cause the design not to meet the established goals, design changes can be made and retested, if warranted.

The several fire scenarios used when analyzing a system will produce upper and lower bounds or a range of system performance characteristics. The fire scenarios selected should include best and worst case fires as well as several likely scenarios for the particular building characteristics and occupancy.

For the purposes of design or analysis, detection and alarm systems have three basic elements: detection, processing, and signaling. The first, detection, is that part of the system that senses fire. The second element involves the processing of signals from the detection portion of the system. Finally, the processing section of the system activates the signaling portion in order to alert occupants and perform other auxiliary signaling operations. Auxiliary functions may include smoke control, elevator capture, fire department signaling, and door closing.

This chapter focuses on the detection and signaling elements of a fire alarm system. Engineering methods for the design and analysis of heat detector response are presented along with several examples. A method to calculate the audibility of fire alarm sounders is also presented. The selection of a system's control panel and the design of auxiliary functions is beyond the scope of this chapter.

Detection

To design the detection portion of a fire alarm system, it is necessary to determine where fire detectors should be placed in order to respond within the goals established for the system. Several different detector types might respond to the expected fire, so it may be necessary to develop several candidate system designs, using various combinations of detector types in order to optimize the system's performance and cost.

A fire signature⁶ is some measurable or sensible phenomenon present during combustion. Table 4-1.1 is a cross-reference of fire signatures and commercially available detector types. The table shows the predominant fire signature to which the detector responds.

Heat Detection

This section discusses an engineering method for determining the placement of heat detectors on a large flat ceiling.

The present practice in designing fire detection systems using heat detectors is to space the detectors at intervals equal to spacings established by tests at Underwriters Laboratories Inc. Listed spacings are determined in full-scale fire tests.⁷

In the Underwriters Laboratories Inc. (UL) test, a burning pan of 190-proof denatured alcohol is located in the center of a test room. Sprinkler heads having a 160°F (71°C) rated operating temperature are located on the ceiling in a square array having 10-ft (3-m) sides. The fire is in the center of the square. The distance between the fire and the ceiling is varied so that the 160°F (71°C) sprinkler head being used operates in approximately 2 min.

As shown in Figure 4-1.2, detectors of the type being tested are located at the corners of squares having 20-, 30-, 40-, and 50-ft (6.1-, 9.1-, 12.2-, and 15.2-m) sides. The spacing of the last detector to operate prior to a sprinkler head operating becomes the detector's listed spacing. A similar test procedure is employed by Factory Mutual Research Corporation (FMRC) to arrive at an approved detector spacing.

Table 4-1.1 Fire Signatures and Commercially Available Detectors

Fire Signature/ Detector Type	Electromagnetic Radiation Wave Length 1700 to 2900 Angstroms	Electromagnetic Radiation (thermal) 6500 to 8500	Invisible Products of Combustion Less Than 0.1 Micron	Visible Smoke and Products of Combustion More Than 0.1 Micron	Rapid Change in Temperature	High Temperature
Ultraviolet detector	X					
Infrared detector		X				
Sub-micron particle detector						
Wilson cloud chamber			X			
Infrared particle detector						
Smoke detector photoelectric ionization				X		
photo beam			X	X		
Rate-of-rise heat detector					X	
Rate anticipation heat detector						X
Fixed temperature heat detector						X

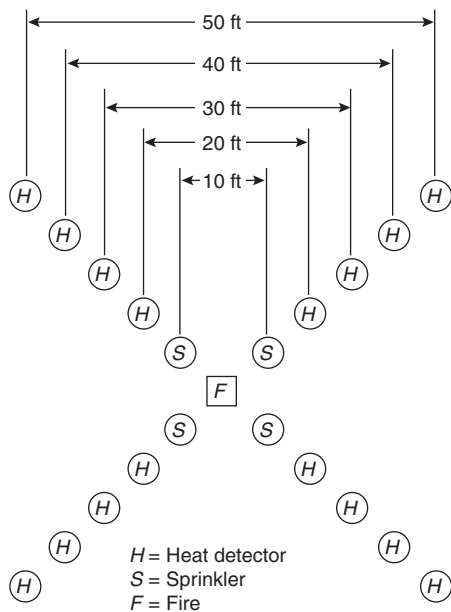

Figure 4-1.2. Detector test layout.

Most codes require that detectors be spaced at intervals equal to the UL or FMRC spacing. NFPA 72, National Fire Alarm Code®, 1999 edition, requires that the installed spacing be less than the listed spacing to compensate for high ceilings, beams, and air movement. High ceilings mean that the fire plume will entrain more ambient air as it rises. This condition has the effect of cooling the gases and reducing the concentration of fire products. Beams, joists, walls, or sloped ceilings alter the flow of combustion products. This situation can serve to restrict or enhance the

operation of a fire detector. For instance, consider the case where a fire detector is located on a ceiling between two parallel beams and a fire occurs at floor level between the beams. If the distance between the beams is small compared to the horizontal distance from the fire to the detector, the beams will act as a channel directing the flow of hot gas to the detector, thus speeding operation. NFPA 72 allows detector spacing to be increased beyond the listed spacing in areas, such as corridors, with narrow walls to confine the smoke and heat produced by the fire. Systems can be designed using this type of code approach; however, this approach will not permit quantitative assessment of detector response or measure the ability of a given system design to meet specific design goals relating to fire size, allowable damage, or hazard.

The best possible location for a heat detector is directly over the fire. If there are specific hazards to be protected, the design should include detectors directly overhead or inside of the hazard. In areas without specific hazards, detectors should be spaced evenly across the ceiling. When detectors are evenly spaced, as shown in Figure 4-1.3, the point that is farthest from any detector will be in the middle of four detectors. The spacing between detectors is

$$S = 2^{1/2}r \tag{1}$$

For a given detector, the problem is to determine the maximum distance the detector can be located from the fire and still respond within the design goals of the system. This requires a method for predicting detector response, based on fire size and growth rate, ceiling height, and detector characteristics.

Fire plume and ceiling-jet models can be used to estimate the temperature and velocity of fire gases flowing past a detector. The heat transfer can be calculated, and the response of the detector can be modeled.

Figure 4-1.3. Detector spacing.

Figure 4-1.4. Heat transfer to a ceiling-mounted detector.

Figure 4-1.4 describes the heat transfer taking place between a heat detector and its environment. The total heat transfer rate to the unit, \dot{q}_{total} , can be expressed by the relationship

$$\dot{q}_{total} = \dot{q}_{cond} + \dot{q}_{conv} + \dot{q}_{rad} \quad (\text{kW or Btu/s}) \quad (2)$$

where

\dot{q}_{cond} = conduction

\dot{q}_{conv} = convection

\dot{q}_{rad} = radiation heat transfer rates

During the initial stage of fire growth, radiation heat transfer can be neglected. Also, the elements of most commercially available heat detectors are thermally isolated from the remainder of the unit. In these cases, it can be assumed that the heat lost from the heat-sensitive element by conduction to other parts of the detector, and to the ceiling by conduction, is negligible in comparison to the convection heat transfer taking place. This exclusion leaves a net rate of heat transfer to the detector equal to \dot{q}_{conv} . The convective heat transfer rate to the detector is described by

$$\dot{q} = \dot{q}_{conv} = hA(T_g - T_d) \quad (\text{kW or Btu/s}) \quad (3)$$

where

h = convective heat transfer coefficient in kW/(m²·°C) or Btu/(s·ft²·°F)

A = area being heated

T_d = detector temperature

T_g = temperature of the gas heating the detector

Treating the detector element as a lumped mass, m (kg or lbm), the change in its temperature is found by

$$\frac{dT_d}{dt} = \frac{\dot{q}}{mc} \quad \text{deg/s} \quad (4)$$

where c is the specific heat of the element being heated and has units of kJ/(kg·°C) or Btu/(lbm·°F) and \dot{q} is the heat transfer rate. This equation leads to the following relationship for the change in temperature of the detector with respect to time:

$$\frac{dT_d}{dt} = \frac{hA(T_g - T_d)}{mc} \quad (5)$$

Heskestad and Smith⁹ have proposed use of a time constant, τ , to describe the convective heat transfer to a particular detector element:

$$\tau = \frac{mc}{hA} \quad \text{s} \quad (6)$$

$$\frac{dT_d}{dt} = \frac{T_g - T_d}{\tau} \quad (7)$$

Note that τ is a function of the mass, area, and specific heat of the particular detector element being studied. For a given fire-gas temperature and velocity and a particular detector design, an increase in mass increases τ . A larger τ results in slower heating of the element.

The convective heat transfer coefficient, h , is a function of the velocity of the gases flowing past the detector element and the shape of the detector element. For a given detector, if the gas velocity is constant, h is constant. It has been shown¹⁰ that the convective heat transfer coefficient for spheres, cylinders, and other objects similar to a sprinkler or heat detector element is approximately proportional to the square root of the Reynolds number, Re :

$$Re = \frac{ud}{\nu} \quad (8)$$

where

u = gas velocity

d = diameter of a cylinder or sphere exposed to convective heating

ν = kinematic viscosity of the gas

For a given detector, this equation means that h and, hence, τ , is approximately proportional to the square root of the velocity of the gases passing the detector. This relationship can be expressed as a characteristic response time index, RTI, for a given detector:

$$\tau u^{1/2} \approx \tau_0 u_0^{1/2} = \text{RTI} \quad (9)$$

Thus, if τ_0 is measured in the laboratory at some reference velocity u_0 , this expression is used to determine the τ at any other gas velocity, u , for that detector. The product, $\tau u^{1/2}$, is the response time index, RTI.

The use of RTI as a heat transfer function is a simplification. The determination of RTI assumes that τ (and therefore h) is proportional to the square root of the gas velocity, regardless of the magnitude of the velocity. The flow of gases past irregularly shaped objects such as detectors and sprinklers is very complex. Even the flow past cylinders is too complex to use a simple relationship for the heat transfer coefficient (i.e., constant RTI). Hollman showed that the heat transfer coefficient (and therefore τ) is actually proportional to the Reynolds number raised to a fractional power, n , that varies from 0.330 to 0.805 depending on the value of the Reynolds number.¹⁰ For values of Re between 40 and 4000, which is probably the range for most fire detection scenarios, the value of n is given as 0.466. This value is close to 0.5 (square root), but may explain some of the variation found in the experimental determination of τ and RTI.

Plunge tests performed on a variety of heat detectors by Bissell¹¹ show variations in τ and RTI, while other tests produced reasonable results for a variety of test parameters. It is possible that further analysis may show that an RTI based on $n = 0.5$ is reasonable and that the potential errors are insignificant in the context of fire and detector modeling. On the contrary, it may be found that some other value for n produces better results.

The exponent n may vary over ranges of Reynolds numbers less than those reported by Hollman. Some detector geometries are aerodynamically designed to channel fire gases to the detector element. The ability to affect the gas flow is a function of both the flow velocity and whether the flow is turbulent or laminar. These effects introduce additional variables that complicate the determination of a heat transfer function.

An added source of error in heat transfer modeling is that the temperature-sensing element of a heat detector is never completely isolated from the detector body. This setup results in conductive heat loss that may not be accounted for when using only one time constant. Kokkala has shown that for some detectors as much as 10 percent of the heat gained by convection is lost by conduction to the detector body.¹² A two-time-constant approach, similar to the C parameter used in modeling the response of sprinkler heads, is suggested by Kokkala. In a plunge test, the velocity may be high enough so that the conduction heat loss is negligible when compared to the heat gain by convection. In actual fire conditions, this conduction heat loss may contribute to the variation in RTI as it is currently used.

The magnitude of the potential error resulting from the assumption that RTI is constant has not been investigated. Future research and analysis should also consider the possibility that it might be best to test and report several discrete values for τ (hence h).¹³ An example is using a plunge test to find τ at three different velocities. The slow, medium, and fast velocities should be representative of the range of possible fire-gas velocities.

A continuous curve of τ versus u for every model detector would be ideal. However, the economic feasibility of testing must be considered. At the present time, heat detectors are tested in ovens to determine their operating

temperatures, and are tested in full-scale fire tests to determine their listed spacing (relative sensitivity). A single oven could be used to test for operating temperature and τ at several different velocities as discussed above. This type of testing would be more repeatable (precise), have a lower environmental impact, and give results that can be directly used by engineers in performance-based analysis and design. The test data could be used to calculate a listed spacing comparable to that determined in the present full-scale test so that current code-based design methods could continue to be used.

The remainder of the calculations in this chapter will be made using RTI as a heat transfer function. The user will readily see how other functions, when available, can be incorporated into the equations to effect other solutions.

Heskestad and Smith⁹ developed a test apparatus at Factory Mutual Research Corporation to determine the RTI of sprinkler heads. In the test, called a *plunge test*, the sprinkler head is suddenly lowered into the flow of a hot gas. The temperature and velocity of the gas are known and are constant during the test. The equation for the change in the detector temperature is then

$$\frac{dT_d}{dt} = \left(\frac{1}{\tau}\right)(T_g - T_d) \quad (10)$$

Since the gas temperature is constant during the test, the solution to this equation is

$$T_d - T_a = (T_g - T_a) \left[1 - \exp\left(\frac{-t}{\tau}\right) \right] \quad (11)$$

where T_a is the ambient, or initial, temperature of the sprinkler or detector at time $t = 0$. T_d is the temperature of the detector at time t . Rearranging the equation gives

$$\tau = \frac{t}{\ln[(T_g - T_a)/(T_g - T_d)]} \quad (12)$$

By measuring the response time, t_r , of the unit in the plunge test, this equation can be used to calculate τ_0 at the test velocity u_0 . This calculation is done by substituting the response temperature and time for T_d and t . The sensitivity of the detector or sprinkler can then be expressed as

$$\tau_0(\text{at } u_0) = \frac{t_r}{\ln[(T_g - T_a)/(T_g - T_r)]} \quad (\text{s}) \quad (13)$$

In terms of the response time index, this equation becomes

$$\text{RTI} = \frac{t_r u_0^{1/2}}{\ln[(T_g - T_a)/(T_g - T_r)]} \quad (14)$$

The RTI has units of $\text{m}^{1/2}\text{s}^{1/2}$ or $\text{ft}^{1/2}\text{s}^{1/2}$.

A plunge test can be used to determine the RTI for a heat detector or a sprinkler. Knowing the RTI, the change in temperature of similar units can be calculated for any history of fire gases flowing past it. The form of the heat transfer equation is

$$\frac{dT_d}{dt} = \frac{u^{1/2}(T_g - T_d)}{\text{RTI}} \quad (15)$$

This equation is used to calculate the temperature of a fixed-temperature heat detector or sprinkler exposed to

fire gases. The equation can be used to determine the time at which the unit reaches its operating temperature.

The use of a lumped mass model may not hold for rate-of-rise heat detectors and rate-compensated heat detectors. The heat transferred to a fixed-temperature heat detector either heats a sensing element until it melts, or it heats two dissimilar metals of a snap disk. In each case, the element itself is exposed to the hot gases. This result is not true for rate-of-rise heat detectors or rate-compensated heat detectors.

Most commercial rate-of-rise heat detectors operate when the expansion of air in a chamber exceeds the rate at which the air can escape through a small vent hole. For this type of detector, it is also necessary to model heat transfer from the detector body to the air in its chamber. Then, the expansion of the air and its escape through a vent hole must be accounted for. The response time index determined in a plunge test may not be constant as fire-gas velocities or temperatures vary. Hence, RTI is only an approximation of how the detector responds. Also, it has been hypothesized, but not tested, that rate-of-rise detectors may be modeled by simply comparing the rate of change of gas temperature to their rated response threshold.¹³ This hypothesis may be true since their rated response in degrees per minute or degrees per second is actually the measured rate of gas temperature change in the test apparatus. Thus, it would be expected that if the velocity of the fire gases was on the same order of magnitude as in the test, the rate of change of gas temperature would be the measure for detector response.

A rate-compensated detector consists of a metallic shell surrounding two bowed metal struts. There are electrical contacts on the struts. The struts and shell expand at different rates as the detector is heated. When heated fast, the outer shell expands and causes the bowed struts to straighten and close the contacts, signaling an alarm. This condition usually occurs at temperatures below the rated operating temperature. However, if the unit is heated more slowly, the difference between the expansion rates of the inner and outer parts is such that the contacts close at or near the unit's rated temperature. For rates of temperature rise up to approximately 22°C/min (40°F/min), rate-compensated detectors tend to respond when the surrounding gas temperature reaches the unit's rated operating temperature.¹⁴

Obviously, the rate-compensated type of heat detector cannot be treated as a lumped mass when calculating its response to a fire. However, at rates of temperature rise less than approximately 22°C/min (40°F/min), they can be modeled by simply assuming that they respond when the surrounding gas temperature reaches their operating temperature.

From the discussion above, it is evident that the response of fixed-temperature heat detectors can be modeled. It is necessary to know the temperature at which the detector is rated to operate. For rate-of-rise heat detectors, it is necessary to know the rate of change in the detector's temperature at which it will alarm. The RTI or τ_0 and u_0 for the detector are also needed.

In order to calculate the response of a heat detector, it is necessary to know the temperature and velocity of the gases flowing past it. Some fire plume models or ceiling-jet models may give functional relationships for temperature

and velocity that can be substituted into the heat transfer equation and integrated. Other models may not be suitable for an analytical solution. In this case, the fire model should be used to produce data on time-versus-temperature and time-versus-gas velocities. These data can then be used to numerically solve the detector heat transfer equation.

Most fire and ceiling-jet models do not model the temperature and velocity profile as a function of distance from the ceiling. This lapse introduces error and uncertainty in the results. Marrion¹⁵ showed that maximum temperature and velocity occurs between 1 and 3 in. (25 and 76 mm) below the ceiling for small (5- to 7-in. [127 to 178 mm] diameter) gasoline pan fires with a ceiling clearance of about 14 ft (4.3 m). Others have reported maximums at a distance down from the ceiling of approximately one-tenth the distance from the fuel to the ceiling. Alpert¹⁶ reports ceiling jet thickness to be approximately 5 to 12 percent of the ceiling to fuel distance. Users are cautioned when modeling detector mechanisms that are not within this range.

When the responses of multiple detectors or sprinklers are modeled, no provisions are made to account for sprinkler spray cooling of the room, and therefore, the activation of additional elements (beyond the first) may be inaccurately predicted. For more information on this topic the reader is referred to the references for works by Cooper, Delichatsios and Alpert, and Heskestad.¹⁷⁻¹⁹

Heat Detection—Steady-State Fires

Alpert¹⁶ presented the following series of equations to calculate temperature and velocity of fire gases in a ceiling jet as a function of heat release rate and position for steady-state fires:

$$T_g - T_a = \frac{[5.38(\dot{Q}/r)^{2/3}]}{H} \text{ } ^\circ\text{C} = \frac{[4.74(\dot{Q}/r)^{2/3}]}{H} \text{ } ^\circ\text{F}$$

where $r/H > 0.18$, and

$$T_g - T_a = \frac{(16.9\dot{Q}^{2/3})}{H^{5/3}} \text{ } ^\circ\text{C} = \frac{(14.9\dot{Q}^{2/3})}{H^{5/3}} \text{ } ^\circ\text{F}$$

where $r/H \leq 0.18$, and

$$u = \frac{(0.20\dot{Q}^{1/3}H^{1/2})}{r^{5/6}} \text{ m/s} = \frac{(0.25\dot{Q}^{1/3}H^{1/2})}{r^{5/6}} \text{ ft/s}$$

where $r/H > 0.15$, and

$$u = 0.95 \left(\frac{\dot{Q}}{H} \right)^{1/3} \text{ m/s} = 1.2 \left(\frac{\dot{Q}}{H} \right)^{1/3} \text{ ft/s}$$

where $r/H \leq 0.15$.

In the above series of equations,

T_g = maximum, near ceiling, fire-gas temperature in °C or °F

T_a = ambient temperature in °C or °F

\dot{Q} = total heat release rate of the fire in kW or BTU/min

r = radial distance from the axis of the fire plume in m or ft

H = height above the origin of the fire in m or ft

u = maximum, near ceiling, fire-gas velocity in m/s or ft/s

This model assumes that the temperature and velocity of the fire gases at a point away from the source are related to the instantaneous heat release rate of the fire. This assumption neglects the time required for transport of the fire gases from the source to the detector. Also, because the correlations are based on the total heat release rate rather than only the convective heat release rate, errors will be introduced when the convective fraction differs from that in the tests used to develop the correlations.

For a constant gas temperature and constant gas velocity, the basic heat transfer equation can be solved:

$$\frac{dT_d}{dt} = \frac{T_g - T_d}{\tau} \quad (7)$$

$$dT_d = \int_0^t \frac{1}{\tau} (T_g - T_d) dt$$

$$\Delta T_d = T_d - T_a = (T_g - T_a) \left[1 - \exp\left(\frac{-t}{\tau}\right) \right] ^\circ\text{C}$$

or, substituting the equation for RTI

$$\Delta T_d = T_d - T_a = (T_g - T_a) \left[1 - \exp\left(\frac{-tu^{1/2}}{\text{RTI}}\right) \right] ^\circ\text{C}$$

The response of heat detectors to fires with ceiling jets having a near constant gas temperature and velocity can be modeled using the above equations.

EXAMPLE 1:

A 4-m² pool of kerosene is burning under a flat ceiling that is 6 m high. The ambient temperature is 20°C. What would be the temperature of a ceiling-mounted heat detector having an RTI of 55 m^{1/2}s^{1/2} after a 30-s exposure if it were located 6 m from the center of the plume?

SOLUTION:

From Table 3-4.11 in this handbook the chemical heat of combustion of kerosene is 40.3 kJ/g. The convective heat of combustion is listed as 26.2 kJ/g, which is a convective fraction of about 65 percent. For Alpert's correlations we must use the total heat release rate, hence the total or chemical heat of combustion. This calculation assumes that the convective fraction will be approximately the same as the convective fraction in the experimental data Alpert used to develop the correlations for temperature and velocity. From Table 3-4.5 the mass burning rate is given as approximately 67 g/m²·s. The total heat release rate is

$$\begin{aligned} \dot{Q} &= H_c \dot{m}'' A \text{ kW} \\ \dot{Q} &= 40.3(67)4 \text{ kW} \\ \dot{Q} &= 10,800 \text{ kW} \end{aligned}$$

An r/H ratio greater than 0.18 indicates that the detector is located in the ceiling jet temperature profile. In this example,

$$\frac{r}{H} = \frac{6}{6} = 1 > 0.18$$

Therefore,

$$T_g - T_a = \frac{[5.38(\dot{Q}/r)^{2/3}]}{H} ^\circ\text{C}$$

$$T_g - 20 = \frac{[5.38(10,800/6)^{2/3}]}{6} ^\circ\text{C}$$

$$T_g - 20 = 132.7^\circ\text{C}$$

$$T_g = 153^\circ\text{C}$$

The velocity of the fire gases in the ceiling jet is given by

$$u = \frac{(0.20\dot{Q}^{1/3}H^{1/2})}{r^{5/6}} \text{ m/s}$$

$$u = \frac{[0.20(10,800)^{1/3}(6)^{1/2}]}{6^{5/6}} \text{ m/s}$$

$$u = 2.4 \text{ m/s}$$

The resulting detector temperature after 120 s is now calculated:

$$\Delta T_d = T_d - T_a = (T_g - T_a) \left[1 - \exp\left(\frac{-tu^{1/2}}{\text{RTI}}\right) \right] ^\circ\text{C}$$

$$\Delta T_d = (153 - 20) \left[1 - \exp\left(\frac{-30(2.4)^{1/2}}{55}\right) \right] ^\circ\text{C}$$

$$\Delta T_d = 76^\circ\text{C}$$

$$T_d = 76 + T_a = 76 + 20 = 96^\circ\text{C}$$

EXAMPLE 2:

What would be the response time of the detector in the above example if its temperature rating was 57°C?

SOLUTION:

$$\Delta T_d = T_d - T_a = (T_g - T_a) \left[1 - \exp\left(\frac{-tu^{1/2}}{\text{RTI}}\right) \right] ^\circ\text{C}$$

Rearranging and substituting the rated response temperature T_r for T_d , and response time t_r for t ,

$$t_r = \frac{\text{RTI}}{u^{1/2}} \ln \left(\frac{T_g - T_a}{T_g - T_r} \right) ^\circ\text{C}$$

$$t_r = \frac{55}{2.4^{1/2}} \ln \left(\frac{153 - 20}{153 - 57} \right) ^\circ\text{C}$$

$$t_r = 12 \text{ s}$$

Heat Detection, Growing Fires, and Quasi-Steady-State Modeling

A growing fire can be modeled by assuming the fire to be composed of a series of increasing steady heat release rates. This model is referred to as quasi-steady-state modeling. The first step is to break the heat release rate curve into a series of small time intervals. For each interval, use the average heat release rate for that interval to calculate the fire-gas temperature and velocity. Then, starting at ambient temperature, calculate the change and resulting temperature of the detector at the end of the first interval. Using that new detector temperature at the start of the next interval, use the next gas temperature and ve-

locity to calculate the detector temperature at the end of the interval. Continue until you have reached the time of interest or until the detector temperature exceeds its operating temperature.

EXAMPLE 3:

A stack of wood pallets is burning under a flat ceiling that is 6 m high. Table 4-1.2, showing heat release rates, is given below. The ambient temperature is 20°C. What would be the temperature of a ceiling-mounted heat detector having an RTI of 55 m^{1/2}·s^{1/2} after a 180-s exposure if it were located 6 m from the center of the plume?

SOLUTION:

As in the previous examples, the detector is located in the developed ceiling jet. The first step is to calculate the change in temperature and the velocity for each heat release rate in the table. For the period 0 to 10 s, the heat release rate is given as 5 kW. The change in temperature and the velocity of the ceiling jet at the detector are

$$T_g - T_a = \frac{\left[5.38 \left(\frac{\dot{Q}}{r} \right)^{2/3} \right]}{H} \text{ } ^\circ\text{C}$$

$$T_{g,1} - T_a = \frac{\left[5.38 \left(\frac{5}{6} \right)^{2/3} \right]}{6} = 0.794^\circ\text{C}$$

$$T_{g,1} = 20.794^\circ\text{C}$$

$$u = \frac{(0.20\dot{Q}^{1/3}H^{1/2})}{r^{5/6}} \text{ m/s}$$

$$u_1 = \frac{[0.20(5)^{1/3}(6)^{1/2}]}{6^{5/6}} = 0.188 \text{ m/s}$$

Next calculate the change in detector temperature ΔT_d as a result of that exposure by assuming the temperature and velocity to be steady over short intervals.

$$\frac{dT_d}{dt} = \frac{T_g - T_d}{\tau} = \frac{u^{1/2}(T_g - T_d)}{RTI}$$

Table 4-1.2 Example 3—Heat Release Rates

Δt	\dot{Q}	Δt	\dot{Q}
0	0	100	469
10	5	110	567
20	19	120	675
30	42	130	792
40	75	140	919
50	117	150	1055
60	169	160	1200
70	230	170	1355
80	300	180	1519
90	380		

$$\Delta T_d = T_{d,n} - T_{d,n-1} = \frac{u^{1/2}(T_{g,n} - T_{d,n-1})}{RTI} \Delta t^\circ\text{C}$$

$$T_{d,n} = \left[\frac{u^{1/2}(T_{g,n} - T_{d,n-1})}{RTI} \Delta t \right] + T_{d,n-1}^\circ\text{C}$$

Initially, the detector is not exposed to hot gases and is at ambient temperature. For the first step or interval, the detector is exposed and the resulting detector temperature at the end of the interval ($T_{d,1}$) is calculated.

$$T_{d,1} = \left[\frac{u^{1/2}(T_{g,1} - T_{d,0})}{RTI} \Delta t \right] + T_{d,0}^\circ\text{C}$$

$$T_{d,1} = \left[\frac{(0.188)^{1/2}(20.794 - 20)}{55} 10 \right] + 20 = 20.063^\circ\text{C}$$

To simplify the process, set up a table or a spreadsheet, as shown in Table 4-1.3, to complete the calculations. Rounding to two significant digits is done last. After 120 seconds of exposure the detector temperature is approximately 32°C. If the detector were rated at 57°C, it would not have responded.

Heat Detection—Potential Errors: Steady-State and Quasi-Steady-State Modeling

There are many sources of potential error in these calculations. These include the following: uncertainty in the operating temperature, uncertainty in the ambient temperature, and inaccuracies in the fire-gas temperature and velocity correlations. Because the magnitude of these potential errors is unknown or unreported, a tolerance or confidence interval for the answer cannot be estimated.

In addition, it has been assumed that use of the ceiling-jet model is valid for the examples above. The model assumes an infinite ceiling for the ceiling jet to flow outward without encountering walls and developing a layer. In the first example, the gas velocity was 2.4 m/s, and the calculation was done for a period of 120 s. The leading edge of the ceiling jet would then be approximately 48 m (2.4 m/s × 120 s) from the fire location. This dimension can be used

Table 4-1.3 Example 3—Spreadsheet Calculations

t	\dot{Q}	ΔT_g	T_g	u	ΔT_d	T_d
0	0	0		0	0	20
10	5	0.794	20.794	0.188	0.063	20.063

120	675	20.896	40.896	0.965	1.935	32.001

as a test to determine if additional error is possible because limitations of the model have been exceeded.

Evans and Stroup²⁰ published a computer program called DETACT-QS, which uses Alpert's equations to calculate the response of heat detectors. That program requires the following input: ceiling height, H ; ambient temperature, T_a ; distance from fire axis to detector, r ; detector response or activation temperature, T_r ; and detector response time index (RTI). The user must also input history of time versus heat release rate for the fire. The program uses the quasi-steady-state method demonstrated above to calculate the detector response.

Heat Detection—Power-Law Fires

Heskestad and Delichatsios⁸ presented functional relationships for modeling the temperature and velocity of fires whose heat release rates grow according to the power-law relationship:

$$\dot{Q} = at^p \text{ kW}$$

where

a = constant for a particular fuel describing the growth of the fire (kW/s²)

t = time (s)

p = positive exponent

\dot{Q} = heat release rate (kW)

NFPA 72, Appendix B, uses a constant called the *fire growth time*, t_g , in lieu of a to describe the fire intensity. The fire growth time is defined as the time at which a power-law fire would reach a heat release rate of 1055 kW (1000 Btu/s). In terms of t_g , the power-law equation becomes

$$\dot{Q} = \left(\frac{1055}{t_g^2} \right) t^p \text{ kW}$$

The nondimensional functional relationships given by Heskestad and Delichatsios²¹ for temperature and velocity of fire gases in a ceiling jet are

$$u_p^* = \frac{u}{(A^{1/(3+p)} \alpha^{1/(3+p)} H^{(p-1)/(3+p)})} \quad (16)$$

$$u_p^* = f\left(t_p^*, \frac{r}{H}\right)$$

$$\Delta T_p^* = \frac{\Delta T}{A^{2/(3+p)} (T_a/g) \alpha^{2/(3+p)} H^{-(5-p)/(3+p)}} \quad (17)$$

$$\Delta T_p^* = g\left(t_p^*, \frac{r}{H}\right)$$

where

$$A = \frac{g}{C_p T_a \rho_0} \quad (18)$$

$$t_p^* = \frac{t}{A^{-1/(3+p)} \alpha^{-1/(3+p)} H^{4/(3+p)}} \quad (19)$$

All variables are described in this chapter's nomenclature section.

For $p = 2$ power-law fires, the above nondimensional equations reduce to the following:

$$u_2^* = \frac{u}{(A^{1/5} \alpha^{1/5} H^{1/5})}$$

$$\Delta T_2^* = \frac{\Delta T}{A^{2/5} (T_a/g) \alpha^{2/5} H^{-3/5}}$$

$$t_2^* = \frac{t}{A^{-1/5} \alpha^{-1/5} H^{4/5}}$$

Heskestad and Delichatsios²¹ presented correlations to the functional relationships for fires whose release rates vary according to the power-law equation, with $p = 2$. These fires are referred to as t^2 fires. It has been shown^{22,23} that the $p = 2$ power-law fire growth model can be used to model the heat release rate of a wide range of fuels. The original correlations were used in several publications and popular calculation programs for ceiling-jet and heat-detector modeling, including the first two editions of this handbook.^{8,9,20,23-26}

Subsequently Heskestad and Delichatsios found that an incorrect value for the heat of combustion of wood resulted in the correlations being in error. All examples in this chapter that use these correlations have been updated or replaced. The corrected data correlations are as follows:²⁷

$$t_{2f}^* = 0.861 \left(1 + \frac{r}{H} \right)$$

t_{2f}^* is the nondimensional time at which the heat front reaches the detector. When $t_2^* < t_{2f}^*$, the heat front has not reached the detector position. Therefore, $\Delta T_2^* = 0$.

For $t_2^* \geq t_{2f}^*$,

$$\Delta T_2^* = \left[\frac{(t_2^* - t_{2f}^*)}{(0.146 + 0.242r/H)} \right]^{4/3}$$

This relationship may also be expressed as

$$\Delta T_2^* = \left[\frac{(t_2^* - t_{2f}^*)}{D} \right]^{4/3}$$

where

$$D = 0.146 + 0.242 \frac{r}{H}$$

$$\frac{u_2^*}{(\Delta T_2^*)^{1/2}} = 0.59 \left(\frac{r}{H} \right)^{-0.63}$$

The above correlations assume that the convective heat release rate is approximately 75 percent of the total heat release rate. The following equations are more useful forms and are used with the nondimensional equations for ΔT_2^* and u_2^* by first multiplying α by the convective fraction X :

$$\alpha_c = X\alpha \text{ kW/s}^2$$

$$t_{2f}^* = 0.813 \left(1 + \frac{r}{H} \right) \quad (20)$$

$$\Delta T_2^* = 0$$

when $t_2^* < t_{2f}^*$.

For $t_2^* < t_{2f}^*$,

$$\Delta T_2^* = \left[\frac{(t_2^* - t_{2f}^*)}{(0.126 + 0.210r/H)} \right]^{4/3} \quad (21)$$

This may also be expressed as

$$\Delta T_2^* = \left[\frac{(t_2^* - t_{2f}^*)}{D} \right]^{4/3}$$

where

$$D = 0.126 + 0.210 \frac{r}{H} \quad (22)$$

$$\frac{u_2^*}{(\Delta T_2^*)^{1/2}} = 0.59 \left(\frac{r}{H} \right)^{-0.63} \quad (23)$$

Beyler found that these correlations for temperature and velocity could be substituted into the heat transfer equation and integrated.²⁸ Beyler's analytical solution was published in *Fire Technology*²⁹ and is repeated here.

The analytical solution for the instantaneous rate of change of detector temperature is

$$\frac{dT_d(t)}{dt} = \frac{4}{3} \frac{\Delta T}{\Delta T_2^*} \Delta T_2^{*1/4} \frac{(1 - e^{-Y})}{(t/t_2^*)D} \quad (24)$$

The analytical solution for change in detector temperature is

$$\Delta T_d = T_d(t) - T_d(0) = \frac{\Delta T}{\Delta T_2^*} \Delta T_2^* \left[1 - \frac{(1 - e^{-Y})}{Y} \right] \quad (25)$$

where

$$Y = \frac{3}{4} \sqrt{\frac{u}{u_2^*}} \sqrt{\frac{u_2^*}{(\Delta T_2^*)^{1/2}}} \left(\frac{\Delta T_2^*}{RTI} \right) \left(\frac{t}{t_2^*} \right) D \quad (26)$$

and as previously defined,

$$D = 0.126 + 0.210 \frac{r}{H} \quad (22)$$

In a design situation, the objective is to determine the spacing of detectors required to respond to a specific fire scenario. The detector must respond when the fire reaches a certain threshold heat release rate or in a specified amount of time. Time and heat release rate are interchanged using the fire growth model. The steps in solving this type of problem using the $p = 2$ power-law model are outlined below and are discussed in more detail in the examples following this section. The referenced equation numbers assume that the correlations used are the ones for a variable convective fraction. The procedure would be the same if using the correlations for the fixed, 75 percent convective fractions except that α is not multiplied by the convective fraction when used in the equations. For design problems,

1. Determine the environmental conditions of the area being considered.
 - a. ambient temperature, T_a (convert to absolute temperature)
 - b. ceiling height or height above fuel, H
2. Estimate the fire growth characteristic α or t_g for the fuel expected to be burning. If t_g is used, calculate the

corresponding α . Multiply α by the convective fraction to get α_c before using in the equations.

3. Establish the goals of the system: required response time t_r or maximum permitted threshold heat release rate \dot{Q}_T .
4. Select the detector type to be used. For fixed-temperature units, this choice establishes the detector response temperature T_r and its RTI, or τ_0 and u_0 .
5. Make a first estimate of the distance, r , from the fire to the detector necessary to meet the system goals.
6. Assume that the fire starts obeying the power-law model at time $t = 0$.
7. Set the initial temperature of the detector and its surroundings at ambient temperature.
8. Using Equation 20, calculate the nondimensional time, t_{2f}^* , at which the initial heat front reaches the detector.
9. Calculate the factor A defined in Equation 18.
10. If the equations for a variable convective fraction are used, multiply α by the convective fraction X to get α_c and use result that with the required response time in Equation 19 to calculate the corresponding value of t_2^* .
11. If t_2^* is greater than t_{2f}^* , continue with Step 12. If not, try a new detector position, r , closer to the fire and return to Step 8.
12. Calculate the ratio u/u_2^* using Equation 16.
13. Calculate the ratio $\Delta T/\Delta T_2^*$ using Equation 17.
14. Use Equation 21 to calculate ΔT_2^* .
15. Equation 23 is used to calculate the ratio $u_2^*/(\Delta T_2^*)^{1/2}$.
16. Use Equations 22 and 26 to calculate D and Y .
17. Equation 25 can now be used to calculate the resulting temperature of the detector.
18. If the temperature of the detector is below its operating temperature, this procedure must be repeated using a smaller r . If the temperature of the detector exceeds its operating temperature, a larger r can be used.
19. Repeat this procedure until the detector temperature is about equal to its operating temperature. The required spacing of detectors is then $S = 1.41r$.

This same procedure is used to estimate the response of rate-of-rise heat detectors. The difference is that in Step 17, Equation 24 is used to calculate rate of change of the detector temperature. This result is then compared to the rate at which the detector is designed to respond.

The discussion and procedure so far has centered around the solution of a design problem. The question asked was, How far apart must detectors of a specific design be spaced to respond within specific goals to a certain set of environmental conditions and a specific fire scenario?

The second type of problem that must be addressed is the analysis of an existing system or the analysis of a proposed design. Here the spacing of detectors or sprinklers is known. The engineer must still estimate the burning characteristics of the fuel and the environmental conditions of the space being analyzed. The equations can then be solved in a reverse fashion to determine the rate of heat release or the time to detector response. The technique is as follows:

1. Determine the environmental conditions of the area being considered.
 - a. ambient temperature, T_a (convert to absolute temperature)

- b. ceiling height or height above fuel, H
2. Estimate the fire growth characteristic α or t_g for the fuel expected to be burning. If t_g is used, calculate the corresponding α . Multiply α by the convective fraction to get α_c before using in the equations.
3. Determine the spacing of the existing detectors or sprinklers. The protection radius is then $r = S/\sqrt{2}$.
4. Determine the detector's rated response temperature and its RTI, or τ_0 and u_0 .
5. Make a first estimate of the response time of the detector or estimate the heat release rate at detector response and calculate the corresponding response time using the power-law equation.
6. Assume that the fire starts obeying the power-law model at time $t = 0$.
7. Set the initial temperature of the detector and its surroundings at ambient temperature.
8. Using Equation 20, calculate the nondimensional time, t_{2f}^* , at which the initial heat front reaches the detector.
9. Calculate the factor A defined in Equation 18.
10. Use the estimated response time along with Equation 19 to calculate the corresponding value of t_2^* .
11. If t_2^* is greater than t_{2f}^* , continue with Step 12. If not, try a longer estimated response time or a larger estimated heat release rate and return to Step 8.
12. Calculate the ratio u/u_0^* using Equation 16.
13. Calculate the ratio $\Delta T/\Delta T_2^*$ using Equation 17.
14. Use Equation 21 to calculate ΔT_2^* .
15. Equation 23 is used to calculate the ratio $u_2^*/(\Delta T_2^*)^{1/2}$.
16. Use Equations 22 and 26 to calculate D and Y .
17. Equation 25 can now be used to calculate the resulting temperature of the detector.
18. If the temperature of the detector is below its operating temperature, this procedure must be repeated using a longer estimated response time. If the temperature of the detector exceeds its operating temperature, a smaller t_r can be used.
19. Repeat this procedure until the detector temperature is about equal to its operating temperature. The resulting response time, t_r , can be used to calculate either the total heat release rate or the convective heat release rate at response using the power-law equation.

As in the design problem, this technique can be used to estimate the response of existing systems of rate-of-rise heat detectors. The difference is that in Step 4 the set point or rate of temperature rise at which the detector will respond must be determined from the manufacturer's data. In Step 17, Equation 24 is used to determine the rate at which the temperature of the detector is changing.

Heat Detection—Potential Errors:

Power-Law Fire Modeling

When the exact conditions of velocity and temperature of fire gases flowing past a detector are not known, errors are introduced in the design and analysis of fire detector response. Graphs in Heskestad and Delichatsios' report show the errors in calculated fire-gas temperatures and velocities.²² An exact treatment of these errors is beyond the scope of this chapter, though some discussion is warranted.

Plots of actual data and calculated data show that errors in ΔT_2^* can be as much as 50 percent, though generally there appears to be much better agreement.^{22,23} The maximum errors occur at r/H values of about 0.37. All other plots of actual and calculated data, for various r/H , show much smaller errors. In terms of the actual change in temperature over ambient, the maximum errors are on the order of 5 to 10°C. The larger errors occur with faster fires and lower ceilings.

At $r/H = 0.37$, the errors are conservative when the equations are used in a design problem. That is, the equations predicted lower temperatures. Plots of data for other values of r/H indicate that the equations predict slightly higher temperatures.

Errors in fire-gas velocities are related to the errors in temperatures. The equations show that the velocity of the fire gases is proportional to the square root of the change in temperature of the fire gases.²² In terms of heat transfer to a detector, the detector's change in temperature is proportional to the change in gas temperature and the square root of the fire-gas velocity. Hence, the expected errors bear the same relationships.

Based on the discussion above, errors in predicted temperatures and velocities of fire gases will be greatest for fast fires and low ceilings. Sample calculations simulating these conditions show errors in calculated detector spacings on the order of plus or minus 1 m, or less.²³

Similar to Alpert's steady-state model, the power-law ceiling-jet model assumes a flat infinite ceiling. If the leading edge of the ceiling jet has passed the detector position and not reached a wall or other obstruction, then the model is within its stated parameters. The nondimensional time that the heat front reaches some position, r/H , is given by the equation for t_{2f}^* . The corresponding nondimensional time at response is given by the equation for t_2^* . Setting these equal to each other and solving for r at $t = t_r$ gives the radial distance from the fire to the leading edge of the heat front. Using the equations for a user-entered convective fraction,

$$t_{2f}^* = 0.813 \left(1 + \frac{r}{H} \right)$$

and

$$t_2^* = \frac{t_r}{A^{-1/5} \alpha_c^{-1/5} H^{4/5}}$$

$$t_{2f}^* = t_2^*$$

$$0.813 \left(1 + \frac{r}{H} \right) = \frac{t_r}{A^{-1/5} \alpha_c^{-1/5} H^{4/5}}$$

$$r = \frac{(t_r/A^{-1/5} \alpha_c^{-1/5} H^{4/5})/0.813 - 1}{H} = \frac{t_r^*/0.813 - 1}{H}$$

Selection of Data for Design and Analysis

In order to calculate the required spacing of heat detectors or sprinklers to respond to a given fire, the following information is required:

1. *System goals:* desired fire size (heat release rate) at response or time to detector response from the start of open flaming

2. Fire growth constant α or t_g
3. Ambient temperature
4. Height above the fuel or ceiling height

In addition to the above, the heat capacity of air at constant pressure, C_p , the density of air, ρ_0 , and the gravitational constant, g , are used in the calculations. It is also necessary to know the characteristics of the detector for which the spacing calculations are being made. Specifically, the response temperature and the RTI of the detector must be known.

Establishing system goals is not within the scope of this chapter. However, it should be pointed out that, no

matter what the goals are, they must be expressed in terms of heat release rate or time to detector response. The system's goals may actually be to limit damages to some dollar value, provide adequate escape time, or limit the production of toxic gases. In order to calculate required detector spacing using this system, these goals would have to be translated. For instance, as the fire grows, at what time or heat release rate must the detector respond so that the fire department can be summoned and extinguish the fire before damage levels are exceeded or conditions become untenable due to toxic gases?

Table 4-1.4 is a list of furniture calorimeter tests done at the National Bureau of Standards.^{16,24} The tests provide

a database of heat release rate, particulate production, and radiation from a variety of common furnishings. The table provides the corresponding a or t_g for the calorimeter tests.²³ The virtual time data in the table is the approximate time at which the heat release rate in the test began to follow the $p = 2$ power-law model ($\dot{Q} = at^2$ kW). Prior to this time, the behavior of the fire cannot be predicted with this model. Figure 4-1.5 shows some test data along with a power-law curve superimposed.

The data in Table 4-1.4 can be used to select a or t_g for use in spacing calculations. However, in many cases the data in this table will not match the scenario being studied. If the heat-release-rate-versus-time history can be obtained or approximated for the expected fuel, the a or t_g can be calculated using curve fitting techniques.²³

In most cases, since the exact fuel that will be involved in a fire cannot be known, the rigorous calculation of a is not warranted. Engineering judgment can be used to select an a or t_g that approximates the severity of the fire. The data in Table 4-1.4 suggest a range of 50 to 500 s for t_g . Only a few rapidly developing fires had a t_g below 50 s. Three slow fires had values above 500 s for t_g .

Table 4-1.4 also lists the maximum heat release rate reached during the power-law growth. The heat release rate model $\dot{Q} = at^2$ does not predict when a fuel package stops following the model or when the fuel is depleted. This task is an important point often missed by many designers. A simple test is to calculate the mass of fuel consumed from $t = 0$ to the time of interest. For $p = 2$ power-law fire growth rate, the total energy consumed is

$$E = \int_{t=0}^t \dot{Q} = \int_{t=0}^t \alpha t^2 \text{ kJ}$$

$$E = \frac{\alpha t^3}{3} \text{ kJ}$$

Knowing the heat of combustion, H_c , for the fuel permits calculation of the mass of fuel necessary to release a given amount of energy in the time period:

$$E = mH_c \text{ kJ}$$

$$m = \frac{E}{H_c} \text{ g or kg (depending on the units for } H_c)$$

When doing a design or analysis, try several different fire growth rates to determine the effect of their variance on the calculations. In some cases, the effect will be minimal. In other cases, this type of sensitivity analysis will show that a more thorough analysis of the possible fuels and fire scenarios is warranted.

The selection of an ambient temperature can have a measurable effect on the calculations. The calculations assume that the detector or sprinkler starts out at the same temperature as the ambient air when the fire starts. Hence, if a temperature of 20°C is assumed for the spacing calculations and the actual temperature at the time of the fire is 10°C, the system's goals will not be met. For design calculations to be conservative, the lowest expected ambient temperature should be used.

Figure 4-1.5. Test 27 chair.

The relationships presented by Heskestad and Delichatsios²¹ are correlated to fire test data using the ceiling height above the fuel surface for H . If this height varies, the larger value of H will produce more conservative results in the calculations for detector spacing or response. The most conservative results are obtained when the floor-to-ceiling height is used, since this height is the maximum vertical distance from fuel to detector.

The values for C_p , ρ_0 , and g should be 1.040 kJ/(kg·K), 1.1 kg/m³, and 9.81 m/s², respectively. Slight variations in these constants have negligible effects on the calculations.

As previously mentioned, the design or analysis calculations are done for a particular detector or sprinkler. Therefore, it is necessary to know the unit's operating temperature. The response time index or τ_0 and u_0 are also needed. Operating temperature is obtained from manufacturer's data. The detector's sensitivity is best determined by conducting a plunge test.⁹

In the absence of plunge test data, a detector's UL-listed spacing can be used as a measure of detector sensitivity. Heskestad and Delichatsios analyzed UL test data and calculated time constants, τ_0 , for various combinations of UL-listed spacing and detector operating temperature.²² The Appendix Subcommittee of NFPA 72 expanded the table to include a larger selection of detectors.⁸ That table is reproduced here as Table 4-1.5.

Heat Detection Design and Analysis Examples Using the Power-Law Fire Model

Analysis and design problems will be used to show how fire protection engineers can use the techniques presented in this chapter. The examples show the sensitivity of these techniques to changes in variables and input parameters. A design problem is first worked by hand to solve the equations presented earlier in the section on heat detection. The remaining examples were worked using a spreadsheet written to solve the equations.

Table 4-1.5 Time Constants for Any Listed Detector
 τ_0 (s)^a

Listed Spacing (ft)	UL (°F)						FMRC All Temp.
	128°	135°	145°	160°	170°	196°	
10	400	330	262	195	160	97	195
15	250	190	156	110	89	45	110

25	124	100	78	48	32		48
30	95	80	61	36	22		36
40	71	57	41	18			
50	59	44	30				
70	36	24	9				

These time constants are based on an analysis of the Underwriters Laboratories Inc. and Factory Mutual Research Corporation listing test procedures. Plunge test results performed on the detector to be used will give a more accurate time constant.

^aAt a reference velocity of 5 ft/s

(Reproduced from NFPA 72-1993, Appendix B.⁸)

EXAMPLE 4:

A fire detection system is being designed for an un-sprinklered manufacturing building. The area being considered has a large, flat ceiling 5.0 m high. Ambient temperature is normally 20°C, but on weekends it is cut back to 10°C. It will be assumed that the fire scenario involves the ignition of a stack of wood pallets. The pallets are stacked 1.5 m (5 ft) high. Fire tests⁸ show that this type of fire follows the $p = 2$ power-law equation with a t_g of approximately 150 s. The corresponding α can be calculated:

$$\dot{Q} = \alpha t^2 \text{ kW}$$

$$\alpha = \frac{1055}{t_g^2} = \frac{1055}{150^2} = 0.047 \text{ kW/s}^2$$

The goal is to detect the fire before it reaches a total heat release rate of 2500 kW. Fixed-temperature heat detectors will be used. The detectors have a 57°C (135°F) operating temperature and a UL-listed spacing of 30 ft. From Table 4-1.5 the time constant is found to be 80 s. This time constant is referenced to a gas velocity of 1.5 m/s and can be used with Equation 9 to calculate the detector's RTI.

First, use the power-law equation to calculate the time that the fire would reach a total heat release rate of 2500 kW:

$$\dot{Q} = \alpha t^2 \text{ kW}$$

$$t = \sqrt{\frac{\dot{Q}}{\alpha}} = \sqrt{\frac{2500}{0.047}} = 231 \text{ s}$$

The RTI is calculated using Equation 9 and a reference velocity, u_0 , of 1.5 m/s (5 ft/s):

$$RTI = \tau_0 u_0^{1/2} = 80 \sqrt{1.5} = 98 \text{ m}^{1/2} \text{ s}^{1/2}$$

As described previously in Step 5 for design of a proposed system, it is necessary to make a first guess at the required detector spacing. In this case, try using $r = 6.0$ m. Use Equation 20 to calculate the nondimensional time, t_{2f}^* , at which the initial heat front reaches the detector. Use the distance from the top of the fuel package to the ceiling for H .

$$t_{2f}^* = 0.813 \left(1 + \frac{r}{H} \right)$$

$$t_{2f}^* = 0.813 \left(1 + \frac{6.0}{3.5} \right) = 2.207$$

Next, Equation 18 is used to calculate A . Note that in this equation the ambient temperature, T_a , must be expressed as an absolute temperature. In this case add 273 to °C to get K (Kelvin).

$$A = \frac{g}{C_p T_a \rho_0}$$

$$A = \frac{9.81}{1.040(10 + 273)1.1} = 0.030$$

The nondimensional time corresponding to the required response time is now calculated. However, first we must calculate α_c :

$$\alpha_c = Xa = 0.70(0.047) = 0.033 \text{ kW/s}^2$$

$$t_2^* = \frac{t}{A^{-1/5}\alpha_c^{-1/5}H^{4/5}}$$

$$t_2^* = \frac{231}{(0.030)^{-1/5}(0.033)^{-1/5}(3.5)^{4/5}} = 21.256$$

Since $t_2^* > t_{2f}^*$, we know that the heat front has passed the detector location. Next, the ratio of the velocity to the nondimensional velocity is calculated:

$$u_2^* = \frac{u}{(A^{1/5}\alpha_c^{1/5}H^{1/5})}$$

$$\frac{u}{u_2^*} = A^{1/5}\alpha_c^{1/5}H^{1/5}$$

$$\frac{u}{u_2^*} = (0.030)^{1/5}(0.033)^{1/5}(3.5)^{1/5} = 0.322$$

The ratio of the change in gas temperature to the nondimensional gas temperature is calculated:

$$\Delta T_2^* = \frac{\Delta T}{A^{2/5}(T_a/g)\alpha_c^{2/5}H^{-3/5}}$$

$$\frac{\Delta T}{\Delta T_2^*} = A^{2/5}\left(\frac{T_a}{g}\right)\alpha_c^{2/5}H^{-3/5}$$

$$\frac{\Delta T}{\Delta T_2^*} = (0.030)^{2/5}\left(\frac{283}{9.81}\right)(0.033)^{2/5}(3.5)^{-3/5} = 0.855$$

The nondimensional change in gas temperature is now calculated:

$$D = 0.126 + 0.210\left(\frac{6.0}{3.5}\right) = 0.486$$

$$\Delta T_2^* = \left[\frac{(t_2^* - t_{2f}^*)}{D}\right]^{4/3}$$

$$\Delta T_2^* = \left[\frac{(21.256 - 2.207)}{0.486}\right]^{4/3} = 133.142$$

Next, the ratio $u_2^*/(\Delta T_2^*)^{1/2}$ is calculated:

$$\frac{u_2^*}{(\Delta T_2^*)^{1/2}} = 0.59\left(\frac{r}{H}\right)^{-0.63}$$

$$\frac{u_2^*}{(\Delta T_2^*)^{1/2}} = 0.59\left(\frac{6.0}{3.5}\right)^{-0.63} = 0.420$$

Y is now calculated:

$$Y = \frac{3}{4}\sqrt{\frac{u}{u_2^*}}\sqrt{\frac{u_2^*}{(\Delta T_2^*)^{1/2}}}\left(\frac{\Delta T_2^*}{\text{RTI}}\right)\left(\frac{t}{t_2^*}\right)D$$

$$Y = \frac{3}{4}\sqrt{0.322}\sqrt{0.420}\left(\frac{133.142}{98}\right)\left(\frac{231}{21.256}\right)(0.486) = 1.979$$

The resulting temperature of the detector at $t = 231$ s, $T_d(t)$, can now be calculated. Assume that the temperature of the detector at the start of the fire, $T_d(0)$, is the same as ambient temperature, T_a .

$$\Delta T_d = T_d(t) - T_d(0) = \frac{\Delta T}{\Delta T_2^*} \Delta T_2^* \left[1 - \left(\frac{1 - e^Y}{Y}\right)\right]$$

$$\Delta T_d = T_d(t) - T_d(0)$$

$$= 0.855(133.142) \left[1 - \left(\frac{1 - e^{-1.979}}{1.979}\right)\right]$$

$$\Delta T_d = T_d(t) - T_d(0) = 64.264$$

$$T_d(t) = \Delta T_d + T_d(0) = 64.264 + 10 = 74.264 = 74^\circ\text{C}$$

After 231 s, when the heat release rate has reached 2500 kW, the detector located 6 m from the fire axis has reached an approximate temperature of 74°C. Note that the answer has been rounded to two significant digits, one more than the least precision of any of the variables. This rule is the alternate rule for rounding as discussed in the introduction of this chapter.

The detector actuation temperature is 57°C. This result indicates that the detector has responded before the fire has reached 2500 kW. Since the calculated temperature is higher than the actuation temperature, a larger r can be tried. The calculations should be repeated until the calculated detector temperature is approximately equal to the actuation temperature.

For this example the answer converges on a radial distance of approximately 7.4 m. The spacing between detectors is

$$S = r\sqrt{2} = 7.4\sqrt{2} = 10.5 \text{ m}$$

EXAMPLE 5:

This example will show how an existing heat detection system or a proposed design can be analyzed to determine its response time or fire size at response. The scenario used in Example 4 will be repeated, except that the manufacturing building has an existing system of heat detectors, which are spaced evenly on the ceiling at 15.0-m intervals. The detector characteristics are the same as above. The actuation temperature is 57°C and the RTI is 98 $\text{m}^{1/2}\cdot\text{s}^{1/2}$. The ceiling height is 5 m, and the height of the pallets is 1.5 m. Ambient temperature is 10°C. α is 0.047 kW/s^2 ($t_g = 150$ s) and α_c is 0.033 kW/s^2 .

The maximum radial distance from the fire axis to a detector is calculated first, using Equation 5.

$$S = r\sqrt{2} \text{ m}$$

$$r = \frac{S}{\sqrt{2}} = \frac{15.0}{\sqrt{2}} = 10.6 \text{ m}$$

The next step in the analysis is to estimate the response time of the detector or the fire size at response. In the design above, the fire grew to about 2500 kW in 231 s when the detector at a distance of 7 m responded. The radial distance in this example is larger and should result in

a slower response and larger fire size at response. A first guess at response time might be 6 min or 360 s. The fire size (total heat release rate) at 360 s is

$$\dot{Q} = at^2 \text{ kW}$$

$$\dot{Q} = 0.047(360)^2 = 6091 \text{ kW}$$

The remaining calculations for the resulting detector temperature are similar to those in Example 4. Rather than show the detail, a spreadsheet was used to complete the calculations. The resulting detector temperature at 360 s was calculated to be approximately 84°C.

This result indicates that the detector response time is less than the estimated 6 min. Therefore, a smaller response must be tried. If the calculated temperature were lower than the actuation temperature, a larger t would be tried. The calculations are repeated until the calculated detector temperature is approximately equal to the actuation temperature. In this case, the response time converges at 295 s. This result corresponds to a fire size at response of 4070 kW. It is at this time and heat release rate that the detector temperature reaches its actuation temperature of 57°C.

This example assumes that the fire continues to follow the power-law relationship through the burning period. If there is not enough fuel available, it is possible for the heat release rate curve to flatten out before reaching 4070 kW. These calculations do not predict when this development will happen. These calculations also do not predict how the detector temperature changes after the fire stops following the power-law relationship. It may be that sufficient heat continues to be released and the detector eventually responds. It is also possible for the fire gases to cool sufficiently to preclude detector actuation unless additional fuel becomes involved in the fire.

Comparing Example 4 with Example 5 shows how detector spacing affects response time. A difference in spacing of 4.4 m (15 – 10.6 m) results in a difference of approximately 64 s in the detector response time. Because the fire is accelerating according to the $p = 2$ power-law relationship, the resulting difference in fire size at response is 1570 kW.

EXAMPLE 6:

A warehouse is used to store sofas and other furniture. The sofas are similar to one tested by the National Bureau of Standards in their furniture calorimeter.³⁰ Burning characteristics are assumed to be similar to the sofa used in Test 38:^{23,30} $a = 0.1055 \text{ kW/s}^2$, $t_g = 100 \text{ s}$; peak heat release rate = 3000 kW. The sofas are stored one or two high. Assume a convective fraction of 65 percent.

The building has a flat roof and ceiling. The distance from the floor to the ceiling is 4.6 m. When the sofas are stacked two high, the distance from the top of the fuel package to the ceiling is 2.4 m. Ambient temperature in the warehouse is kept above 10°C. (See Figure 4-1.6.)

Based on maximum allowable property loss goals established by the owner, it is desirable to detect a fire and notify the fire department prior to a second fuel package becoming involved. The original NBS report³⁰ contains data on radiation measured during Test 38. This informa-

Figure 4-1.6. Example 6—Warehouse.

tion can be used along with other techniques presented in this handbook to determine when a second item might ignite. For instance, it might be determined that furniture across a 2-m aisle might ignite when the fire reaches a total heat release rate of 3000 kW. The objective would then be to detect the fire soon enough so that the fire can be extinguished or controlled before the fire reaches total 3000 kW. In this example, it is assumed that the fire must be detected when it reaches a total heat release rate of about 2000 kW.

The fire detection system will consist of fixed-temperature heat detectors connected to a control panel that is, in turn, connected to the local fire department. The detector to be used has a fixed temperature rating of 57°C and an RTI of $42 \text{ m}^{1/2} \cdot \text{s}^{1/2}$.

The problem is determining the spacing of detectors required to detect this fire. When the computer program runs, the user is prompted for all of the above information. In this example, the data are fixed except for the distance from the top of the fuel and the ceiling (2.4 m) is used, the calculations indicate that the detectors must be spaced 7.3 m apart to respond when the fire reaches a heat output of 2000 kW.

For a worst-case analysis, the distance from the floor to the ceiling (4.6 m) is used. This distance results in a required detector spacing of 5.9 m.

A more realistic worst-case scenario would be when the sofas are not stacked two high. With one sofa on the floor, the distance from the fuel to the ceiling would be about 3.7 m. The required detector spacing would then be 6.5 m.

These results are summarized in Table 4-1.6. This table clearly shows the relationship between ceiling height and detector response. The greater the distance from the fire to the ceiling, the closer the detectors must be spaced to respond within the goals of the system. Designs based on the floor-to-ceiling distance are conservative and representative of a worst-case condition. More realistic designs are based on the most probable or the greatest expected vertical clearance between fuel and detector.

Table 4-1.6 Example 6—Ceiling Height or Height above Fuel versus Detector Spacing

Ceiling Height, H (m)	Required Spacing, S (m)
2.4	10.3
3.7	9.2
4.6	8.4

Table 4-1.7 Example 7—Ceiling Height or Height above Fuel versus Response Time

Ceiling Height, H (m)	Response Time, t_r (s)
2.4	140
3.7	150
4.6	160

EXAMPLE 7:

For the same conditions in Example 6, if the detector spacing is fixed at 10.3 m ($r = 7.3$ m), how does the ceiling height affect the response time of the system?

Using the spreadsheet, the results, after rounding, are summarized in Table 4-1.7.

EXAMPLE 8:

This example will show how to select a detector type to economically meet the system's goals. The fire scenario and goals used in Examples 6 and 7 will be used: $H = 2.4$ m; $T_a = 10^\circ\text{C}$; RTI = $42 \text{ m}^{1/2}\cdot\text{s}^{1/2}$; $X = 65$ percent, $t_g = 100$ s.

In Example 6, it was found that heat detectors with a fixed temperature rating of 57°C and an RTI of $42 \text{ m}^{1/2}\cdot\text{s}^{1/2}$ must be spaced 10.3 m apart to meet the system's goals—a response at 2000 kW. Here, the spacing of rate-of-rise heat detectors will be estimated.

The detector to be used is rated to respond when its temperature increases at a rate of $11^\circ\text{C}/\text{min}$ or more. The detector's RTI will be assumed to be the same as the detector in Example 6. The calculation procedure is the same as for fixed temperature detectors except that, in the last step, the equation for the rate of temperature change is used:

$$\frac{dT_d(t)}{dt} = \frac{4}{3} \frac{\Delta T}{\Delta T_2^*} \Delta T_2^{*1/4} \frac{(1 - e^{-\gamma})}{(t/t_2^*)D}$$

Solving the equations, it is found that the rate-of-rise heat detectors can be spaced up to 25 m apart and respond at approximately 2000 kW total heat release rate.

If the total area of the warehouse is 5000 m^2 , approximately 48 fixed-temperature heat detectors would be required to meet the established goals. The same goals can be met with approximately 8 rate-of-rise heat detectors. Additional detectors might be required due to obstructing beams or walls. It should also be pointed out that the use of m^2 for calculating the required number of units is only an estimate. The detector does not cover an area that is 625 m^2 ($25 \text{ m} \times 25 \text{ m}$). It is covering a circular

area having a radius no more than about 17.7 m. That is, all points on the ceiling must be within the protection radius of a detector for the calculations to be valid. If one used a "rated area" for a detector rather than a radial measurement, it could be concluded that a single detector in this example could cover a space that was 125 m long if it were only 5 m wide.

By trying different detector types or detectors with higher sensitivities, project goals might be met with a fewer number of detectors. The scenario in this example shows that, to detect the same fire, a much greater number of fixed-temperature heat detectors than rate-of-rise heat detectors is required. This conclusion is not always the case. Many fires will develop slowly and cause high ceiling temperatures without ever exceeding the rate of temperature rise necessary to actuate a rate-of-rise heat detector. As a backup, most commercially available rate-of-rise heat detectors have a fixed-temperature element also. The rate-of-rise element and the fixed-temperature element should be considered separately when designing or analyzing a system.

EXAMPLE 9:

In this example, a combination fixed-temperature and rate-of-rise heat detector will be analyzed and the response of the two elements will be compared. For an installed spacing of 10.0 m ($r = 0.707$ m), the effect of fire growth rate on response time will be shown. The following conditions from examples 6, 7, and 8 will be repeated: $H = 2.4$ m; $T_a = 10^\circ\text{C}$; RTI = $42 \text{ m}^{1/2}\cdot\text{s}^{1/2}$; $X = 65$ percent. The fixed-temperature element response threshold is $T_r = 57^\circ\text{C}$, and the rate-of-rise threshold is $dTr/dt = 11^\circ\text{C}/\text{min}$.

The results are shown in Table 4-1.8 and Figure 4-1.7. For fire growth times up to $t_g = 509$ s, the rate-of-rise element responds faster. For fires that grow slower (increasing t_g), the fixed-temperature element will respond faster.

For larger installed spacings, such as the 25-m spacing calculated in the previous example for the spacing of the rate-of-rise detector, the crossover point occurs sooner. The results for a 25-m spacing are shown in Table 4-1.9 and Figure 4-1.8. For fire growth times up to $t_g = 228$ s, the rate-of-rise element responds faster. For fires that grow slower (increasing t_g), the fixed-temperature element will respond faster.

EXAMPLE 10:

In this example, the effects of fire growth rate on detector spacing will be examined. The scenario used in Examples 6 through 9 will be used again. The following conditions from these examples will be repeated:

$H = 2.4$ m; $T_a = 10^\circ\text{C}$; $\text{RTI} = 42 \text{ m}^{1/2}\cdot\text{s}^{1/2}$; $X = 65$ percent. The fixed temperature element response threshold is $T_r = 57^\circ\text{C}$ and the rate-of-rise threshold is $dT_r/dt = 11^\circ\text{C}/\text{min}$.

In Examples 6, 7, and 8, the rate of fire growth followed the power-law equation with an α of $0.1055 \text{ kW}/\text{s}^2$ or $t_g = 100$ s. Calculations were done for several values of t_g . The results are summarized in Table 4-1.10 and Figure 4-1.9.

For fixed-temperature detectors, if the fire grows at a faster rate (smaller t_g), a smaller spacing is required to meet the system's goals. If the fire grows at a slower rate, a larger detector spacing is allowed. This relationship clearly shows the effects of thermal lag on detector response. At slow rates of growth, the detector is immersed in the hot fire gases and, despite thermal lag, has time to absorb the heat before the fire reaches the maximum permissible heat release rate. The effects of thermal lag are less important at slow rates of fire growth.

The rate-of-rise detector also experiences thermal lag. However, the curve peaks at approximately $t_g = 110 \text{ m}^{1/2}\cdot\text{s}^{1/2}$ and $S = 25$ m. For the rate-of-rise detector, as

Table 4-1.10 Required Detector Spacing as a Function of Fire Growth Time, t_g

t_g	Required Spacing (m)	
	Fixed-Temperature	Rate-of-Rise

500	17	12
600	18	10

Figure 4-1.9. Required detector spacing as a function of fire growth time, t_g .

the fire growth rate slows (larger t_g), thermal lag decreases as it did for the fixed temperature detector. However, as the rate of fire growth slows, so does the rate of change of the detector's temperature. For this particular detector and fire scenario, at fire growth times greater than about 110 s, the detector spacing must be reduced so that the threshold rate of change of the detector temperature is reached before the maximum permissible heat release rate is reached.

EXAMPLE 11:

In this example a detector is exposed to the ceiling jet for a fire with $t_g = 150$ s and a 75 percent convective fraction. Ambient temperature is 10°C. The ceiling is 4 m high, and the detector is located at a radial distance of 5 m from the fire. The RTI of the detector is 50. Plot the detector temperature and the fire-gas temperature at the detector location for t up to 240 s.

The detector remains at ambient temperature until the ceiling jet first reaches the detector position. At what time does the ceiling jet first reach the detector? This result is found by setting $t_{2f}^* = t_2^*$ and solving for t . First, α_c is calculated:

$$\alpha = \frac{t_g^2}{1055} = \frac{1055}{150^2} = 0.047 \text{ kW/s}^2$$

$$\alpha_c = X\alpha = 0.75(0.047) = 0.035 \text{ kW/s}^2$$

$$t_{2f}^* = t_2^*$$

$$0.813 \left(1 + \frac{r}{H} \right) = \frac{t}{A^{-1/5} \alpha_c^{-1/5} H^{4/5}}$$

$$t = 0.813 \left(1 + \frac{r}{H} \right) = A^{-1/5} \alpha_c^{-1/5} H^{4/5} s$$

$$t = 0.813 \left(1 + \frac{5}{4} \right) = (0.030^{-1/5})(0.035^{-1/5})(4^{4/5}) = 21.86 = 22 \text{ s}$$

The heat front reaches the detector at about 22 s, and heating begins. Prior to this point, the detector and gas temperature surrounding the detector are at ambient temperature.

The method to calculate the detector temperature is the same as in previous examples. To calculate the change in ceiling-jet gas temperature, combine the following equations and solve to ΔT :

$$\Delta T_2^* = \frac{\Delta T}{A^{2/5} (T_a/g) \alpha_c^{2/5} H^{-3/5}}$$

and

$$\Delta T_2^* = \left[\frac{(t_2^* - t_{2f}^*)}{(0.126 + 0.210r/H)} \right]^{4/3}$$

$$\Delta T = A^{2/5} \left(\frac{T_a}{g} \right) \alpha_c^{2/5} H^{-3/5} \left[\frac{(t_2^* - t_{2f}^*)}{(0.126 + 0.210r/H)} \right]^{4/3}$$

A spreadsheet solution is shown in Table 4-1.11 and graphed in Figure 4-1.10.

EXAMPLE 12:

A sprinkler system is being installed in a large exhibition hall. The building has a flat roof deck supported by open space frame trusses. The distance from the underside of the roof deck to the floor is 12 m. Ambient temperatures do not usually fall below 5°C.

Table 4-1.11 Example 11—Ceiling Jet and Detector Temperature as a Function of Time

t (s)	T_g (s)	T_d (s)

240	148	120

Figure 4-1.10. Example 11—Ceiling jet and detector temperature as a function of time.

Three different designs for the sprinkler system have been proposed. All three are designed to provide the same water density over a specified area. Each proposal uses a sprinkler with a temperature rating of 74°C and an RTI of 110 m^{1/2}·s^{1/2}. The only difference among the three systems is the spacing of the sprinklers and the branch lines that feed them. The first proposal uses a square array with a spacing of 3.0 m. The second and third proposals are based on square array spacings of 3.7 m and 4.6 m, respectively.

What effect will the three different spacings have on the size of the fire when the system responds? Assume two different fire scenarios. In the first, the fire grows at a moderate rate with $t_g = 200$ s. The second fire scenario has a slower fire growth rate with $t_g = 500$ s. For both, assume a convective fraction of 75 percent. Results of the calculations are shown in Table 4-1.12 after rounding.

The calculations show an increase of about 25 percent in the fire size at response when the spacing is increased 50 percent from 3.0 to 4.6 m. The increased spacing may result in a lower system cost. However, closer spacings mean that the sprinkler system will probably respond sooner. The fire protection engineer can use this type of analysis to assist in choosing a system that best meets the project's overall goals.

EXAMPLE 13:

A fire impacting elevator machinery can result in passengers or fire fighters being carried to a fire floor or being trapped between floors. Elevator safety codes generally do not require any sprinkler protection or detection at the top of shafts since the fuel load is typically insufficient to actuate a sprinkler or affect persons in the cars.

Smoke detection is used in elevator lobbies and machine rooms to recall elevators to a safe level when smoke threatens the elevator shaft. The presence of sprinklers in the elevator machine room presents another risk: the possibility of water discharge on energized controllers and motors and on the elevator brakes. To reduce this risk, in addition to smoke detection, heat detectors may be used to ensure that equipment is de-energized upon or prior to the discharge of water. To accomplish this task, some codes may require a heat detector with a lower temperature rating and a lower RTI within 0.61 m of every sprinkler in an elevator machine room. Are these requirements sufficient to assure response before the sprinkler to a range of possible fire scenarios?

SOLUTION:

For this example, use an ambient temperature of 15°C and a ceiling height or clearance of 4 m. Assume the actuation temperature of the sprinklers is 74°C and the actuation temperature of the heat detectors is 57°C. The RTI of the sprinklers is 110 m^{1/2}·s^{1/2}, and the RTI of the detectors is 42 m^{1/2}·s^{1/2}. Spacing of the sprinklers is 3.0 m. Calculate the response of the sprinkler and the heat detector to a fast fire, $t_g = 50$ s, and a slow fire, $t_g = 600$ s. Assume a 75 percent convective fraction.

A sprinkler spacing of 3.0 m results in a worst case radial distance of 2.12 m. The heat detector could be an additional 0.61 m beyond at $r = 2.73$ m. The results of the calculations are summarized in Table 4-1.13.

These calculations show that the heat detector will respond before the sprinkler. Depending on the actual conditions, additional calculations should be tried for different fire scenarios and for changes in other variables such as RTI, ambient temperature, ceiling clearance, and so forth.

Smoke Detection

In order to determine whether or not a smoke detector will respond to a given \dot{Q}_{cr} , a large number of factors must be evaluated. These include the following: smoke aerosol characteristics, aerosol transport, detector aerodynamics, and sensor response.

Smoke aerosol characteristics at the point of generation are a function of the fuel composition, the combustion state (smoldering or flaming), and the degree of vitiation of the combustion air. The characteristics considered include particle size and distribution, particle number or concentration at various sizes, composition, color, and refractive index. Given the dynamic nature of fire growth and spread and fuels involved, ventilation conditions will change over time, thus affecting the smoke produced.

Transport considerations include (1) changes to the aerosol characteristics that occur with time and distance from the source and (2) transport time. Changes in the aerosol largely relate to the particle size and concentration, and result from the processes of sedimentation, agglomeration, and coagulation. Transport time is a function of the characteristics of the travel path from the source to the detector, which include ceiling height and configuration (sloped, beamed, etc.), intervening barriers such as doors, and buoyancy effects such as layering and thermal inversions.

Table 4-1.12 Example 12—Effects of Sprinkler Spacing on Fire Size at Response and Time to Response

S (m)	$t_g = 200$ s		$t_g = 500$ s	
	t_r (s)	\dot{Q}_T (kW)	t_r (s)	\dot{Q} (kW)
3.0	350	3300	800	2700
3.7	370	3600	840	3000
4.6	400	4100	890	3400

Table 4-1.13 Example 13—Sprinkler and Heat Detector Response to Different Fire Growth Rates

	Response Time (s)	
	$t_g = 50$ s	$t_g = 600$ s
Sprinkler	65	370
Heat Detector	50	300

Once smoke reaches the detector, other factors become important, namely the aerodynamic characteristics of the detector and the type of sensor. The aerodynamics of the detector relate to the ease with which smoke can pass through the detector housing and enter the sensor. In addition, the location of the entry portion of the housing relative to the velocity profile of the detector normal to the plane of the ceiling is also a factor. Finally, different sensing modes (e.g., ionization or photoelectric) will respond differently, depending on the characteristics of the transported aerosol. Within the family of photoelectric devices, there will be variations depending upon the wavelengths of light and the scattering angles employed. Also, algorithms used to sample and weight the sensor's response are introduced by the manufacturer and affect the detector's response.

Standard practice for the design of smoke detection systems is much the same as that for heat detection systems. Recommended spacing criteria are established based on detector response to a specific parameter, such as the optical density within an enclosure. A variety of smoke tests are used to verify that the detector responds between defined upper and lower activation thresholds and within required response times to a range of different types of smoke. This information translates into recommended spacing criteria that is intended to ensure that the detector responds within defined parameters. In some cases, the recommended spacing can be increased, or must be decreased, depending on factors such as compartment configuration and air flow velocity.⁸

In applications where estimating the response of a detector is not critical, the recommended spacing criteria provide sufficient information for the design of a basic smoke detection system. If the design requires detector response within a certain time frame, optical density, specified heat release rate, or temperature rise, then additional analysis may be required. In this case, information concerning the expected fuel, fire growth, sensor, and compartment characteristics is required. The following examples show various performance-based approaches to evaluating smoke detector response.

Modeling Smoke Detector Response—General

The response of smoke detectors to fire conditions is not easily modeled. The response characteristics of smoke detectors vary widely compared with thermal detectors. In addition, less is known about the production and transport of smoke in the early stages of a fire. Natural and forced air currents have a larger effect on the movement of smoke at the time of interest (very early in the fire) than they do on the stronger thermal currents required to alarm heat detectors.

A comparison of how smoke detectors operate with the smoke measurement methods most often employed and reported by researchers shows that smoke measurements do not generally include the factors that we need to model smoke detector response.¹³ Thus, there is a gap between the data generated by fire researchers and the data needed to model smoke detector response.

For example, fire researchers most often measure and report data on heat release rate, temperature and velocity of fire gases, and the optical density or obscuration per unit distance of the smoke at various locations. Of these, only optical density and obscuration relate to smoke. Although called *obscuration*, it is more accurately called *attenuation* since the light beam may be absorbed, reflected, or refracted by the smoke. These are calculated as follows:

Percent obscuration, O :

$$O = 100 \left(I - \frac{I}{I_0} \right)$$

Percent obscuration per unit distance, O_u

$$O_u = 100 \left[1 - \left(\frac{I}{I_0} \right)^{1/l} \right]$$

Optical density, D

$$D = \log_{10} \left(\frac{I_0}{I} \right) = -\log_{10} \left(\frac{I}{I_0} \right)$$

Optical density per unit distance, D_u (m^{-1})

$$D_u = \frac{D}{l} = \frac{1}{l} \log_{10} \left(\frac{I_0}{I} \right) = -\frac{1}{l} \log_{10} \left(\frac{I}{I_0} \right) \text{ m}^{-1}$$

where I_0 is the initial intensity of a light beam reaching a photocell, I is the intensity of the light beam in the presence of smoke, and l is the distance between the source and the photocell.

Optical density and obscuration are useful data for evaluating visibility. However, the only commercially available smoke detector that operates by sensing the attenuation of a light beam is the projected-beam-type smoke detector. Further, these measurements are sensitive to the wavelength of light used. Thus, to be valuable for estimating the response of a projected-beam smoke detector, the data must be measured and reported using the same wavelength as the light source used by the detector.

The two most common types of smoke detectors are ionization type and photoelectric type. Neither type operates using light attenuation. Without a correlation between the optical density data and the response characteristics of a particular detector, accurate modeling is not possible.

In addition, detectors often use complex response algorithms rather than simple threshold or rate-of-change response levels. The algorithms are used to reduce false and nuisance alarms and to enhance fire signature matching. These algorithms vary from detector to detector and are generally not published by the manufacturers. Thus, even if correlations between optical density and the response of scattering- and ionization-type smoke detectors were available, the actual response of each model is affected by the signal sampling algorithm.

Nevertheless, there are methods that can be used to grossly estimate smoke detector response. These estima-

tion methods may not provide accurate prediction of time to detector response because the potential errors in the estimation methods are not generally known and the response algorithms for a particular detector are not known. Without knowledge of the accuracy of the models and the potential errors, these estimation methods should not be used to compare detector response to other model calculations such as egress time calculations or time to untenability. Estimation methods are best used to compare changes in the response of a particular detector as a result of changes in spacing or location, while holding all other variables constant.

In addition to these estimation methods, actual fire tests with detectors present may provide information to compare smoke detector response to other factors such as egress time, structural response, heat release rate, and so forth. Product performance tests may be sources of data. Although, the actual response may not be reported in manufacturer's literature, the minimum and maximum permissible performance imposed by the test standard provides ranges of possible response.

Modeling Smoke Detector Response—Light Obscuration Smoke Detectors

For projected-beam-type detectors, fire or smoke models that calculate the optical density per unit length, D_u , in a space or the total optical density in the path of the detector, D , may be used to determine when the detector would respond. Manufacturer specifications will typically indicate at what levels of total obscuration or total optical density the detectors respond. Projected-beam smoke detectors generally have adjustable response thresholds.

Many fire models estimate the unit optical density, D_u , in a uniform upper layer or volume. This method is referred to as zone modeling. The optical density over the entire length of the beam is then determined by multiplying D_u by the path length, l . The path length is the distance between the source and receiver or the projected-beam smoke detector. This method assumes homogenous distribution of smoke throughout the path, an assumption which may not be valid.

Another method to model the response of projected-beam obscuration-type detectors is to calculate the unit optical density, D_u , at several discrete points or in several discrete segments between the source and the receiver of the projected-beam smoke detector. This approach is a form of field modeling. The optical density per unit length is then multiplied by the length of that particular segment. The total optical density of the path is then the sum of all of the densities for the individual segments.

Modeling Smoke Detector Response—Light Scattering (Photoelectric) Smoke Detectors

The amount of light scattered by smoke is very complex and is related to factors such as the particle number density and size distribution, refractive index, the wavelength of the light source, and the angle between the source and the receiver. Some of these variables can be de-

scribed by the manufacturer for a particular detector. Some require information about the smoke produced by the fuel and its transport to the detector location.

Information about smoke properties related to light scattering is presently limited to a few types of fuels and is not readily available to practicing fire protection engineers. In addition, the data may not be in a useable format. For instance, the data must match the wavelength of the light source used in the detector being modeled. Scattering data at other wavelengths introduces errors and uncertainties.

Meacham has shown that it is possible to model the response of light-scattering detectors using information about smoke properties obtained by small-scale testing of various fuels.^{31,32} However, the recommended test methods have not been further developed, tested, or incorporated into fire test programs.

At the present time, there are no practical methods available to directly model the response of light-scattering-type detectors. However, obscuration or optical density modeling, as discussed above for obscuration-type detectors, can be used in a limited way to estimate scattering-type smoke detector response.

A scattering-type detector responds at different optical densities for different types of smoke. For example, a scattering-type smoke detector that responds at an optical density of $.029 \text{ m}^{-1}$ (2.0%/ft obscuration) to smoke produced by a smoldering gray cotton lamp wick may not respond until an optical density of 0.15 m^{-1} (10%/ft) is reached for smoke from a kerosene fire. At the response threshold, both types of smoke are scattering the same amount of light to the receiver of the scattering photoelectric smoke detector. There are many factors involved in this effect. One is that the darker smoke from the kerosene fire does not reflect as much light as the lighter colored smoke from the lamp wick.

Another way to understand the differing response of a scattering-type detector to two types of smoke is to consider the amount of light being scattered when both smoke samples have the same optical density. Both samples of smoke equally block our vision of the light reflected by an object. One type of smoke may be composed of large, highly reflective smoke particles that cause the incident light to scatter in many directions. Thus, it reduces the amount of light in the forward direction. The other type of smoke may consist of a smaller number of larger particles that absorb light more readily than they reflect it. Though they have equal optical densities, one is more likely to scatter light and set off a scattering-type detector.

In order to model the response of a scattering-type detector using obscuration or optical density, it is necessary to know the optical density required for a particular type of smoke to alarm a particular model detector. For example, many manufacturers label their smoke detectors with a unit optical density, D_u , or unit obscuration, O_u , based on a calibration test that is part of UL standard number 268.³³ That number indicates the unit optical density required for that detector to respond to smoke having very specific characteristics. The optical density required to alarm a particular detector as quoted by the manufacturer is just

one value for a given particle size distribution, concentration, color, and so on used in the laboratory calibration test of that model detector. If the smoke and conditions are similar to that used in the test of the detector, the specified alarm threshold can be used in calculations.

It is not sufficient to have data for a particular fuel and detector combination. It is known that smoke changes as it moves away from a fire.³⁴ There may be changes in the number, size, shape, and velocity of the particles. The optical density at response to any smoke signature other than the laboratory calibration test will be different and will vary with different fuels and burning modes.

Threshold response data to various fuels for a particular detector are not readily available. Some manufacturers may provide data if available and when requested. Product performance and safety tests as well as fire tests with detectors present are useful sources of limiting performance data. Product standards typically test detectors in rooms with specified fuels and smoke buildup rates and velocities. The detectors must respond at certain levels or within certain time limits. While the exact performance data may not be made available, the test limits are useful for estimating the range of possible detector response.

Modeling Smoke Detector Response— Ionization Smoke Detectors

The signal produced by the chamber of an ionization detector has been shown to be proportional to the product of the number of particles and their diameter.³⁵⁻³⁸ The exact signal produced by an ionization smoke detector is given by a more complex equation in the literature and requires an additional number called the chamber constant. The chamber constant varies with each different model of detector.

Given the quantity and size distribution of smoke particles and the chamber constant (from the manufacturer), it is possible to model the ionization smoke detector. Unfortunately, there are no fire models that provide the required detector model input. In addition, manufacturer specifications do not presently include chamber constants.

Newman modified the chamber theory to account for ionization detector sensitivity to the small electrical charge carried by some fire aerosols.³⁹ Newman also developed a method to model ionization smoke detector sensitivity as a function of the soot yielded by a particular fuel. Using his method, the change in a detector's signal, ΔI , can be related to the optical density of smoke measured at a particular wavelength, D_{λ} .

To use the method proposed by Newman it is necessary to know what change in detector chamber signal, ΔI , will cause a detector or system to alarm. Although manufacturers do not presently provide this data, they may be persuaded to do so in the future.

Newman's work was done using a small-scale apparatus and three ionization smoke detectors. A wider range of tests, including some full-scale testing, is needed to verify this method. Presently, the only way to model ionization detector response is to use the optical density esti-

mations as discussed for scattering-type photoelectric smoke detectors.

Modeling Smoke Detector Response— Entry Resistance

In addition to smoke characteristics and the detector's operating mechanism, the ability to get the smoke into the chamber affects the response of the unit. For spot-type photoelectric- and ionization-type smoke detectors, entry resistance is caused by bug screens, chamber design, and the detector's aerodynamic characteristics.

In a scenario where the optical density at the detector location is increasing with time, the optical density inside the detector chamber will always be less than that outside the detector chamber. Similarly, if a detector is placed in a smoke stream having a constant optical density, there will be a time delay before the optical density inside the chamber approaches that outside the detector. As with heat transfer to heat detectors, smoke entry resistance can be characterized by a detector time constant, τ :

$$\frac{dD_{ui}}{dt} = \frac{1}{\tau} (D_u - D_{ui}) \text{ s}^{-1} \cdot \text{m}^{-1}$$

where

$D_{ui} \text{ (m}^{-1}\text{)}$ = optical density per unit length inside the detector chamber

$D_u \text{ (m}^{-1}\text{)}$ = optical density per unit length outside the detector

τ = detector time constant (s)

If the time constant and the rate of change of optical density outside the detector are constant, then this equation can be solved. Further, substituting D_{ur} for the optical density outside the detector at response and D_{uo} for the optical density required inside the detector to produce response yields the following:^{40,41}

$$D_{ur} = D_{uo} + \tau \left(\frac{dD_u}{dt} \right) \left\{ 1 - \exp \left[-D_{ur} \frac{1}{\tau} \left(\frac{dD_u}{dt} \right) \right] \right\} \text{ m}^{-1}$$

Heskestad proposed that the time constant could be represented by the following:

$$\tau = \frac{L}{u} \text{ s}$$

where L is the detector's characteristic length and u is the velocity of the ceiling jet flowing past the detector.

The characteristic length is thought to be a property of the detector that is independent of the smoke and ceiling-jet properties. It is interpreted as the distance the smoke would travel at the velocity u before the optical density inside the detector reaches the value outside of the detector. Combining the equations,

$$D_{ur} = D_{uo} + \frac{L}{u} \left(\frac{dD_u}{dt} \right) \left\{ 1 - \exp \left[-D_{ur} \frac{u}{L} \left(\frac{dD_u}{dt} \right) \right] \right\} \text{ m}^{-1}$$

The exponential term is small compared to the rest of the equation, allowing the equation to be simplified.⁴⁰ Simplification of the equation is not necessary when calculations are made using a computer. However, the simplified form clearly shows the effect of entry resistance:

$$D_{ur} = D_{uo} + \tau \left(\frac{dD_u}{dt} \right) m^{-1}$$

or

$$D_{ur} = D_{uo} + \frac{L}{u} \left(\frac{dD_u}{dt} \right) m^{-1}$$

This form of the entry resistance equation clearly shows that when the optical density outside a detector is increasing with time, the optical density inside the detector will lag behind if there is any entry resistance.

Heskestad and, later, Bjorkman et al.⁴² have plotted test data to determine the L number for a variety of smoke detectors. Additional work has been done by Marrion and by Oldweiler to study the effects of detector position and gas velocity on the L number.^{15,43}

Bjorkman et al., Marrion, and Oldweiler all observed variations in L that may be attributed to a dependence on velocity. Marrion's and Oldweiler's data also imply that there may also be a dependence on the characteristics of the smoke. Table 4-1.14 below summarizes the results from the works cited above.

Examination of the data and analysis work cited above shows that more work needs to be done to study the effects of low velocities and smoke characteristics on detector entry characteristics. The sharp increase in L at lower velocities appears to indicate that entry resistance may be related to smoke particle size. It is also possible that L is a function of the smoke momentum at low velocities. Thus, the time lag would be inversely proportional to the velocity squared.

Table 4-1.14 Range of Characteristic Length (L) Numbers

Researcher	Ionization Detector L (m)	Scattering Detector L (m)
Heskestad ⁴⁰	1.8	15 ^a
Bjorkman et al. ⁴²	3.2 ± 0.2 ^b	5.3 ± 2.7 ^c
Marrion ¹⁵	Not tested	7.2, ^d 11.0–13.0, ^e 18.4 ^f
Oldweiler ⁴³	4.0–9.5, ^g 4.3–14.2 ^h	Not tested

^aolder style detector with more elaborate labyrinth

^b L determined by best fit for three test velocities

^c L based on a single test velocity and a limited number of tests (complete equation used)

^dlow L number at low test velocity

^erange of L for several fuels and detector positions

^f L increased by adding "fence" to further restrict smoke entry

^grange of L for a variety of velocities using simplified equation for entry resistance

^hrange of L for a variety of velocities using simplified equation for entry resistance

Engineers can use L as a measure of entry resistance and the resulting time lag. However, in scenarios where the ceiling-jet velocity is low, there will be greater uncertainty in the results.

Without validation of L as a measure of lag time, manufacturers and test laboratories are not measuring or reporting L in their literature. Nevertheless, the range of L numbers reported in Table 4-1.14 can be used to estimate possible errors in detector response time.

Smoke Detection Calculation Examples

EXAMPLE 14:

The smoke level measured outside of a detector at the time of response in a laboratory calibration test is listed on manufacturers' specifications as the optical density or obscuration required to alarm the unit. Because of entry resistance, the smoke level inside the detector will be less. The specified response is for a particular type of smoke and is measured in a laboratory test apparatus. An example of one calibration test is the gray smoke test listed in the UL 268 smoke detector test standard.³³

In the test, the smoke detector response threshold must not exceed 0.0581 m⁻¹ (4.0%/ft). Velocity in the test chamber is 9.8 m/min. The test starts with clear air. A smoldering cotton lamp wick is used to increase the optical density in the test chamber. The rate of increase of optical density in the chamber must fall within the following limits:

$$3.7 \times 10^{-3} \leq \frac{dD_u}{dt} \leq 5.3 \times 10^{-3} m^{-1} \cdot \text{min}^{-1}$$

What is the range of optical density inside of the detector at the time of response (D_{uo}) if the detector has an L of 3 m? What would it be if the detector had an L of 14 m?

SOLUTION:

For $L = 3$ m and $dD_u/dt = 3.7 \times 10^{-3} m^{-1} \cdot \text{min}^{-1}$,

$$D_{ur} = D_{uo} + \frac{L}{u} \left(\frac{dD_u}{dt} \right) m^{-1}$$

$$D_{uo} = D_{ur} - \frac{L}{u} \left(\frac{dD_u}{dt} \right) m^{-1}$$

$$D_{uo} = 0.0581 - \frac{3}{9.8} (3.7 \times 10^{-3}) = 0.057 m^{-1}$$

For $L = 3$ m and $dD_u/dt = 5.3 \times 10^{-3} m^{-1} \cdot \text{min}^{-1}$,

$$D_{uo} = 0.0581 - \frac{3}{9.8} (5.3 \times 10^{-3}) = 0.056 m^{-1}$$

For $L = 14$ m and $dD_u/dt = 3.7 \times 10^{-3} m^{-1} \cdot \text{min}^{-1}$,

$$D_{uo} = 0.0581 - \frac{14}{9.8} (3.7 \times 10^{-3}) = 0.053 m^{-1}$$

For $L = 14$ m and $dD_u/dt = 5.3 \times 10^{-3} m^{-1} \cdot \text{min}^{-1}$,

$$D_{uo} = 0.0581 - \frac{14}{9.8} (5.3 \times 10^{-3}) = 0.051 m^{-1}$$

These calculations indicate that the actual quantity of this particular type of smoke required to alarm the detector varies from 0.051 to 0.057 m⁻¹ or from 3.5 to 3.9 percent/ft.

Smoke production and characteristics. The fuel characteristics of primary concern for smoke detection are (1) material and (2) mode of combustion. These two parameters are important for determining pertinent features of expected products of combustion, such as particle size, distribution, concentration, and refractive index. The importance of these features with regard to smoke detection are well documented^{6,31,32} and are discussed by Mulholland in Section 2, Chapter 13.³⁴ Assuming a well-mixed smoke-filled volume, data on smoke characteristics for given fuels can provide an estimation of detector response.

EXAMPLE 15:

The design objective is to detect the smoke from a flaming 200-g (0.5-lb) polyurethane pillow in less than 2 min. The pillow is located in a 36 m² room with a ceiling height of 2.5 m (8 ft). Assume that the pillow is burning at a steady rate of 50 g/min. Can the design objective be met? What assumptions are required?

SOLUTION:

The total mass loss at 2 min is 100 g. Given this information, the optical density in the room can be calculated from the relationship (see Section 2, Chapter 13):

$$D_u = \frac{D_m M}{V_c} \quad (29)$$

where D_m [mass optical density (m²/g)] can be taken from Table 2-13.5 in Section 2, Chapter 13 as 0.22 m²/g.

$$D_u = \frac{(0.22 \text{ m}^2/\text{g})(100 \text{ g})}{(36 \text{ m}^2)(2.5 \text{ m})} = 0.244 \text{ m}^{-1}$$

Assuming the detector will respond at the UL upper sensitivity limit of 0.14 m⁻¹ (black smoke),³³ it can be assumed that the detector will respond within 2 min. This approach is simplified, however, and assumes that the smoke is confined to the room, is well mixed, can reach the ceiling level, and can enter the detector.

EXAMPLE 16:

Polyurethane mattresses are stored in a room that is 50 m × 75 m × 10 m high. A goal has been set to detect a flaming fire before approximately 350 g of fuel has been consumed. Using a projected beam smoke detector with sensitivity settings that can vary from 20 percent to 70 percent total obscuration in 10 percent increments, what is the minimum sensitivity setting for response to this fire? Assume the smoke is mixed evenly throughout the space.

SOLUTION:

The mass optical density, D_m , for a flaming polyurethane mattress is given in this handbook on p. 2-264 as 0.22 m²/g. The volume of the room is 37,500 m³.

From the equation for mass optical density, calculate the resulting unit optical density in the room when 350 g of fuel is consumed:

$$D_m = \frac{D_u V}{\Delta m} \text{ m}^2/\text{g}$$

$$D_u = \frac{\Delta m D_m}{V} \text{ m}^{-1}$$

$$D_u = \frac{350(0.22)}{37,500} = 0.002 \text{ m}^{-1}$$

Knowing D_u and assuming the path length of the beam to be 75 m, the ratio of light reaching the receiver of the unit can be calculated:

$$\frac{I}{I_0} = 10^{-D_u l}$$

$$\frac{I}{I_0} = 10^{-0.002(75)} = 0.708$$

Next, the percent obscuration caused by the smoke is calculated:

$$O = 100 \left(1 - \frac{I}{I_0} \right)$$

$$O = 100(1 - 0.708) = 29.2$$

Thus, a projected beam smoke detector would have to be set to respond at about 30 percent total obscuration or less to meet the design objective.

Discussion related to the use of D_m . The previous two examples used the mass optical density, D_m , to calculate the expected optical density, D_u , in a space when a certain mass of fuel was consumed. D_m data are typically measured in small-scale tests due to the need for accurate measurements of mass loss and optical density. The use of D_m from small-scale tests to calculate the resulting D_u in a large-scale scenario introduces error. Some comparisons show qualitative correlation. However, it has been reported that the correlation breaks down with complex fires.³⁴

Stratification. In the context of this chapter, smoke dilution refers to a reduction in the quantity of smoke available for detection at the location of the detector. This dilution can occur either through natural convection (entrainment in the plume or the ceiling jet) or by effects of a heating or ventilation system. In many cases, forced ventilation systems with high exchange rates cause the most concern. In the early stages of fire development, when smoke production rate is small and the plume is weak, smoke can easily be drawn out of the room and away from area smoke detectors. In addition, high velocity air flows out of supply and into return vents creating defined patterns of air movement within a room. Such flows can either keep smoke away from detectors that are located outside of these paths, or, in some cases, inhibit smoke from entering a detector located directly in the air flow path.

Although there currently are no quantitative methods for estimating either smoke dilution or air flow effects on smoke detector siting, these factors must be considered qualitatively. It should be clear, however, that the air flow effects become larger as the required fire size at detection, \dot{Q}_{cr} , gets smaller. If the application warrants, it

may be useful to obtain velocity profiles of the air movement within a room or to perform small-scale smoke tests under various conditions to aid in the smoke detector placement analysis.

The potential for smoke stratification is another concern in the detection of low-energy fires and fires in rooms or volumes with very high ceilings. Stratification occurs when the temperature within the plume equals that of the surrounding air, and there is insufficient thermal energy from the fire to force the smoke higher. Once this point of equilibrium is reached, the smoke layer will maintain its height above the fire, regardless of the ceiling height, until additional energy is provided.

Unlike the effects of air flow on smoke dilution, stratification effects can be calculated using the relationship⁴⁴

$$\dot{q}_{\text{conv}} > 0.352H^5/2T_s^{3/2} \quad (27)$$

where

\dot{q}_{conv} = convective heat release rate in W

H = distance from the top of the fuel package (base of the fire) to the ceiling level in m

T_s = difference in ambient gas temperature in °C between the fuel location and ceiling level

This same relationship can also be found in NFPA 92B, *Guide for Smoke Management Systems in Malls, Atria, and Large Areas*, 1991 edition.⁴⁵

EXAMPLE 17:

The design objective is to detect the pyrolysis of overheated PVC cable insulation in a 7-m (23-ft) high, 100-m² (1076-ft²) room. The room is air conditioned, with a temperature differential of 10°C (18°F) between the base of the switch equipment and the ceiling. The proposed design has smoke detectors mounted at the ceiling level. Assuming the critical fire size is 1000 W, will there be sufficient thermal energy to force the smoke to the ceiling level?

SOLUTION:

In this case, one can rearrange Equation 27 and solve for H :

$$H < \left(\frac{\dot{q}_{\text{conv}}}{0.352T_s^{3/2}} \right)^{2/5}$$

where $\dot{Q}_{\text{cr}} = 1000 \text{ W}$, and $T_s = 10^\circ\text{C}$ (18°F). This result indicates that the highest level of smoke rise is estimated to be 6 m (20 ft). As a result, the design objective may not be achieved by the proposed design. This approach is also valid for evaluating the effects of stratification in a high-ceiling room where a larger fire might be expected. However, the effects of heating and air conditioning systems and warm or cold walls are not considered.

EXAMPLE 18:

The design objective is to detect the flaming combustion of a chair located in the lobby of an office building in order to initiate smoke management functions. The lobby is located at the lowest level of a 20-m (64-ft) high atrium. The atrium has offices on three sides and a glass facade to

the outside on the other. The atrium is air conditioned, with a temperature differential of 20°C (36°F) between the lobby and the ceiling level. The proposed design is for smoke detectors to be mounted at the ceiling level. Is there sufficient thermal energy to force the smoke to the ceiling level?

SOLUTION:

First, a value for \dot{Q}_{cr} must be selected for the burning chair. From an analysis of the chair and a review of published heat release data, it is determined that the chair most closely resembles the metal frame chair with padded seat used in Test 53 of the NIST furniture heat release rate tests.⁸ This chair had a maximum heat release rate of 280 kW, which can be used as \dot{q}_{conv} (or in this case \dot{Q}_{cr} , the critical fire) in Equation 27. Equation 27 can then be rearranged to solve for H :

$$H < \dot{Q}_{\text{cr}} / (0.352T_s^{3/2})^{2/5}$$

where $\dot{Q}_{\text{cr}} = 280,000 \text{ W}$ and $T_s = 20^\circ\text{C}$ (36°F). In this case, the highest point of smoke rise is estimated to be 38 m (125 ft). Thus, the smoke would be expected to reach the ceiling-mounted detector.

It should be noted that air flow concerns were not considered in Examples 12, 13, and 14. In some cases, a system supplying air at a low level and exhausting at an upper level may actually help transport the smoke to the upper levels of a room, where in other cases it may serve to inhibit smoke movement. It should also be noted that, simply because the smoke reaches the level of the detector, there is no guarantee that it can enter the sensor chamber.

Velocity analog. Spot-type smoke detectors, whether commercial or residential, or ionization- or light-scattering type, all require smoke to enter the detection chamber in order to be sensed. This requirement is another factor that must be considered when attempting to estimate smoke detector response. Smoke entry into the detector can be affected in several ways, for example, due to insect screens, chamber configuration, and proximity of the detector to the ceiling.

As previously discussed in this chapter, Heskestad⁴⁶ introduced the concept of smoke detector lag to explain the difference between the optical density outside (D_{up}) and inside (D_{in}) of a detector at the time of activation. Although studies of this relationship have provided useful information concerning smoke detector lag,^{15,41} the difficulty in quantifying L for different detectors and relating it to siting requirements has limited its usefulness. In its stead, the concept of critical velocity (u_c) has been introduced.^{4,47}

Critical velocity, in this context, refers to the lowest gas velocity required for smoke entry into the sensor chamber at a level to sound an alarm at a given threshold. Experimental work has shown this requirement to be in the range of 0.15 m/s for the detectors tested in one study.⁴⁷ When velocities fell below this value, the smoke level outside the detector at the time a specified analog output level was reached rose dramatically compared to levels when the velocity was above the critical value. This figure can be useful for design and evaluation purposes, as it is close to the low-velocity value (0.16 m/s) at which a detector must respond in the UL smoke detector sensi-

tivity chamber in order to be listed.³³ Thus, the location of a velocity of 0.16 m/s in the ceiling jet for a given fire and ceiling height can be considered as a first approximation design radius for detector siting purposes. It should be noted that the ceiling-jet velocity correlations assume a horizontal, smooth ceiling. A detailed discussion of ceiling-jet flows by Evans is presented in Section 2, Chapter 2. The critical velocity approach can be illustrated with a simplified example.

EXAMPLE 19:

The new owners of a hotel have established a fire detection design objective that the smoke detection system in the grand ballroom must be able to detect a 50-kW fire. The ballroom is 50 m (160 ft) long by 30 m (96 ft) wide with a 7.1-m (23-ft) high smooth ceiling. The existing smoke detectors are installed at a listed spacing of 10 m on center and have a critical velocity of 0.15 m/s. Assuming the fire starts at a point equally spaced between the existing smoke detectors, will the velocity of the ceiling jet from a 50-kW fire be sufficient to force smoke into the detection chamber? Assume there will be no ventilation system effects.

SOLUTION:

The stated design objective is to detect a 50-kW fire. Because it is not stated whether the fire is steady state or growing, this solution will assume a steady-state fire of 50 kW. This assumption allows the use of Alpert's¹⁶ velocity correlations for a steady-state fire. Alpert provides two equations that can be used: one for $r/H = 0.15$, and the other for $r/H > 0.15$. This correlation is generally considered to be valid when r/H is between 0.15 and 2.1. Therefore, the ratio r/H must be determined first. In addition, the fire source should be at a distance of at least 1.8 times the ceiling height from the nearest enclosure wall.

The installed spacing is 10 m (32 ft) on center. Using the relationship $S = 2^{1/2}r$, the radial distance is found to be approximately 7.1 m (23 ft). Given that H is also 7.1 m (23 ft), the ratio r/H is found to be 1.0. This value is greater than 0.15; thus the following equation can be used:

$$U = \frac{0.195\dot{Q}^{1/3}H^{1/2}}{r^{5/6}}$$

By entering the values of $\dot{Q} = 50$ kW, $H = 7.1$ m (23 ft), and $r = 7.1$ m (23 ft), a velocity of 0.37 m/s is calculated. This indicates that, for a steady-state 50-kW fire, there will be sufficient velocity to force smoke into the detectors at their existing locations.

However, if the 50 kW fire as stated is the design fire, \dot{Q}_{do} , and it was determined that the critical fire, \dot{Q}_{cr} , was only 5 kW, the resulting velocity using the steady-state correlation at 5 kW would be 0.17 m/s—very close to the critical velocity of 0.16 m/s. Furthermore, with a relatively small fire and a relatively high ceiling, stratification is likely to be a factor and should be considered. Assuming the room is air conditioned, with a temperature differential of 10°C from the top of the fuel package to the ceiling level, the smoke from a 5-kW fire would stratify at a level of about 7.3 m (23.4 ft)—very close to the ceiling height of 7.1 m (23 ft). Given probable dilution of smoke and errors

in approximations, it could be considered unlikely that a 5-kW fire would be detected under the defined conditions.

In addition to illustrating how the concept of critical velocity can be used for the design of smoke detection systems, it clearly points out the need to adequately define performance and design objectives, and to select correlations that fit those objectives. First, the objectives should be stated in terms of both the design fire and the critical fire. A 50-kW design fire is significantly different from a 50-kW critical fire, and the design for one may not meet the requirements for the other. Second, care should be taken in selecting a ceiling-jet velocity correlation that most closely fits the design objectives. Unless the hazard analysis indicates that the maximum fire size of \dot{Q}_{do} will be 50 kW, it may be better to apply a ceiling-jet velocity correlation, based on a growing fire. In this case, the fire growth rate must also be estimated as part of the evaluation. The following example shows the importance of these factors by using the same ballroom as described in Example 19, and provides more specific performance and design parameters.

EXAMPLE 20:

After additional consultation, the owners of the hotel described in Example 19 have modified their objectives as follows: assuming that a fire will begin in a chair, the smoke detection system for the grand ballroom must be able to detect the fire and initiate an internal response before it spreads beyond the chair of origin. The typical fuel load within the room consists of metal-framed chairs with padded seats and backs, and plywood tables with cotton tablecloths.

The response time from when the alarm signal is indicated at the annunciator until the first staff member arrives is estimated to be 60 s. The delay time from detector activation until alarm initiation, as measured at the sensor, is 10 s. Because of the potential for nuisance alarms, the detection system employs an alarm verification feature that has a minimum delay time of 15 s and a maximum delay time of 60 s.

The existing smoke detectors are installed at a UL-listed spacing of 10 m on center and have a critical velocity of 0.15 m/s. Assuming the fire starts at a point equally spaced between the existing smoke detectors, and there are no ventilation system effects, can the existing smoke detection system be expected to meet the design objectives?

SOLUTION:

The complete solution to a problem like this one may require several steps; for example, determination of the design fire, determination of the critical fire, estimation of ceiling jet velocity at \dot{Q}_{cr} , estimation of smoke production or optical density, and analysis of possible stratification effects. In all cases, however, determination of the design fire and the critical fire is essential.

Given that the goal is to detect the fire while in the chair of origin, a first step might be to estimate the fire size within the chair that could ignite the cotton tablecloth. From analysis of the chair and a review of published heat release data, it is determined that the chair most closely resembles the metal frame chair with padded seat and back used in Test 53 of the NIST furniture heat release rate

tests.⁸ This chair had a maximum heat release rate of 280 kW; a fire growth rate of $\approx 0.0086 \text{ kW/s}^2$; a growth time, t_g , of 350 s; and a virtual start time, t_v , of 50 s.

Assuming that the fire would likely grow up the seatback of the chair and that the seatback is located approximately 0.5 m from the tablecloth, an estimate of the energy output required for ignition of the tablecloth can be made. In this case, using the radiant ignition routine in FIREFORM⁴⁸ and assuming the fuel being easy to ignite (ignition flux of 10 kW/m^2) with a separation distance of 0.5 m, it is estimated that the tablecloth will ignite when the total energy output from the burning chair reaches 139 kW. These parameters define the design fire.

The next step is to calculate the time for the design fire to reach the threshold limit of 139 kW. Using the relationship $\dot{Q} = at^2$, a time of 118 s (about 2 min) is calculated. This calculation is growth time of the fire after it begins to follow an exponential growth rate until the design fire size is reached. Given that the fire would probably start as smoldering combustion, the actual growth time could be considerably larger (1 to 2 hr possible).

The critical fire size can then be estimated by subtracting the various response times and estimating the heat release rate at that moment in time. In this regard, reasonable time delays should be used based on the information provided. The focus should be on obtaining the "most reasonable" worst-case delay for the situation. From the problem statement, this delay is estimated based on the response times given, using the following equation:

$$t_{\text{response}} = t_{\text{transport}} + t_{\text{verify}} + t_{\text{system}} + t_{\text{staff}}$$

where the following assumptions are made:

transport = smoke transport time (unknown)

verify = verification time (60 s maximum)

system = system response time (10 s)

staff = staff response time (60 s)

Momentarily ignoring the smoke transport time and assuming prompt staff response, the result is a maximum detection system response time of 130 s. However, in an actual fire situation, the smoke detector verification time should be at its minimum of 15 s, and not at its maximum of 60 s. Making this assumption, the total response time (still ignoring smoke transport time) is 85 s. This result is less than the 127 s time to ignition of the tablecloth and is used to help define the critical fire size (\dot{Q}_{cr}).

Here, the 85 s is subtracted from the 127 s (that defines the design fire), and the relationship $\dot{Q} = at^2$ is used to calculate the heat release rate at that moment in time. The result is a heat release rate of 15 kW. Assuming no smoke transport time, this result would be the critical fire size at which detection must occur in order to detect the fire and cause the required response before the design fire size is reached.

The next step is to factor in a lag due to the smoke transport time. In order to account for smoke transport lag, Brozovsky⁴⁷ suggests a safety factor that is equivalent to a heat release rate that is 80 percent of the maximum

fire size at the time of detection. This factor would result in a critical fire size of 12 kW and a corresponding response time of 37 s. These values can then be used to determine if the ceiling-jet velocity will exceed 0.16 m/s.

Although several simplifications have been made, this example outlines a methodology for estimating the potential for detector response, given the concepts of design fire and critical fire. In addition, the cross-checking utilized points out the importance of understanding the limitations and boundary conditions of correlations and empirical relationships; i.e., simply because one condition can be met, it does not automatically mean that all others will be met as well, and the complete scenario should be considered. Engineering of smoke detection, especially for low-energy fires, can be a difficult task, and the application of any method for this purpose should include clear statements of all assumptions made.

Temperature approximation method for modeling smoke detection. The temperature approximation theory is another method used to estimate the optical density produced by flaming fires. The theory hypothesizes that the mass concentration of smoke particles at a point is proportional to the change in temperature due to the fire (at that point).⁴⁹ The following assumptions are necessary:

1. Particle size distribution is constant in space and time.
2. Mass generation rate is proportional to mass burning rate.
3. There is no heat transfer between particles or between the particles and the confining surfaces.
4. The smoke does not continue to react as it travels.

Heskestad then hypothesized that the ratio of optical density to temperature rise would be a constant for a particular fuel and burning mode (flaming, smoldering, vertical combustion, horizontal combustion, etc.). There are actually three parts to this hypothesis.

The first is that each fuel and burning mode results in a unique optical density required to alarm a particular model and type of detector. This aspect was discussed previously regarding photoelectric, ionization, and projected-beam smoke detectors. This phenomenon is regularly observed, explained by theory, and accepted by the scientific and engineering community.

The second part of the hypothesis is that for each fuel and burning mode the optical density at a point is proportional to the mass concentration of particles:

$$D_u \propto C$$

The final part of the hypothesis is that, for each fuel and burning mode, the mass concentration of particles is proportional to the change in temperature at a point:

$$C \propto \Delta T$$

Combining these proportionalities, optical density is proportional to the change in gas temperature for a given fuel and combustion mode:

$$D_u \propto \Delta T$$

Therefore, the ratio of optical density to temperature rise is constant for a given fuel:

$$\frac{D_u}{\Delta T_g} = \text{CONSTANT}$$

This hypothesis assumes that the only way to move the smoke particles from the source to the detector at the ceiling is by buoyant forces.

Heskestad and Delichatsios examined experimental data for obscuration and temperature rise at various locations on a ceiling for different fuels. They concluded that while the data showed some variation in time at different radial positions relative to the fire source, the ratio could be approximated as a constant. Table 4-1.15 lists the ratios recommended by Heskestad and Delichatsios for various fuels.

Examining the original data, the last column has been added to show the range of values for each fuel. Averages have also been calculated and listed in the last row of the table for reference.

Others experiments have resulted in data that differ from that of Heskestad and Delichatsios. Bjorkman et al. reported values for polyurethane that are approximately one half that reported by Heskestad and Delichatsios.⁴² The data produced by Heskestad and Delichatsios show the ratio of optical density to temperature rise was not constant. The authors concluded that the variation was the result of slowly changing characteristics of the smoke particles as they left the flaming source and traveled in the plume and ceiling jet. Nevertheless, they concluded that a constant value could be used as a rough approximation to allow engineers to model optical density produced by a fire. Although it has not yet been done, it is possible to examine their original data and place error bars on the values recommended in Table 4-1.15.

A fire model can be used to calculate the temperature rise at a smoke detector location or in a layer. Then, using the ratios reported by researchers, the optical density at that location as a function of time can be approximated.

Discussion related to the use of fire models for heat and smoke detector modeling. Some computer fire models or sets of

computational tools include routines for calculating heat or smoke detector response. It is important for users to understand the underlying detector models being used so that limitations and potential errors can be understood. For heat detection, most computational tools use a lumped mass model as described in this chapter. However, for smoke detection some use a temperature rise model, and some use a mass optical density or specific extinction area model. The specific extinction area σ_f is similar to the mass optical density except that it is based on calculations using the natural log, e , rather than \log_{10} . Most do not include entry resistance modeling. Some permit the use of fuel-specific parameters for smoke yield and mass optical density. Others use preset values.

Radiant Energy Detection

During the combustion process, electromagnetic radiation is emitted over a broad range of the spectrum. Currently, however, fire detection devices operate only in one of three bands: ultraviolet (UV), visible, or infrared (IR), where the wavelengths are defined within the following ranges:⁸

Ultraviolet	0.1	to	0.35 microns
Visible	0.35	to	0.75 microns
Infrared	0.75	to	220 microns

Selection of a specific sensor type for fire detection is based on a number of factors, including fuel characteristics, fire growth rate, ambient conditions, resulting control or extinguishing functions, and environmental conditions in the detection area. More specifically, it includes evaluation of the radiant energy absorption of the atmosphere, presence of nonfire-related radiation sources, the electromagnetic energy of the spark, ember or fire to be detected, the distance from the fire source to the sensor, and characteristics of the sensor.

These factors are important for several reasons. First, a radiation sensor is primarily a *line-of-sight* device, and must "see" the fire source. If there are other radiation sources in the area, or if atmospheric conditions are such that a large fraction of the radiation may be absorbed in the atmosphere, the type, location, and spacing of the sensors may be affected. In addition, the sensors react to specific wavelengths, and the fuel must emit radiation in the sensors' bandwidth. For example, an infrared detection device with a single sensor tuned to 4.3 microns (the CO₂ emission peak) cannot be expected to detect a noncarbon-based fire. Furthermore, the sensor must be able to respond reliably within the required time, especially when activating an explosion suppression system or similar fast-response extinguishing or control system.

Once the background information has been determined, the detection system can be designed. Standard practice for the design of radiant energy detection devices is based on application of generalized fire size versus distance curves that are derived using the inverse square law:⁸

Table 4-1.15 Ratios Recommended by Heskestad and Delichatsios for Various Fuels

Material	$10^2 D_u / \Delta T$ (1/ft ² °F)	Range of Values
Wood	0.02	0.015–0.055
Cotton	0.01/0.02	0.005–0.03
Paper	0.03	Data not available
Polyurethane	0.4	0.2–0.55
Polyester	0.3	Data not available
PVC	0.5/1.0	0.1–1.0
Foam rubber PU	1.3	Data not available
Average	0.4	0.005–1.3

$$S = \frac{kP \exp^{\zeta d}}{d^2}$$

where

S = radiant power reaching the detector (W)

k = proportionality constant for the detector

P = radiant power emitted by the fire

ζ = the extinction coefficient of air

d = the distance between the fire and the detector

This relationship is used to produce sensor response information for specific fuels. By then plotting the normalized fire size versus the normalized distance, the resulting curve defines the maximum distance at which the tested sensor can be expected to consistently detect a fire of a defined size (usually provided in m²). By testing a sensor using various fuels, a family of curves can be developed to assist in system design. These curves (sometimes given in tabular form) are usually provided by the sensor manufacturer.

Before applying the distance obtained from such a curve, one must also consider the sensors' field of view. Because the radiation sensor is a line-of-sight device, the sensitivity of the device to a defined fire size decreases as the fire location is moved off the optical axis of the device. This result means that a fire of X m², which is detectable at a distance Y m on axis from the sensor, may not be detectable at the same distance Y m if it is located 30 degrees off axis. Limitations of viewing angles are also provided by manufacturers.

Ambient conditions should also be considered as part of the evaluation and design process. Factors, such as humidity and dust, can affect the absorption of radiation in the atmosphere, thus limiting the amount of radiation reaching the sensor for a given fire size. Similarly, temperature can affect the relative sensitivity of a sensor. As the ambient temperature increases, the relative sensitivity can decrease. Even if the decrease is small, it can affect the response of the sensor to the expected fire.

Radiation Detection Example

EXAMPLE 21:

The design objective is to detect a 1.0 m² (11 ft²) pool fire of JP4 aircraft fuel in a large hangar in order to activate a fixed suppression system. The hangar dimensions are 50 m (160 ft) by 80 m (257 ft) with a 20-m (64-ft) ceiling height. The ambient temperature at the ceiling level varies between 15°C (59°F) and 60°C (140°F), depending on time of day and season. The humidity also varies by season, with relative humidity of 90 percent possible. What steps should be taken during system design?

SOLUTION:

The first step should be selection of a detection device. Because the hazard is carbon based, IR detection at 4.3 microns is suitable. Also, because IR detectors generally provide a larger surveillance area per device than UV detectors, they could be more cost effective than UV detection in this case.

One should then determine possible sources of interfering radiation and select a device that is resistant to these extraneous sources. Such resistance to false response can be obtained by filtering, use of multiple sensors (e.g., two- or three-channel detector), or a combination.

The next step is to review the manufacturer's data to determine mounting criteria based on the size of the critical fire [1.0 m² (11 ft²)]. Generally, this step begins with the fire size versus distance curve or table. If only a curve is provided, one must then determine the mounting height and lateral distance limits of the detector. Lateral distances are important as related to the sensors' field of view.

Given this information, a device layout design can be made. This design should consider all possible obstructions, and result in all parts of the hangar being monitored. One such design is illustrated in Figure 4-1.11.

As part of the layout, one should consider the possible effects of reduced device sensitivity due to angular displacement, temperature, and humidity. Because manufacturers' criteria vary on these parameters, typical values are used in this solution to illustrate their effects.

Figure 4-1.11. IR detector layout for an aircraft hangar.

For example, the proposed layout has devices utilizing a field of view of 45 degrees. Assuming the nominal sensitivity is such that a 1.0 m² (11 ft²) fire can be detected at 40 m (128 ft), and there is a reduction in sensitivity of 30 percent due to angular displacement, the distance at which a 1.0 m² (11 ft²) fire can be detected at 45 degrees is reduced to 28 m (90 ft). If the manufacturers' data indicate a further reduction in sensitivity for temperature, for example 3 percent at 50°C (122°F), the distance is reduced to about 26.8 m (86 ft). If there are further reductions due to humidity, for example a 3 percent reduction at 90 percent relative humidity, the resulting detection distance at 45 degrees is about 25.6 m (82 ft).

In this example, the viewing distance at 45 degrees is a maximum of 20 m (64 ft), and the design can be considered valid. Had the sensitivity decreased such that the distance dropped below 20 m (64 ft), an alternative layout or different devices must be used. In all cases, the manufacturers' literature should be consulted to determine all pertinent increases or reductions in detector sensitivity due to fuel, distance, angular displacement, and environmental conditions.

Designing Fire Alarm Audibility

In most cases, the purpose of a fire detection and alarm system is to alert the occupants of a building that an emergency exists and to initiate evacuation. In situations such as high-rise or industrial buildings, it may be desirable to provide the occupants with more information, such as the nature and location of the fire. In either case, the purpose of the system is defeated if the signal is not heard and understood by the occupants.

This section demonstrates a method for fire protection engineers to estimate the relative effectiveness and cost of various fire alarm alerting systems during the design process. In the past, the selection and location of fire alarm devices has been based on experience and engineering judgment. The use of this simplified methodology can save thousands of dollars in retrofit costs required to correct deficiencies in an alarm system.

The transmission of sound from a source to a target is a function of many factors, such as humidity; air viscosity and temperature; the frequency of the signal; the location of the source relative to the target; the construction of walls, floors, and ceilings; and the furnishings in the area. *Architectural Acoustics*⁵⁰ contains a good discussion of these and many other factors affecting sound transmission and loss.

Sound power and sound pressure levels are expressed in decibels (dB) relative to a reference. It is assumed that the reader is familiar with this system of measurement. Throughout this chapter sound power level (SWL or L_W) in decibels is referenced to 10^{-12} W. Sound pressure level (SPL or L_p) in decibels is referenced to 2×10^{-5} Pa. This discussion also assumes that the reader is familiar with the concept of A-weighting. The purpose of A-weighting is to adjust sound pressure level measurements to correspond as closely as possible to the way humans perceive the loudness of the many different

frequencies we hear. For instance, a 1000-Hz signal at an SPL of 20 dB would be clearly audible. A 100-Hz signal at the same SPL would not be heard. A-weighting allows a single number to describe the SPL produced by a signal containing frequencies between 20 and 20,000 Hz. The weighting of the various frequencies is established by an internationally accepted A-weighting curve.⁵¹

Typical fire alerting systems consist of a combination of audible and visual signals activated by fire detection systems. The audible devices are usually horns, bells, chimes, or speakers. The visual indicators are usually strobe lights, incandescent lamps, or, occasionally, revolving beacons.

In residential occupancies, fire alerting systems should be capable of awakening a sleeping person and informing him or her that a fire emergency exists. Several studies have been done to establish the sound pressure level required to achieve this goal.^{52,53} These studies suggest an SPL between 55 and 70 dBA will awaken a college-age person with normal hearing. The minimum required SPL is also a function of the background noise or signal-to-noise ratio. These levels establish the SPL required to alert or be audible. They do not address the problem of how the person will perceive the sound or react to it.

Until recently, fire codes did not set forth the SPL that a fire alarm system must produce within a building. NFPA 72⁸ requires signals to be 15 dBA above ambient in areas where people may be sleeping. British standards require fire alarm signals to produce a sound pressure level of 65 dBA or 5 dBA above ambient noise in areas where occupants are not sleeping.⁵⁴ A sound pressure level of 75 dBA at the head of the bed is required in occupancies where people may be sleeping.

The audible design requirements listed above and the remaining discussion and examples in this section all use dBA as a measure of audibility. However, it should be pointed out that for a sound to be perceived as audible, it need only penetrate or be greater than the background noise level at one particular frequency bandwidth. For example, certain facilities such as manufacturing plants may have a background noise level in excess of 85 dBA. An installed fire alarm may produce only 75 dBA at a certain location. Nevertheless, occupants will hear and respond to the fire alarm system. Why? The reason is because the background noise that contributes to the 85 dBA is mostly low frequency sound and the fire alarm is mostly high and midrange frequencies. Figure 4-1.12 illustrates this concept. Like two picket fences, one behind the other, only one picket or octave band must be taller for us to perceive the presence of the second fence or signal. While the balance of this section uses dBA, the procedure and methods apply equally well to work done in a single frequency band.

Visual signals are located to assist people in deciphering potentially confusing alarm signals. The visual signals also help alert occupants in high background noise environments.

Butler, Bowyer, and Kew⁵¹ have described a method to estimate sound pressure levels at some location remote from the sound source. Formulas presented in their

Figure 4-1.12. Penetration of noise by alarm.

study are analogous to standard sound attenuation formulas found in other references.^{50,55} They have been simplified by replacing complex terms with constants for which they have provided tables of data (see Tables 4-1.16 through 4-1.29). The equations and data presented in their study provide a straightforward method for analyzing proposed designs. The same equations and data can be used to determine the power requirement and maximum allowable spacing of signaling devices required to achieve a specified sound pressure level. The technique presented in their study is suitable for acoustically simple buildings only. Complex building arrangements and materials may require a more rigorous analysis using other methodologies which are beyond the scope of this chapter.

To demonstrate how signaling systems can be designed and analyzed, two scenarios will be considered. Both scenarios are based on a typical dormitory or office layout. The building has long corridors with rooms of equal size on each side. Each room is approximately 5 m wide by 6 m deep. The walls consist of two layers of Sheetrock (total of 25.4 mm thick) separated by wood studs. The wall cavities contain 75-mm-thick mineral fiber insulation. The floors are concrete with carpeting. The ceiling is 3 m high and consists of acoustical tiles. The

room doors are solid core with good edge seals. The alerting systems will be designed to achieve a 75 dBA sound pressure level at the farthest point in the rooms.

In the first scenario, wall-mounted fire alarm speaker/light combinations are spaced equally in the corridor. Calculations determine the maximum allowable spacing of the speakers in order to achieve the design goal of 75 dBA in the rooms.

In the second scenario, speakers are placed in each room as well as in the corridor. Calculations determine the size of the speaker and the power needed to drive that speaker to achieve the design goal of 75 dB. Calculations are also presented to determine the required spacing of speakers in the corridor to achieve a sound level of 65 dB.

Unless otherwise noted, the following formulas and data are from Butler, Bowyer, and Kew.⁵¹

Scenario A:

In this scenario, the fire alerting system, or sounder, will consist of wall-mounted speaker/light combinations in the corridors only.

L_W is the sound power level of a horn, bell, speaker, or any sounder (dBA referenced to 10^{-12} W).

$$L_W = L + 20 \log_{10} r + 11 \text{ dB}$$

where L is the manufacturer's stated output in dBA at a distance r meters. A typical compression driver-type fire alarm speaker powered at 2 W has an L equal to 94 dBA at 3.05 m.⁵⁶ Therefore,

$$L_W = 94 + 20 \log_{10} (3.05) + 11$$

$$L_W = 115 \text{ dB}$$

L_{P1} is the sound pressure level (dBA referenced to 2×10^{-5} Pa) produced outside of a room wall from one speaker.

$$L_{P1} = L_W + C_3 + C_4 + C_5$$

where

C_3 = correction for the number of directions that the sounder propagates

C_4 = correction for the characteristics of the corridor walls, ceiling, and floor

C_5 = function of the distance from the sounder to the center of the bedroom wall

From Table 4-1.18⁵¹ C_3 is -3 dB, because the speaker propagates in two directions along the corridor; from Table 4-1.19 C_4 is -9 dB, because the floor and ceiling are acoustically soft; and C_5 is unknown since the required spacing of the corridor speakers has not yet been determined. Table 4-1.20 provides C_5 values for determined distances.

A worst-case condition exists for a room located farthest from a speaker. In this situation the room is located equally between two speakers. Since each unit propagates sound to the room, the sound pressure level outside of the room is higher than if there were only one speaker. The sound pressure level is not double that for a single

Table 4-1.18 Adjustment for Number of Directions of Sound Propagation (C_3)

Number of Directions	C_3
Single direction (e.g., positioned at one end of a corridor)	0
Two-directional (e.g., positioned in the length of a corridor)	-3

speaker. For equally spaced sounders, Table 4-1.21 indicates to add 3 dB to the level expected from a single unit. Therefore,

$$L_{P1} = 115 - 3 - 9 + C_5 + 3$$

$$L_{P1} = 106 + C_5$$

L_{P2} is the sound pressure level at the farthest point in a room. To achieve the established goals, L_{P2} must be 75 dBA. In this situation, with the speaker located outside of the occupied space,

$$L_{P2} = L_{P1} - R + C_2 + C_6 + C_7 + 11 \text{ dBA}$$

200	+23

where

- R = average sound reduction index for the wall
 C_2 = function of the distance from the wall to the point of interest
 C_6 = function of the area of the room wall (see Table 4-1.22)
 C_7 = function of the frequency of the sound reaching the wall (see Table 4-1.23)

Table 4-1.23 Adjustment for Frequency of Maximum Output of Sounders (C_7)

Frequency of Sounder	C_7
500 Hz	0
1000 Hz	-3
2000 Hz	-5
4000 Hz	-9

In this case, from data presented by Butler, Bowyer, and Kew,⁵¹ the sound reduction index R for the wall is about 40 dB. (See Table 4-1.24.) This value is based on incident sound in the range of 100 to 3150 Hz. Sound attenuation through the door is about 26 dB. (See Table 4-1.24.) The average sound reduction index, R , for the combined door and wall is 34 dB, if the door is 10 percent of the area. (See Table 4-1.25.) C_2 is found to be -27 dB, because there are 6.5 m from the center of the wall to the corner of the room. (See Table 4-1.25.) Since the wall is 15 m², C_6 is +11.5 dB. (See Table 4-1.22.) If it is assumed that the sound reaching the wall is a maximum at a frequency of 2000 Hz, C_7 = 15 dB. (See Table 4-1.23.) Therefore,

$$L_{P2} = (106 + C_5) - 34 - 27 + 11.5 - 5 + 11 \text{ dBA}$$

$$L_{P2} = 62.5 + C_5 \text{ dBA}$$

If there were no loss of sound pressure level between the speaker and the room wall due to distance, C_5 would be zero and L_{P2} would be 62.5 dBA. This result shows that even if the two speakers were right outside the room, the goal of 75 dBA in the room would not be met. In fact, the resultant noise level in the room would be slightly less than the 65 dBA required by British standards⁵⁴ to alert nonsleeping persons. The sound level of 62.5 dBA would exceed the 55 dBA reported by Nober et al.³² to alert sleeping college-age persons in a quiet ambient setting.

To meet the goal of 75 dBA in the room, either the sound system or the environment would have to be changed. Fire alarm speakers are normally available with multiple power taps such as 4, 2, 1, 1/2, and 1/4 W. A single unit may allow choice of two or three different power levels, which allows balancing of the system after installation.

If a 4-W power input were used, this would be a doubling of the 2 W originally tried in the previous calculation. Because decibels are logarithmic, a doubling of power results in a change of 3 dB in L_W ($10 \times \log_{10} 2 = 3$). This action alone would not be sufficient to meet the 75-dBA goal. In addition, the higher sound pressure level in the immediate vicinity of the speaker might be discomforting. If the fire alarm system were also used for voice communication, a speaker tapped at 4 W in a small corridor might sound very distorted and be unintelligible.

It is also possible to change the sound pressure level in dBA by changing the frequency of the source. In general, the higher the frequency, the higher the attenuation as the sound waves pass through a wall. Hence, a lower frequency would increase the sound pressure level in the room. In the calculations above, it was assumed that the predominant frequency of the source was 2000 Hz. This frequency resulted in a C_7 of -5 dBA. According to Table 4-1.23, if this frequency were 500 Hz, C_7 would be 0 dBA. This adjustment would increase the SPL in the room by 5 dBA.

Changes could be made to the building design that would make it possible to meet the design goal. For instance, the use of a lighter-weight door or one without good edge sealing could increase sound transmission to the room by as much as 12 dBA. (See Tables 4-1.26 through 4-1.29.) However, changes such as this one

Table 4-1.27 Average Sound Reduction Indices (dB) of Partitions Incorporating a Door of 20-dB Attenuation (i.e., light door with edge sealing) (100–3150-Hz frequency range)

would tend to defeat other goals such as fire resistance and resistance to smoke spread. If the floor and ceiling were hard surfaces without carpeting or tiles, C_4 could be increased from -9 to 0 dBA. (See Table 4-1.30.) Changes

—	25	30	35	40	45	50

such as this would probably be resisted for reasons other than fire safety.

The only remaining alternative is to provide speakers in each of the rooms.

Scenario B:

In this case, a speaker in each room powered at only 1/4 W will be tried in addition to the speaker in the corridor. The problem, then, is to select a speaker with a sound power output that can meet the goal of 75 dB at the pillow.

$L = ?$ at $r = 3.05$ m (3.05 m is a commonly used reference point.)

$$L_W = L + 20 \log_{10} r + 11 \text{ dB}$$

$$L_W = L + 20 \log_{10} (3.05) + 11 \text{ dB}$$

$$L_W = L + 21 \text{ dB}$$

L_{P2} is the sound level at the bed. In this case, with the speaker in the occupied space,

$$L_{P2} = L_W + C_1 + C_2 \text{ dBA}$$

where C_1 is a correction for how close the sounder is to an adjacent surface, and C_2 is a correction for the distance from the speaker to the bed. In this case, the speaker is on the wall and close to the ceiling. Therefore,⁵¹ C_1 is +7 dB, and C_2 is -27 dB (approximately 6.5 m from the speaker to the bed). (See Tables 4-1.16 and 4-1.17.) Therefore,

$$L_{P2} = (L + 21) + 7 - 27 \text{ dBA}$$

$$L_{P2} = L + 1 \text{ dBA}$$

To get $L_{P2} = 75$ dBA, L must be at least 74 dBA. The smallest and least expensive fire alarm speaker available is a 4-in. paper cone speaker. A typical speaker of this size and type, powered at 1/4 W, has an L equal to 75 dB at 3.05 m.⁵⁸ This speaker would meet the design goal in the room, without even considering any sound contribution from corridor-mounted speakers.

For the corridor speakers in Scenario B, L_{P1} is the sound pressure level at a point farthest from a speaker.

$$L_{P1} = L_W + C_3 + C_4 + C_5 \text{ dBA}$$

where C_3 and C_4 are the same as in Scenario A (-3 and -9 dB, respectively). C_5 is a function of the spacing, which is to be determined. If a single corridor speaker tapped at only 1/4 W is used, with an L of 85 dB at 3.05 m,⁵⁶

$$L_W = L + 20 \log_{10} r + 11 \text{ dB}$$

$$L_W = 85 + 20 \log_{10} (3.05) + 11 \text{ dB}$$

$$L_W = 106 \text{ dB}$$

$$L_{P1} = 106 - 3 - 9 + C_5 \text{ dBA}$$

$$L_{P1} = 94 + C_5$$

The goal is to maintain a 65-dBA sound pressure level in the corridors (L_{P1}).

Therefore, C_5 must be -29 dBA or more for L_{P1} to be 65 dBA or higher. From Table 4-1.20,⁵¹ it is found that distance of 50 m between source and target in the corridor could be exceeded and still meet the 65-dBA goal.

Cost Analysis

Scenario A:

For comparison purposes, assume that sufficient changes could be made to the building and alarm system to allow speakers to be mounted in the corridor only at a spacing of 3 m. A typical dormitory with about 30 bedrooms per floor requires approximately 24 speakers per floor in the corridors. In a building with seven floors, this requirement amounts to 168 speakers. At 2 W per speaker, the result would be 336 W. This setup requires three 125-W power amplifiers at an installed cost of about \$1400.00 each. This amount does not include other fixed costs, such as control equipment and detectors, that are the same for each of the scenarios.

Assume each corridor unit to be a speaker/light combination. The average installed cost, including backbox, wiring back to a control panel on the first level, and conduit, would total to about \$135.00 per unit. The total cost is then

$$\text{TOTAL} = (3 \times \$1400.00) + (168 \times \$140.00)$$

$$\text{TOTAL} = \$27,720$$

Scenario B:

In this case, there are thirty 4-in paper cone speakers per floor at an average cost of \$100.00, installed. Assume a total of four speaker/light units per floor in the corridors. The calculations show that the system goals are met with only one or two units in the corridors. However, the halls may be split by smoke doors or they may be irregular in shape. Also, system reliability is increased by using more than one unit.

Each bedroom speaker and corridor speaker is powered at 1/4 W. For seven floors, this setup gives a total power requirement of 59.5 W. Therefore, one 60-W amplifier, at a unit cost of \$1125.00, is needed. The total cost is then

$$\text{TOTAL} = \$1125.00 + (7 \times 30 \times \$100.00) \\ + (7 \times 4 \times \$135.00)$$

$$\text{TOTAL} = \$25,905.00$$

Summary

The estimates show the relative costs of the different scenarios, not the actual costs. The real costs of the systems are affected by factors such as whether the building is new or existing. If existing, the price is affected by the extent of other renovations. Also, the estimates do not reflect the cost of other parts of the system. The balance of the system includes such items as smoke and heat detectors, equipment for elevator capture, and air handler controls.

The relative costs of the two systems in Scenarios A and B under "Cost Analysis" differ by only 7 percent. In a building of this size and type, such a small margin cannot be considered significant enough to conclude that one system is more economical than the other.

The small difference in the costs of the two systems is due to the additional cost of amplifiers needed to power the system that has only corridor units. The total number of units (corridor + room) in Scenario B is 70 more than in Scenario A. The reduced power requirement offsets the added cost of their installation.

Scenario A has a higher equipment cost but a lower installation cost than Scenario B. This result means that the relative costs of the two systems will be slightly sensitive to the type of equipment used and the cost of installation labor. By changing the figures used in the cost estimates, it can be shown that the variance is only a few percent and probably not significant.

If the building were four stories or less in height, the difference in relative cost reduces to about two percent. Again, this amount is not considered to be a significant difference.

By increasing the size of the building to twelve stories, Scenario B becomes significantly less expensive than Scenario A. Above this height, the combined use of room and corridor units becomes increasingly economically attractive.

Changing the size of each floor has about the same effect as changing the height of the building. Therefore, increasing the floor area makes Scenario B more viable. A reduction in floor area and building height does not make the corridor-only system attractive, unless the building is only a few stories in height. Then, a voice system is probably not needed. From an economics standpoint, a corridor-only horn/light system is probably best, since the cost of these units is generally less than that of speakers. Again, this conclusion assumes that sufficient changes could be made to the building design to increase the level of sound penetrating the corridor walls.

Obviously, if the sound loss from the corridor to the individual rooms is less, Scenario A starts to look better. This situation has the effect of raising the height above which Scenario B becomes significantly less expensive. However, changing construction features to reduce sound loss may reduce the passive fire resistance of the structure below an acceptable level as well as decrease the privacy level.

There are other factors to consider when choosing between different systems. In Scenario A, the quantity of speakers in the corridors and the high power levels driving each speaker (2 W each) can cause sound distortion. Voice messages may not be intelligible in the bedrooms even though there is enough sound to wake a sleeping occupant. Also, the high sound levels (106 dBA plus) in the corridors approach uncomfortable levels.

It is clear from the discussions above that a system with room speakers in conjunction with corridor units is the most desirable case. That system has the added advantage of eliminating most of the uncertainties in the design of the system. It is easier and more accurate to calculate sound levels at a point in the same room as the sound source than it is to estimate sound losses through composite walls.

This cost-benefit analysis shows that a fire alarm alerting system with units in each office or bedroom can be installed at about the same cost or less than a corridor-

only system. In addition, there is a higher confidence level that the system with the sounders in each room will perform its intended function: to awaken and alert sleeping occupants.

Designing Fire Alarm Visibility

Visual alarm notification is an important part of a fire alarm system. This visual aspect is especially important in cases where the ambient noise level is high, building occupants may be sleeping, or building occupants or their visitors may have hearing impairments. In these cases, it should be expected that the visual alarm will be required to alert occupants and initiate evacuation or relocation. As such, one first needs to determine a suitable intensity required to obtain this function.

In many cases, a suitable intensity can be obtained from regulatory documents, such as building codes, fire codes, or the Americans with Disabilities Act. These references typically give a required appliance intensity and a maximum size space that can be covered by an appliance with that intensity. If additional guidance is needed, reference can be made to appropriate documentation on alerting of persons by visual means.⁵⁷ It is also possible that a reference may cite a required level of illumination to alert someone. This requirement should not be confused with the intensity of the lamp providing the signal. The two are related by the inverse square law where E is the illumination (lumens per unit area), I is the intensity of the light source (candela), and d is the on-axis distance between the light source and the point where the illumination is measured. See Figure 4-1.13.

$$E = \frac{I}{d^2}$$

In cases where flashing signals are required, the source strength or output is cited as *effective intensity*. Ef-

Figure 4-1.13. Relationship between intensity of lamp and level of illumination required to alert someone.

fective intensity is used to equate the perceived brightness of a flashing light to that of a steady light. It can be calculated using the relationship,⁵⁸

$$I_e = \frac{(\int_{t_1}^{t_2} I dt)}{(a + t_2 - t_1)} \tag{28}$$

where

I_e = effective intensity

I = instantaneous intensity

t_1 = the time (s) of the beginning of that part of the flash where I exceeds I_e

t_2 = the time (s) of the ending of that part of the flash where I exceeds I_e

In the United States, the value of 0.2 is usually used for the constant a . This relationship is shown graphically in Figure 4-1.14.

If the duration of the flash is less than one millisecond, Equation 28 can be further simplified to⁵⁸

$$I_e = 5 \int I dt$$

where the integration is performed over the complete flash cycle.

As part of a test program to determine signaling applications for the hearing impaired, UL determined that an illumination of 0.398 lumens/m² (0.037 lumens/ft²) as viewed on axis from a single flashing light source located in the center of one wall of a 6.1 m by 6.1 m (20 ft by 20 ft) room was the minimum required by their objective. It was also determined that, by increasing the "square" dimensions in increments of 3 m (10 ft) in both directions (length

Figure 4-1.14. Peak versus effective intensity. (Source: R.P. Schifilliti Associates, Inc., Reading, MA)

and width), the minimum illumination value of 0.398 lumens/m² could be used to extrapolate the required signal intensity as the room size increased.

For example, if the room size were increased to 12.2 m by 12.2 m (40 ft by 40 ft), the effective intensity, cd eff, of the flashing strobe signal could be determined using the inverse square law and solving for *I*:

$$E = \frac{I}{d^2}; \text{ therefore}$$

$$I = Ed^2 = (0.398 \text{ lumens/m}^2)(12.2 \text{ m}^2) = 59.2 \text{ candela}$$

Thus, one signal rated at 60 cd eff would be sufficient for the space. Using the same approach, but smaller squares, one would also find that two signals rated at 30 cd eff, or four signals rated at 15 cd eff each, would also be applicable.

Designers should check with the authority having jurisdiction or the current edition of NFPA 72 regarding the use of multiple flashing lights.

EXAMPLE 22:

The design objective is to evaluate the visual alarm notification system installed in a large open space for suitability in providing signals for the hearing impaired. The space is 21 m (70 ft) by 37 m (120 ft), with a 6.5-m (20-ft) ceiling height. The notification appliances are located 2 m (6.5 ft) above floor level and are spaced as shown in Figure 4-1.15. The signals are rated at 45 cd eff each. Is the required illumination of 0.398 lumens/m² currently provided?

SOLUTION:

The first step is to section off the space into blocks that are anticipated to be covered for each signal. In this case, the result is six blocks, each 12.2 m (40 ft) long by 10.5 m (34 ft) wide. This step is illustrated in Figure 4-1.16.

Given these dimensions, one could calculate the illumination at point A, where

$$E = \frac{45 \text{ cd}}{(10.5 \text{ m})^2} = 0.41 \text{ lumens/m}^2$$

This is greater than the minimum required illumination of 0.398 lumens/m². However, application of this method requires the blocks of coverage by a signal to be

Figure 4-1.15. Notification appliance (▲) locations.

Figure 4-1.16. Sections for anticipated signal (▲) coverage.

square, with the lateral distance (90 degrees) being equal to one-half the coverage distance on-axis. In this case, the lateral distance is 12.2 m (40 ft), and this is the figure that should be used to calculate the illumination throughout the entire block. In doing this, one finds that the illumination provided is

$$E = \frac{45 \text{ cd eff}}{(12.2 \text{ m})^2} = 0.29 \text{ lumens/m}^2$$

which is below the minimum required 0.398 lumens/m². This outcome results in areas of the space not having the required illumination. This outcome is illustrated in Figure 4-1.17.

To determine what intensity is required for the signals in order to provide the required 0.398 lumens/m², the inverse square law can be applied using the value *d* = 12.3 m. This application results in a required incident intensity of 60 cd eff for each existing signal location.

By applying this method of dividing spaces into squares and applying the inverse square law, the intensity of signals and their required spacing can be calculated for spaces of any shape and size. Tradeoffs can be made between the number of signals and the intensity of signals to best fit the application (e.g., one signal of 60 cd eff versus four properly spaced signals of 15 cd eff each).

In cases where a minimum required illumination at all points in a space is specified (as opposed to the minimum effective intensity on-axis within a square), the illumination can be calculated using the inverse square law, the cosine law, and the cosine cubed law. In this case, the inverse square law provides the illumination on-axis, application of the cosine law provides the illumination at a perpendicular surface within the same plane as the signal, and application of the cosine cubed law provides the illumination at parallel surfaces within the same plane as the signal.

With this information, it should be possible to calculate visual fire alarm signals for most situations. In all cases, a value for the required effective intensity at some point within the room is required. If not provided at the beginning of the design process, one should determine an effective intensity based on the specific application and the condition of the occupants being alerted.

Nomenclature

- a fire intensity coefficient (Btu/s³ or kW/s²)
- A area (m² or ft²)
- A $g/(C_p T_a \rho_0)$ [m⁴/(s²·kJ) or ft⁴/(s²·Btu)]
- c specific heat of detector element [Btu/(lbm·R) or kJ/(kg·K)]
- C_p specific heat of air [Btu/(lbm·R) or kJ/(kg·K)]
- d diameter of sphere or cylinder (m or ft)
- D $0.188 + 0.313 r/H$
- Δt change in time (s)
- ΔT increase above ambient in temperature of gas surrounding a detector (°C or °F)
- ΔT_d increase above ambient in temperature of a detector (°C or °F)
- ΔT_p^* change in reduced gas temperature
- f functional relationship
- g functional relationship
- g gravitational constant (m/s² or ft/s²)
- h_c convective heat transfer coefficient [kW/(m²·°C) or Btu/(ft²·s·°F)]
- H ceiling height or height above fire (m or ft)
- ΔH_c heat of combustion (kJ/mol)
- H_f heat of formation (kJ/mol)
- L_p sound pressure level
- L_W sound power level
- m mass (lbm or kg)
- p positive exponent
- \dot{q} heat release rate (Btu/s or kW)
- \dot{q}_{cond} heat transferred by conduction (Btu/s or kW)
- \dot{q}_{conv} heat transferred by convection (Btu/s or kW)
- \dot{q}_{rad} heat transferred by radiation (Btu/s or kW)
- \dot{q}_{total} total heat transfer (Btu/s or kW)
- \dot{Q} heat release rate (Btu/s or kW)
- \dot{Q}_{cr} critical heat release rate
- \dot{Q}_{do} design heat release rate

- \dot{Q}_i ideal heat release rate
- \dot{Q}_p predicted heat release rate (Btu/s or kW)
- \dot{Q}_T threshold heat release rate at response (Btu/s or kW)
- r radial distance from fire plume axis (m or ft)
- ρ_0 density of ambient air (kg/m³ or lb/ft³)
- Re Reynolds number
- RTI response time index (m^{1/2}·s^{1/2} or ft^{1/2}·s^{1/2})
- S spacing of detectors or sprinkler heads (m or ft)
- t time (s)
- t_c critical time—time at which fire would reach a heat release rate of 1000 Btu/s (1055 kW) (s)
- t_r response time (s)
- t_v virtual time of origin (s)
- t_{2f} arrival time of heat front (for $p = 2$ power-law fire) at a point r/H (s)
- t_{2f}^* reduced arrival time of heat front (for $p = 2$ power-law fire) at a point r/H (s)
- t_p^* reduced time
- T temperature (°C or °F)
- T_a ambient temperature (°C or °F)
- T_d detector temperature (°C or °F)
- T_g temperature of fire gases (°C or °F)
- T_s rated operating temperature of a detector or sprinkler (°C or °F)
- U velocity (m/s)
- u instantaneous velocity of fire gases (m/s or ft/s)
- u_0 velocity at which τ_0 was measured (m/s or ft/s)
- u_p^* reduced gas velocity
- ν kinematic viscosity (m²/s or ft²/s)
- x vectorial observation point (m or ft)
- Y defined in Equation 27
- τ detector time constant— $mc/(hA)$ (s)
- τ_0 measured at reference velocity u_0 (s)

CHAPTER 2

Hydraulics

John J. Titus

Introduction

Hydraulics may be regarded as the application of knowledge about how fluids behave to the solution of practical problems in fluid flow. It is generally held to describe the behavior and effects of water in motion in both closed conduits and open channels. In the field of fire protection we are concerned primarily with the closed conduit flow regime. In this chapter we will restrict our discussion to the behavior and properties of water flowing in pipes as the phenomenon of paramount interest.

Fluid Statics

Physical Properties of Fluids

Solution of any flow problem requires a basic knowledge of the physical properties of the fluid being considered. A brief description of the most basic properties follows.

1. **Density:**
$$\rho = \frac{m}{V}$$

The density of a fluid is the mass of the fluid per unit volume, expressed in SI units as kg/m^3 and in English, or U.S. customary, units as slugs/ft^3 (or $\text{lb}\cdot\text{s}^2/\text{ft}^4$). The density of water at 4°C ($\sim 40^\circ\text{F}$) is $1000 \text{ kg}/\text{m}^3$ ($1.94 \text{ lb}\cdot\text{s}/\text{ft}^4$).

2. **Specific weight:**
$$\gamma = \rho g$$

As the representation of the force exerted by gravity on a unit volume of fluid, specific weight takes on units of weight per unit volume. At 4°C , the specific weight of water is $9.81 \text{ kN}/\text{m}^3$ ($62.4 \text{ lb}/\text{ft}^3$).¹

3. **Specific gravity (relative density):** Specific gravity is the ratio of a liquid's density or specific weight to that of water at 4°C .

4. **Viscosity:** The term *viscosity* refers to a proportionality constant in the equation relating cross-sectional velocity variations (or rate of fluid deformation) to shear stresses developed in the fluid flow. (See the section of this chapter titled "Fluid Energy Losses in Pipe Flows.") Viscosity can be considered a measure of a fluid's resistance to deformation or shear or, alternatively, its readiness to flow when acted upon by an external force. In engineering analyses it is useful to think of viscosity as a momentum diffusivity term.

Viscosity is commonly expressed in one of two forms: absolute (or dynamic) viscosity, μ , which is the proportionality constant referred to above, or kinematic viscosity, ν , which is related to the absolute viscosity by the equality

$$\nu = \frac{\mu}{\rho}$$

A wide variety of units is used to express viscosity, depending not only on U.S. customary or SI formulations but also on older English and metric conventions as well as on the type of instrument used to measure this fluid property. A unit based on the c.g.s. (centimeter, gram, second) convention of the old metric system has gained wide favor in the representation of absolute viscosity. This unit, called the *poise*, has dimensions of dyne-seconds per square centimeter or grams per centimeter-second. The centipoise, which equals 0.01 poise, is the form of preference since the viscosity of water at 20°C (68°F) equals one centipoise to a very close approximation. In the English system the unit of viscosity is pound-seconds per square foot. One $\text{lb}\cdot\text{s}/\text{ft}^2$ equals 478.8 poise.

5. **Fluid pressure:** Pressure is a force per unit area that arises when a fluid is subjected to a compressive stress. Units may be Newtons/ m^2 , lb/ft^2 , lb/in^2 , or the equivalent.

John J. Titus, P.E., is a former research associate at the Center for Fire-safety Studies at Worcester Polytechnic Institute, Worcester, Massachusetts. He has been active in engineering design and contracting of fire suppression and detection systems since 1971. Mr. Titus is a partner in MBS Fire Technology, Inc., a fire protection engineering consulting firm based in central Massachusetts.

lent. Pascal's law states that the pressure in a fluid at rest is the same in all directions, a condition different from that for a stressed solid where the stress on a plane depends upon the orientation of that plane. For an infinitesimal fluid element in a larger static body of fluid, a free body diagram of the vertical forces may be drawn as in Figure 4-2.1. The pressure difference $[(p + dp) - p]$ is due only to the weight of the fluid element. Since the weight of the element is given by $mg = \rho g dz dA$, a summing of forces in the vertical direction gives

$$dp dA = -\rho g dz dA \tag{1a}$$

$$dp = -\rho g dz \tag{1b}$$

In integral form, Equation 1b becomes

$$\int_1^2 \frac{dp}{\rho g} = -\int_1^2 dz = -(z_2 - z_1) \tag{2}$$

where the path endpoints 1 and 2 refer to different elevation levels.

To integrate Equation 2, it is necessary to establish a functional relation between pressure p and the term ρg . Where density varies with pressure, the fluid is considered compressible, and the functional relation may be complex. For fluids that may be considered incompressible, such as water, ρ is a constant at any specified temperature. Equation 2 then becomes

$$p_2 - p_1 = -\rho g(z_2 - z_1) \tag{3}$$

The term $(z_2 - z_1)$ may be called a static *pressure head*, which can be expressed in feet, inches, or meters of water, or some height unit of any liquid. A simplified form of Equation 3 is often written

$$\rho = \gamma h \tag{4}$$

where h = elevation of the column of liquid above a reference surface (i.e., $z_2 - z_1$). For water at 60°F (15.6°C), γ is taken equal to 62.4 lb/ft³ (16.02 kg/m³). The pressure cor-

Figure 4-2.1. Notation for basic equation of fluid statics.

responding to a head of h feet, then, is $0.433h$ lb/in.² (psi), or approximately 3 kPa per meter elevation. The head corresponding to a pressure of one psi (0.07 bar) is, inversely, 2.3 ft (0.7 m). Note that Equation 4 is valid only for a homogeneous, noncompressible fluid at rest, and that regardless of the shape of the container, points in the same horizontal plane experience the same pressure.

The vertical distance h is termed the *head* of a fluid. A pressure due only to the weight of a column of fluid is called a static pressure and can be measured by a standard Bourdon-type gage (see Figure 4-2.4). Such a measure is generally referred to as gage pressure. The term *absolute pressure* takes into account the pressure exerted by the atmosphere as well, which at sea level is approximately 14.7 psi (1 bar), equivalent to a 33.9-ft- (10.3-m-) high column of water. A pressure less than atmospheric is called a vacuum pressure, a perfect vacuum being zero absolute pressure. Since most fluid properties of interest are not significantly affected by small changes in atmospheric pressure, most fluids calculations are in terms of gage pressure, although this fact is not often indicated in standard calculation nomenclature. When they are explicitly identified, gage pressure is denoted by the term psig and absolute pressure by psia. If not stated otherwise, psi may be taken to designate gage pressure.

Pressure Measuring Devices

1. Manometer tube: Pressure measurement in a manometer tube is obtained by measuring the vertical displacement of a relatively heavy fluid (usually mercury), which will rise a smaller vertical distance than water in proportion to the ratio of its specific weight to that of water. Depending on the actual arrangement of the manometer tubing, a gage equation can be written to solve for the pressure head. For the manometer shown in Figure 4-2.2, the gage equation is written by proceeding from the open

Figure 4-2.2. Manometer.

end through the tube to point A' , adding terms when descending a column and subtracting when ascending. Using mercury as the manometer fluid, we can write

$$(y + z)\gamma_{Hg} - z\gamma_{Hg} - x\gamma + (x + z)\gamma = p_A \quad (5)$$

Combining terms, generalizing the result, and expressing in terms of feet of water (head),

$$\frac{P_A}{\gamma} = ys + z \quad (6)$$

where s is the specific gravity of the manometer fluid.

2. Piezometer tube (Figure 4-2.3): Literally a *pressure measuring tube*, a piezometer consists essentially of a narrow tube rising from a container enclosing a fluid under pressure. Through the relation among pressure, height, and specific weight, the height to which the fluid rises in the tube represents the pressure of the contained fluid. While useful for some laboratory work, piezometer tubes are not generally feasible in practical applications.

3. Bourdon gauge (Figure 4-2.4): The standard pressure measuring device used in a wide variety of fluid pressure measurement applications is the Bourdon gauge. The gauge contains a curved tube of elliptical cross section that undergoes a change in curvature with change in pressure. A dial hand, connected to the inner tube through a linkage system, indicates gauge pressure on a numerical dial face. Bourdon gauges are factory calibrated and reasonably accurate instruments if not damaged by pressure surge or impact force. A field reading, unless known to be correct, cannot be assumed to be accurate and should be checked by independent means.

Forces on Submerged Plane Areas Due to Fluid Pressure

It is sometimes of interest to determine the magnitude of the resultant force on a submerged area and the location of the center of pressure where the resultant force

Figure 4-2.3. Piezometer.

Figure 4-2.4. Standard Bourdon gauge.

can be assumed to act. Consider the following example of a tank that has a rectangular window in an inclined wall (Figure 4-2.5). The magnitude of the resultant force can be determined from

$$F_R = \gamma h_c A \quad (7)$$

The center of pressure of the area is the point at which the resultant force can be considered to act. Its location is determined from the relation

$$l_p = l_c + \frac{I}{l_c A} \quad (8)$$

where I = the moment of inertia of the area about its centroidal axis.

Figure 4-2.5. Tank with a rectangular window in an inclined wall.

For a vertical wall, the center of pressure is located at a distance $d/3$ from the bottom (where d is the total depth below the free surface), and at a distance $l/3$ from the bottom of an inclined wall or area (where l is the length of the face of the wall).

Conservation Laws in Fluid Flows

Fluid flow may be characterized as uniform or nonuniform, steady or unsteady, compressible or incompressible, laminar or turbulent, rotational or irrotational, and one-, two-, or three-dimensional or some combination thereof. Real flows may be modeled as approximations of ideal flows when real properties do not depart significantly from the ideal characteristics defined by these terms.

For example, uniform flow occurs when the average velocity of a fluid does not change in either magnitude or direction anywhere along the flow path. Thus, liquid flow in a constant head pipeline of unchanging diameter is considered uniform flow. Steady flow, on the other hand, is determined with reference to a stationary point in the flow path. For steady flow to occur, the velocity of flow at that point must remain constant with time. This condition implies that the fluid density, the pressure head, and the volume rate of flow also are invariant with time. Thus, liquid flow in a constant head pipeline of varying diameter may be considered steady, nonuniform flow. It is important to note that a flow may be considered uniform (no change in magnitude or direction of the velocity) in a curved pipeline as long as the reference direction of the velocity vector is taken in the direction of the flow. We can then say that the velocity of the fluid does not change direction with respect to its enclosing boundaries.

We can also consider this flow one-dimensional whenever it is permissible to say that velocities or accelerations normal to the general direction of the flow are negligible. Clearly, real flow in a real-world structure has three dimensions, but a one-dimensional analysis is highly desirable as it represents a considerable mathematical simplification. Fortunately, a very large number of practical engineering flow problems involving water can be modeled as one-dimensional, steady flow problems, particularly many pipeline flows. In such cases it is possible to apply basic physical principles of conservation of mass and conservation of energy in the direction of flow to obtain the energy balance at any point in the flow. In fire flow hydraulics, it is common practice to introduce additional simplifying assumptions, such as the requirements that the fluid be incompressible and that flow properties be invariant with temperature and pressure. It then follows directly that with no flow additions or subtractions, the volumetric flow rate at any point in a fluid stream must be a constant. This statement of mass conservation, known as the equation of continuity, can be expressed mathematically as

$$\rho_1 A_1 v_1 = \rho_2 A_2 v_2 = \text{constant} \quad (9)$$

If the fluid is considered incompressible, as is the case with water, Equation 9 becomes

$$A_1 v_1 = A_2 v_2 = \text{constant} = Q \quad (9a)$$

By applying the principal of conservation of energy to a flowing fluid, an expression can be derived that gives the theoretical net energy balance of the fluid at any point along its flow path. This is known as the Bernoulli equation, which can be written as

$$\frac{p_1}{\gamma} + \frac{v_1^2}{2g} + z_1 = \frac{p_2}{\gamma} + \frac{v_2^2}{2g} + z_2 \quad (10)$$

In this form, units are ft lb/lb of fluid or, simply, ft of fluid. Each term thus represents a fluid head. Multiplying each term by the specific weight, γ , converts the equation to units of pressure. Changes in internal energy of the fluid are ignored and are assumed to be negligible. The form of Equation 10 suggests that the flow of liquid (or transport of fluid energy) results from three principal causes: pressure difference, gravity, and inertia. Equation 10 expresses an ideal condition fulfilled by the three components of head corresponding to these three causes. The assumption of incompressibility (i.e., constant density) requires that the product of the velocity of flow and the cross-sectional area of the flow of any conserved portion of the stream be constant; the ideal flow streamlines, therefore, converge as the velocity increases and diverge as the velocity decreases. If it could be assumed that the total Bernoulli head were, indeed, constant or, equivalently, if it were possible to obtain total head simply as a function of the coordinates of the moving fluid element, then many hydrokinetic problems could be solved theoretically by mathematically manipulating and extrapolating the Bernoulli equation. Unfortunately, this is not the case. Other energy transfers are possible, and these require use of a more general form of the equation. In addition to the pressure, velocity, and position (elevation) energies possessed by the fluid at sections 1 and 2, energy may be added to the fluid (work done on the fluid by a pump), lost by the fluid (through friction), or extracted from the fluid (work done by the fluid). Therefore, we write the Bernoulli energy conservation expression in the more general form

$$\left(\frac{p_1}{\gamma} + \frac{v_1^2}{2g} + z_1 \right) + h_A - h_L - h_E = \left(\frac{p_2}{\gamma} + \frac{v_2^2}{2g} + z_2 \right) \quad (10a)$$

Energy at Section 1

Energy Lost
Energy Extracted
Energy at Section 2

EXAMPLE 1:

Water flows from a reservoir through a pipeline as shown in the following diagram. The flow is considered frictionless and discharges freely at point C.

- (a) What is the total head (total specific energy) at point B?
- (b) What is the discharge velocity at point C?

SOLUTION:

- (a) At *A*, both the velocity and gage pressures are considered to be zero. By Bernoulli, then, the total head would be written as

$$h_A = 0 + 0 + 150 \text{ ft} = 150 \text{ ft}$$

or, in SI unit equivalents,

$$h_A = 0 + 0 + 45.7 \text{ m} = 45.7 \text{ m}$$

At *B*, the fluid has a nonzero velocity head and is under hydrostatic pressure. As long as we consider the flow frictionless, the total head is constant. Therefore,

$$h_B = h_A = 150 \text{ ft} (45.7 \text{ m})$$

- (b) At *C*, the pressure head is again zero, since the discharge is at atmospheric pressure. Once more by Bernoulli,

$$h_C = 0 + \frac{v^2}{2g} + 0$$

$$v^2 = 2(32.2)(150)$$

$$v = 98.3 \text{ ft/s}$$

or, in SI unit equivalents,

$$v^2 = 2(9.81)(45.7)$$

$$v = 29.9 \text{ m/s}$$

Note that we could calculate the actual values of the pressure and velocity heads at point *B* if we had more information about the system. For example, we could de-

termine \dot{Q} , the discharge at point *C*, knowing the area and type of discharge opening (see the section of this chapter titled "Free Discharge at an Opening"). This determination is simply an application of the continuity equation. Knowing the pipeline diameter at point *B* allows us to apply continuity constraints once again to calculate v_B from which the velocity head may be determined. The pressure head at *B* is simply a function of the weight of the vertical column of water.

The components of the Bernoulli equation may be expressed graphically in terms of energy levels existing at any points in the flow regime. In Figure 4-2.6 a simple system representing a realistic flow is shown. Water flows from a reservoir (with presumed constant surface elevation) to atmosphere. The flow is accompanied by losses of energy represented by h_L . The losses may occur in many places such as at valves, bends, and sudden changes in pipe diameter. Generally, the most important loss is that due to friction between the moving fluid and the pipe wall. Since there are always energy losses in real flows, the total energy of the system decreases in the direction of flow. The line connecting all points representing the total energy is called the *energy gradient* (EG). It must always decrease in the direction of flow unless energy is added to the system, such as by a pump. The *hydraulic gradient* (HG) connects the points representing the sum of static pressure and elevation energies (i.e., the heights to which water in piezometer tubes would rise). Note that the hydraulic gradient may increase in the direction of flow if velocity head is converted to pressure head at any point (such as at an increase in pipe diameter). Thus, the relationship between the energy and hydraulic gradients can be written as

$$EG = HG + \frac{v^2}{2g} \tag{11}$$

Figure 4-2.6. Realistic flow characteristics.

Fluid Energy Losses in Pipe Flows

General Considerations

That part of hydraulics which treats fluid energy losses due to friction in piping is well known and well utilized in fire protection engineering. Losses to friction are due to shear stresses set up within a moving fluid in a conduit by an imposed pressure gradient. Flow driven by the pressure force is restrained by drag forces acting at the conduit wall. To better visualize this phenomenon, it is useful to introduce the concept of the boundary layer. For many fluids, such as air or water, motion through a stationary conduit or pipe is characterized in most practical situations by a nearly constant velocity cross section everywhere except in a very thin layer near the wall of the pipe. This layer thickness may be as little as 0.1 mm but may vary significantly with the nature of the fluid, the velocity of flow, and the surface roughness of the conduit. We may visualize boundary layer flow (see Figure 4-2.7) in terms of a velocity profile. Theory* holds that a very thin (molecular) layer of fluid sticks to the conduit wall. The tendency of the next fluid layer to move due to an imposed force creates a shearing stress, τ , between the layers. If the boundary is thought of as many fluid lamina sliding on each other, then we can expect the velocities of these lamina to increase with distance y from the wall until, at the edge of the boundary layer, the local velocity reaches the free-stream velocity of the fluid. The factor relating the velocity profile to the developed stress in the fluid is termed the fluid viscosity. The relationship was expressed mathematically by Newton as

$$\tau = \mu \frac{du}{dy} \quad (12)$$

The smaller the value of fluid viscosity, the thinner the boundary layer will be. The first layer of fluid sticks or adheres to the surface of the conduit while lamina above it successively slide on each other, exerting drag forces that, for most fluids, are proportional to the viscosity (so-called Newtonian fluids). The rate of change of the velocity between successive lamina is a measure of the unit shearing force between them. A curve joining the tips of velocity vectors plotted for the different lamina in the boundary layer is called a velocity profile. Laminar (smooth, streamline) flow [see Figure 4-2.8(a)] is characterized by a parabolic velocity profile with maximum velocity attained at the theoretical centerline of the flow. Turbulent flow, by contrast, is rough (nonstreamline) flow [see Figure 4-2.8(b)], characterized by an essentially uniform average velocity across the flow section, with only a very thin boundary layer close to the wall where viscous forces predominate. The velocities associated with laminar flows are generally so low as to be impracticable from a design standpoint. Most flows of interest, therefore, are turbulent, and the use of an assumed uniform or average velocity to calculate kinetic energy and velocity pressures

Figure 4-2.7. Velocity profile.

Figure 4-2.8. Laminar (a) and turbulent (b) pipe flow velocity profiles for the same volume.

does not introduce significant error. In those atypical situations where relatively large velocity heads are involved (such as where a pump adds a large amount of energy), a correction factor may be used to relate the actual average kinetic energy to the kinetic energy calculated using average velocity. From continuity considerations,

$$KE = \int_A \rho u^3 dA = \alpha \rho \int_A v^3 dA \quad (13)$$

where

- KE = true kinetic energy of the flow
- v = average velocity of flow
- α = kinetic energy correction factor

For incompressible fluids

$$\alpha = \frac{1}{A} \int_A \left(\frac{u}{v}\right)^3 dA \quad (14)$$

*Early theoretical development of the boundary layer concept is due primarily to Prandtl.^{2,3}

and has the value of approximately 1.1 for most turbulent flow problems. Since the velocity head in water distribution piping is small, this correction factor is usually ignored.

While the development of boundary layer theory and the theory of viscous forces has led to an improved theoretical understanding of the mechanics of pipe flows, most flows of interest in fire protection cannot be fully analyzed from theoretical considerations alone. Fire protection flows are almost always turbulent flows. Despite a great expenditure of effort to develop a general predictive theory of turbulent flow phenomena, a fully descriptive theory does not yet exist. While it is postulated that head losses arise because of friction between the fluid and the pipe wall, there is an additional head loss contribution due to turbulence within the fluid. In turbulent flows the rate of head loss, unfortunately, is not simply a function of velocity but depends also on pipe wall roughness. It is further complicated by the changing interaction between these variables at different velocities and roughness element sizes. Within the last century, however, a large body of empirical flow data has been collected, analyzed, and reduced by several investigators. The major features and limits of applicability of the more important results are presented in the following paragraphs.

Fluid Flow Energy Loss Equations

Theoretical development of the physical relationships describing pipe flows dates from about the middle of the nineteenth century, when Chezy postulated a fundamental proportionality between volumetric flow and pipe size based on the continuity equation. His formula is commonly given as

$$Q = \frac{\pi D^2}{4} v = \frac{\pi D^2}{4} \frac{C}{2} \sqrt{DS} \quad (15)$$

and may also be written as

$$S = \left(\frac{8Q}{\pi C} \right)^2 D^{-5} \quad (16)$$

where D and S are pipe diameter and slope of the energy grade line, respectively. The factor C is a proportionality factor incorporating a significant degree of physical uncertainty. Since, by definition

$$S = \frac{h_L}{L}$$

we may write

$$h_L = \left(\frac{8}{\pi C} \right)^2 \frac{L}{D^5} Q^2 \quad (17)$$

as an expression for pipe flow head loss as a function of pipe diameter and discharge. Use of this equation was limited by uncertainties relating to evaluations of the C -factor, which is not, in fact, a constant for a given size conduit or wall condition as was originally thought.

A theoretically more satisfying approach was taken by Darcy, Weisbach, and others. Their formula, which

bears the names of the two primary investigators, is generally written as

$$h_L = f \frac{L}{D} \frac{v^2}{2g} \quad (18)$$

It postulates a basic proportionality between head loss and the kinetic energy of the flow, as well as to pipe length and diameter. The proportionality factor f , known as the friction factor, became the subject of extensive theoretical and experimental investigation. The value of f for laminar flow can be shown theoretically to be a simple linear function of the Reynolds number, Re , where $Re = D_e v \rho / \mu$. The term D_e is the equivalent flow diameter, which is the actual inside diameter of a circular pipe flowing full. The equivalent diameter, D_e , can be found from the hydraulic radius, r_h , which is defined as the area in flow divided by the wetted perimeter. The wetted perimeter does not include the free fluid surface.

$$D_e = 4r_h$$

For Re less than about 2000 (corresponding to low velocity flows or fluids of high viscosity) the relation is

$$f = \frac{64}{Re} \quad (19)$$

In turbulent flows the roughness of the pipe walls becomes a much more significant factor, and a simple expression to determine f is unavailable.

A systematic investigation of the actual characteristics of piping inner wall surfaces was first performed by Nikuradse in 1933. To simulate varying degrees of roughness in commercial pipes due to corrosion or surface finish, Nikuradse glued sand grains of known sizes to the inside walls of test pipes. The resulting logarithmic plot of friction factor versus Re is shown in Figure 4-2.9. Although the tests are from Nikuradse, the plot is called Stanton's diagram in recognition of his earlier (1914) elucidation of the relation between friction factor and Reynolds number. Note that at sufficiently high Re , the friction factor depends almost entirely on pipe roughness and is essentially independent of Re . In these plots the roughness parameter is expressed as the ratio of the root mean square grain diameter to the pipe diameter. The resulting ratio is termed the relative roughness and is represented mathematically as ϵ/D . Typical roughnesses of new commercial pipe is shown in Table 4-2.1. Several later investigators developed mathematical formulas for expressing Nikuradse's results. Chief among them were Colebrook, Moody, and VonKarman.

Moody plotted various equations on a graph similar to the earlier work of Stanton. The resulting Moody diagram (Figure 4-2.10) is widely used today in conjunction with the Darcy-Weisbach equation to compute friction losses for water flowing in pipe. Figure 4-2.11 (page 4-53) presents relative roughness values for use with the Moody diagram over a wide range of conditions. Other diagrams have been developed for use with the Darcy-Weisbach equation^{4,5} when parameters other than h_L are sought. Essentially, the alternative graphical formulations employ a rearrangement of variables to facilitate solving for some other unknown such as Q or D .

Figure 4-2.9. Nikuradse's sand-roughened-pipe tests.

Table 4-2.1 Values of Absolute Roughness of New Clean Commercial Pipes

Type of Pipe or Tubing	ϵ ft (0.3048 m) $\times 10^6$		Probable Maximum Variation of f from Design (%)
	Range	Design	
Asphalted cast iron	400	400	-5 to +5

Wood stave	600-3,000	2,000	-35 to +20

Source: Pipe Friction Manual, 3d ed. Hydraulic Institute, (1961).

Both experimental and theoretical investigations have yielded uncertain results in the region known as the *critical zone*, wherein the flow changes from laminar to turbulent. Uncertainty may be expected since the transition point is difficult to define precisely and, in fact, varies over a considerable range of Re depending upon the direction of the transition (i.e., flow going from laminar to turbulent or from turbulent to laminar) and the local conditions affecting flow stability. As a practical consideration, however, this uncertainty is of little importance, since most real flows of interest fall well into the turbulent range.

Colebrook developed an empirical transition function for the region between smooth flow and complete turbulence. Flow in this region is sometimes referred to as hydraulically smooth or turbulent smooth. The equation has been presented in various forms, the following expression being commonly used:

$$\frac{1}{\sqrt{f}} = -0.86 \ln \left(\frac{\epsilon/D}{3.7} + \frac{2.51}{Re\sqrt{f}} \right) \quad (20)$$

An alternate and equivalent expression is

$$f = \left[1.14 - 2 \log \left(\frac{\epsilon}{D} + \frac{9.35}{Re\sqrt{f}} \right) \right]^{-2} \quad (20a)$$

This relation forms the primary basis for the Moody diagram.

VonKarman used boundary layer theory to derive an expression characterizing the friction factor for fully turbulent flow within rough-walled pipes. The final numerical form of the equation,

$$\frac{1}{\sqrt{f}} = 1.4 + 2 \log \frac{D}{\epsilon} \quad (21)$$

was adjusted to agree more closely with Nikuradse's experimental results. As pipe roughness decreases, this expression approaches Colebrook's equation.

Perhaps the most widely used flow-energy loss relation is the empirically based Hazen-Williams formula, developed near the turn of the century from observations of

Figure 4-2.10. **Moody diagram.**

a very large number of pipeline flows. The Hazen-Williams equation was originally written in the form

$$V = 0.113CD^{0.63}S^{0.54} \tag{22}$$

where V is the average velocity in feet per second, S is the slope of the energy grade line—that is, the loss of energy per unit length of the pipe—and D is the actual internal pipe diameter in inches. The coefficient C is a friction factor introduced as a constant to represent the roughness of the pipe walls. Table 4-2.2 presents a representative list of C coefficients for various piping materials. Note that the value of C can vary significantly with the piping material, the age of the pipe, and the corrosive qualities of the water.

The Hazen-Williams formula is also encountered in the form

$$Q = 0.285CD^{2.63}S^{0.54} \tag{22a}$$

where Q is volumetric flow rate in gpm and D is in inches. Yet another form, also in the same units for Q and D , is widely used in automatic sprinkler system design. It is arranged to solve for the pressure drop in psi per linear foot of pipe

$$p = \frac{4.52Q^{1.85}}{C^{1.85}D^{4.87}} \tag{22b}$$

In SI units

$$p = \frac{6.05Q^{1.85}}{C^{1.85}D^{4.87}} \times 10^5 \tag{22c}$$

where the units of Q are L/min, D is in mm, and p is in bars per meter of pipe.

Many manufacturers of fire protection equipment, many fire underwriters, and others have published Hazen-Williams-based pipe friction loss data (usually in tabular format) over applicable ranges of pipe sizes, flow rates, and C -factors. A useful calculation aid in a more compact format is the Hazen-Williams nomograph (Figure 4-2.12), which is reproduced here in its generalized form.

The Hazen-Williams formula may be used only for water at or around 60°F (15.6°C), as it does not contain any terms relating to the physical properties of the fluid. The formula does not actually have a sound theoretical basis, but still gives acceptable results in practice with a judicious choice of the C coefficient. Fundamentally, the C -factor is a proportionality constant and, as such, its true value depends as much upon the values chosen for the exponents as it does upon actual pipe roughness. The suggested values are the result of curve-fitting exercises and cannot be expected to accurately and evenly represent flow parameter relationships across the full range of

Figure 4-2.11. **Relative roughness chart.**

observed flow velocities. Allowing the desirability of retaining constant exponents for D and S (i.e., a presumed theoretically stable correlation among all flow parameters in the equation), the value of C for any given flow scenario becomes a narrowly bounded variable that reflects the pipe roughness. Although as in the Chezy formula C is not actually a constant, for practical use it is

assigned a constant value for a given presumed roughness. Unfortunately, as Table 4-2.2 shows, the Hazen-Williams equation is a much better model of smooth pipe flow than of rough pipe flow. As long as the flow velocity is close to that at which C was measured and as long as the pipe roughness is not excessive, the Hazen-Williams relation can be expected to give reliable results. It has

Table 4-2.2 Values of *C* in Hazen-Williams Formula^a

been noted, however, that in rough pipes head loss varies with flow (and velocity) to the power of 2 rather than the power of 1.85 characteristic of smooth pipes.⁶ This observation introduces a significant element of uncertainty into the hydraulic analysis of rough pipe with higher velocity flows.

EXAMPLE 2:

Water at 50°F (10°C) flows through 4 in. (102 mm) Schedule 40 welded steel pipe at a rate of 500 gpm (1892.7 l/m). Compare the friction head losses calculated by the Darcy-Weisbach and Hazen-Williams equations for flow through 100 ft of pipe.

Figure 4-2.12. Nomograph for solution of the Hazen-Williams formula.

SOLUTION:

Basic Data:

For 50°F water, $\nu = 1.41 \times 10^{-5} \text{ ft}^2/\text{s}$

pipe flow area = 0.0884 ft²

$\epsilon = 0.0002$

pipe inside diameter = 0.3355 ft = 4.026 in.

Using the Darcy approach, we first determine Re , ϵ/D , and then enter the Moody diagram (Figure 4-2.10).

$$\text{Flow quantity} = Q = 500 \text{ gpm} \equiv 1.1140 \text{ cfs (31.54 l/s)}$$

$$\text{Velocity} = v = \frac{Q}{A} = \frac{1.1140}{0.0884} = 12.60 \text{ fps (3.8 m/s)}$$

$$Re = \frac{Dv}{\nu} = \frac{0.3355(12.60)}{1.41 \times 10^{-5}} = 3.0 \times 10^5$$

$$\frac{\epsilon}{D} = \frac{0.0002}{0.3355} = 0.0006$$

From the Moody friction chart, $f = 0.0188$.

From Equation 18

$$h_L = \frac{0.0188(100)(12.60)^2}{2(0.3355)(32.2)} = 13.8 \text{ ft} = 5.98 \text{ psi (0.41 bar)}$$

The Hazen-Williams approach—Equation 22b—does not take into account any variability in the physical properties of water. It is more straightforward to apply but will likely be less accurate. If we assume a C-factor of 100 and solve directly for pressure drop in psi per 100 ft we obtain

$$\Delta p = \frac{4.52(100)(500)^{1.85}}{(100)^{1.85}(4.026)^{4.87}} = 10.06 \text{ psi (0.69 bar)}$$

If we assume $C = 140$,

$$\Delta p = 5.40 \text{ psi (0.37 bar)}$$

a drop of nearly 50 percent and much closer to the Darcy result.

Accuracy in using Hazen-Williams clearly depends on a careful choice of C-factor. The Darcy result is not nearly so sensitive to choice of specific roughness ϵ .

Minor Losses

Flows through pipe fittings, valves, or other pipeline fixtures generate additional turbulence and, therefore, additional energy losses. These losses, although termed minor, can be very significant fractions of the total energy loss due to friction in a piping system. In particular, losses due to pipeline obstructions such as swing-type check valves and certain types of flow meters are equivalent to many feet (or meters) of straight pipe losses. Thus, in some instances minor losses may have to be considered major, particularly in systems where there are many fittings, valves, or other appurtenances. Empirical methods are used to determine these losses for a range of flow or obstruction geometries. One common method is to define a *minor loss coefficient* to express head loss as a function of velocity head. Thus,

$$h_L = k \frac{v^2}{2g} \tag{23}$$

where k is a dimensionless loss coefficient. It is sometimes convenient to express such losses in terms of *equivalent length of straight pipe*, or as pipe diameters that produce the same head loss. Thus, by Darcy-Weisbach,

$$\frac{L}{D} = \frac{k}{f} \tag{24}$$

Table 4-2.3 shows local loss coefficients for a number of fittings and flow patterns. Wherever possible manufacturers' data should be used, particularly for valves because of the wide variety of designs even for valves of the same generic type. Such data are often published in the form of flow coefficient or C_v values, which may be used in the equation

$$Q = C_v \sqrt{h_L} \tag{25}$$

C_v is determined from the relation

$$C_v = \pi D^2 \sqrt{\frac{g}{8k}} \tag{26}$$

which results directly from a combination of the continuity equation with the equations above.

EXAMPLE 3:

Table 4-2.4 lists a number of equivalent lengths of standard Schedule 40 pipe for screwed steel fittings and valves. Using the table determine the equivalent length of the 2-in.-diameter pipe network shown below.

SOLUTION:

The line comprises

1 check valve	19.0 ft (5.7 m)
3 90° standard elbows	3 × 8.5 = 25.5 ft (7.7 m)
1 tee (flow through run)	7.7 ft (2.4 m)
1 tee (flow through branch or stem)	12.0 ft (3.7 m)
1 gate valve	1.5 ft (0.5 m)
straight pipe	<u>42.0 ft (12.8 m)</u>
	$L_e = 107.7 \text{ ft (32.8 m)}$

The Darcy equation for determining friction losses through the network would then have the form

$$h_L = \frac{fL_e v^2}{2Dg}$$

Alternately, the loss coefficient approach may be used, where

$$h_L = k \frac{v^2}{2g}$$

This method must be used to find entrance and exit losses. For this example, however, we either refer to manufacturer's data for valve and fitting C_v values or calculate k from the relation

$$k = \frac{fL_e}{D}$$

Energy Losses in Pipe Networks

Flow networks may consist of pipes arranged in series, parallel, or some more complicated configuration. In

Table 4-2.3 Local Loss Coefficients

Use the equation $h_L = kv^2/2g$ unless otherwise indicated. Energy loss E_L equals h_v head loss in feet.

Perpendicular square entrance:

any case, an evaluation of friction losses for the flows is based on energy conservation principles applied to the flow junction points. Methods of solution depend on the particular piping configuration. In general, however, they involve establishing a sufficient number of simultaneous equations or employing a friction loss formula where the friction coefficient depends only on the roughness of the pipe (e.g., Darcy or Hazen-Williams).

Pipes in series: When two pipes of different sizes or roughnesses are connected in series [Figure 4-2.13(a)], head loss for a given discharge, or discharge for a given head loss, may be calculated by applying the energy equation between the bounding points, taking into account all losses in the interval. Thus, head losses are cumulative.

Series pipes may be treated as a single pipe of constant diameter to simplify the calculation of friction losses. The approach involves determining an equivalent length of a constant diameter pipe which has the same friction loss and discharge characteristics as the actual series pipe system. Minor losses due to valves and fittings are also included. Using the previous example once again, we note that application of the continuity equation to the solution allows the head loss to be expressed in terms of only one pipe size.

The lost head in equivalent feet of 6-in. pipe is then given in Darcy-Weisbach form by

$$h_L = f \left(\frac{L_e}{D} \right) \left(\frac{v^2}{2g} \right)$$

L_e can be obtained if f is known. Exact hydraulic equivalence in the velocity head terms depends upon f being a constant over the range of velocities applicable to the problem. In fact, f is not a constant over wide ranges of velocity. Since it varies only slightly with Reynolds number, however, solutions are sufficiently accurate.

Pipes in parallel: Two or more pipes connected as in Figure 4-2.13(b), so that flow is first divided among the pipes and is then rejoined, comprise a parallel pipe sys-

Figure 4-2.13. Energy losses in pipe network: (a) pipes in series, (b) pipes in parallel.

tem. Flows in pipes arranged in parallel are also determined by application of energy conservation principles—specifically, energy losses through all pipes connecting common junction points must be equal. Each leg of the parallel network is treated as a series piping system and converted to a single equivalent length pipe. The friction losses through the equivalent length parallel pipes are then considered equal and the respective flows determined by proportional distribution. For a given Q , an outline of the procedure is as follows:

1. Express each branch of the parallel system as an equivalent length of a single pipe size, including all minor losses between the bounding junction points.
2. Assume a discharge Q'_1 through pipe branch 1.
3. Solve for h_L , using Q'_1 .
4. Using h_L , find Q'_2 and Q'_3 for the remaining branches.
5. Knowing the proportional distribution of flow among the legs, Q'_1 , Q'_2 , and Q'_3 are adjusted so that their sum equals the known Q ; thus,

$$Q_1 = \frac{Q'_1}{\sum Q'_i} Q \quad Q_2 = \frac{Q'_2}{\sum Q'_i} Q \quad Q_3 = \frac{Q'_3}{\sum Q'_i} Q \quad (27)$$

6. h_{L1} , h_{L2} , and h_{L3} are computed for the values of Q_1 , Q_2 , and Q_3 as a check for correctness.

For judicious choice of assumed discharges, solutions are obtained rapidly that agree within a few percent, well within the range of accuracy of the assumed friction factors.

In the case where the head loss is known between points A and B, Q for each branch is found simply by solution of the equation for pipe discharge. The discharges are added to obtain the total flow through the system.

Compound piping networks: Energy loss calculations in compound piping configurations or networks employ

the same basic physical principles as for single pipes. That is, conservation of energy and conservation of mass (continuity) must be satisfied throughout the network. In particular, at each pipe junction

$$\sum Q = Q_1 + Q_2 + \cdots + Q_n = 0 \quad (28)$$

and around each closed loop or circuit

$$\sum h_L = h_{L_1} + h_{L_2} + \cdots + h_{L_n} = 0 \quad (29)$$

The general solution procedure involves setting up a sufficient number of independent equations of these two types and solving simultaneously for the unknowns. For complicated networks straightforward algebraic solution is clearly impractical. A very widely used relaxation method for systematic solution of large networks was developed by Hardy Cross in 1928. The method is well suited for solution by hand and is readily adaptable for machine computation.

We have seen that loss of head in a pipe may be represented generally by an equation of the form $h_L = KQ^n$ (where, for the Hazen-Williams formula, $n = 1.85$). For any single pipe in a network, we may write

$$Q = Q_0 + \Delta \quad (30)$$

where

Q = corrected flow

Q_0 = assumed flow

Δ = flow correction

The problem, so stated, reduces to finding Q to a desired degree of accuracy by successive evaluations of Δ based on updated estimates of Q_0 . We solve for Δ as follows:

$$\begin{aligned} h_L &= KQ^n = K(Q_0 + \Delta)^n \\ &= K(Q_0^n + nQ_0^{n-1}\Delta + \cdots) \end{aligned} \quad (31)$$

If Δ is small relative to Q_0 , the higher-order terms in the expansion may be neglected. Since, for any circuit, $\sum h_L = 0$, we may write

$$\sum KQ^n = 0 = \sum [KQ_0^n + nKQ_0^{n-1}\Delta] \quad (32)$$

to a good approximation. Solving for Δ we have

$$\Delta = \frac{-\sum KQ_0^n}{n\sum KQ_0^{n-1}} = \frac{\sum h_{L_0}}{n\sum (h_{L_0}/Q_0)} \quad (33)$$

The overall formulation is made algebraically consistent by designating clockwise flows positive and counterclockwise flows negative. The calculation procedure is controlled by the requirement that the algebraic sum of all assumed flows must equal zero at each pipe junction. The originally assumed flows are repeatedly and cyclically corrected until the Δ values are negligible, indicating that a hydraulic balance has been reached. Note that pipes common to two circuits are corrected twice in each cycle,

once for each circuit. For a system where total head loss is known, flows can be balanced by correcting assumed head losses instead of flows.

Several other methods exist for determining flows and head losses in compound pipe networks. Many can be performed manually, although computer analysis is desirable and necessary for the more complex methods, particularly those involving unsteady flow. For a review of alternative methods, the reader is referred to Stephen-son⁷ and Walski.⁶

Flow Measurement and Discharge

Flow Measuring Devices

This section deals primarily with the basic principles of operation of some flow measuring devices in common use and, in particular, with the pitot tube and the pipeline differential flow meters that have been standardized by the ASME (American Society of Mechanical Engineers): namely, the Venturi, the flow nozzle, and the square-edge thin-plate concentric orifice.

In general, an incompressible fluid of density ρ , viscosity μ , flows with average velocity v through a metering element of diameter d . The metering element is located in a horizontal metering tube of roughness ε and diameter D . The flow through the element produces a pressure differential Δp sensed by pressure taps located a distance L apart. It can be shown by dimensional analysis that the fundamental parameters involved in fluid metering, namely L , ε , v , ρ , μ , d , D , and Δp , yield relational solutions conventionally formulated as follows:

$$\frac{d\rho v}{\mu} = \text{Re}_d \quad \text{metering element Reynolds number}$$

$$\frac{L}{D} \quad \text{tap location ratio}$$

$$\frac{d}{D} = \beta \quad \text{beta ratio}$$

$$\frac{\varepsilon}{D} \quad \text{relative roughness}$$

$$\frac{v}{\sqrt{2g\Delta p/\rho}} = \bar{K} \quad \text{flow coefficient (pressure coefficient)}$$

Since $v = \bar{K}\sqrt{2g\Delta p/\rho}$, the continuity equation allows the volumetric flow rate measured by the meter to be expressed as

$$Q = \bar{K}A_d\sqrt{2g\Delta p/\rho} \quad (34)$$

where A_d is the flow area of the metering element.

Typically, flow meter calculations are based on the idealized flow of a one-dimensional, frictionless, incompressible fluid in a horizontal metering tube. Real conditions require corrections to the ideal formulation. Conventional corrections for the effects of variations from ideal geometry and flow velocity profile are achieved through the use of modification factors. Thus, in Equation 34 above, \bar{K} in-

cludes pressure and flow modifications which are conventionally defined as

$$\bar{K} = CE \tag{35}$$

where C = coefficient of discharge defined as the ratio of actual flow rate to ideal rate and

$$E = \frac{1}{\sqrt{1 - \beta^4}}$$

and is known as the velocity of approach factor, since it accounts for the one-dimensional kinetic energy at the inlet tap.

The general volumetric flow metering equation is, then,

$$Q = \bar{K}A_d\sqrt{\frac{2g\Delta p}{\gamma}} = CE A_d\sqrt{\frac{2g\Delta p}{\gamma}} \tag{36}$$

Venturi flow meter: Figure 4-2.14 shows a schematically typical Venturi-type flow tube. The divergent cone section reduces the overall pressure loss of the meter. Pressure is sensed through a series of holes in the inlet cone and throat. These holes lead to an annular chamber, and the two chambers are connected to a pressure differential sensor such as a U-tube manometer. ASME standardized discharge coefficients are given in Table 4-2.5. Venturi tubes must be individually calibrated to obtain these coefficients outside the tabulated limits.

Figure 4-2.14. Venturi tube.

Table 4-2.5 ASME Coefficients for Venturi Tubes

Type of Inlet Cone	Re ₂		Value of C	Tolerance (%)
	Minimum	Maximum		
Machined		1,000,000	0.995	±1.00
Rough welded sheet metal	500,000	2,000,000	0.985	±1.50
Rough cast			0.984	±0.70

Determination of volumetric flow rate is a simple calculation employing the general flow metering formula—Equation 36—where C is the applicable tabulated value based on Re_d and E is calculated directly from the beta ratio.

ASME flow nozzle: This nozzle is depicted in Figure 4-2.15. The pressure differential is sensed by either throat taps or pipe wall taps appropriately located. Coefficients of discharge for ASME flow nozzles may be accurately computed from the following equation:

$$C = 0.9975 - 0.00653 \left(\frac{10^6}{Re_d} \right)^a \tag{37}$$

where

$$a = \frac{1}{2} \text{ for } Re_d < 10^6$$

$$a = \frac{1}{5} \text{ for } Re_d < 10^6$$

Volumetric flow rates are calculated in the same manner as for the Venturi tube.

ASME orifice meters: Fluid flowing through a thin, square-edged orifice plate experiences a contraction of the flow stream some distance downstream from the orifice. The minimum area of flow is called the *vena contracta* and its location is a function of the beta ratio. Figure 4-2.16 shows the relative pressure difference due to the presence of the orifice plate and the location of the *vena contracta* with respect to beta. By inspection of Figure 4-2.16 it is clear that the actual location of the pressure taps is critical. Three distinct arrangements for tap locations are specified by the ASME for accurately measuring the pressure differential. These types of tap arrangements are called the *flange*, *vena contracta*, and the $1D$ and $\frac{1}{2}D$. Each has certain advantages and disadvantages and affects the value of the discharge coefficient.

Figure 4-2.15. ASME flow nozzle.

Figure 4-2.16. Relative pressure changes due to flow through an orifice.

Discharge coefficients for orifice metering plates may be calculated from the equation

$$C = C_o + \frac{\Delta C}{Re^a} \tag{38}$$

where C_o and a are obtained from Table 4-2.6. Since the jet contraction downstream of the orifice can amount to nearly half of the orifice area, orifice discharge coefficients are in the order of 0.6 compared to the near-unity coefficients obtained with Venturi tubes and flow nozzles.

Pitot tube: A pitot tube is a device designed to sense stagnation or total pressure for the determination of velocity and volumetric flow rate. A number of commercial devices are available, some of which include a static pressure tap, that are designed for insertion into a water main under pressure through a standard pipe tap or corporation cock. The installed pitot tube measures velocity at a point in the fluid. Conventional practice assumes that the conversion of kinetic energy to flow work in the tube is frictionless. Thus, applying the energy equation to the generalized pitot tube diagram (Figure 4-2.17) we obtain

$$\frac{u_s^2 - u_i^2}{2g} + \frac{p_s - p_0}{\rho_0 g} = 0 \tag{39}$$

where

- u_s = stagnation point velocity
- u_i = ideal streamtube velocity
- p_s = stagnation pressure
- p_0 = static pressure

Since, by definition $u_s = 0$, solving for u_i we obtain

$$u_i = \sqrt{\frac{2g(p_s - p_0)}{\gamma_0}} = \sqrt{\frac{2g\Delta p}{\gamma_0}} \tag{40}$$

Typically, a pipe coefficient, C_p , which is independent of the geometry of the velocity profile, is defined as

$$C_p = \frac{\text{average velocity}}{\text{centerline velocity}}$$

For typical velocity profiles, C_p varies from about 0.75 to 0.97 but usually lies within a narrower range of about 0.80 to 0.90. Knowing the centerline velocity, the flow can be obtained simply by

$$Q = C_p A v_{CL} \tag{41}$$

In situations where pipe velocity profiles are unknown, and therefore average velocities are not available, it may be necessary to obtain velocity measurements at many individual points. Given n velocities, the flow is then

$$Q = \sum_{i=1}^n v_i A_i \tag{42}$$

where

- v_i = velocity at the i th point
- A_i = area of annular ring of flow cross section for which velocity v_i is accurate

Detailed procedures for obtaining accurate pitot traverses are available in the literature along with suggestions for assessing the reliability of water audits, C-factor tests, and so forth, based on pitot gage measurements.^{4,6} See the next section for a discussion of discharge measurements using pitot tubes.

Free Discharge at an Opening

Flow discharging to the atmosphere from a tank, hydrant, nozzle, or open conduit is affected by the area and shape of the opening. The total energy of the fluid is converted into kinetic energy at the orifice according to an

appropriate form of the Bernoulli equation. In the most general case of a closed pressurized tank,

$$\frac{v_0^2}{2g} = z_1 + \frac{p_1}{\rho} \quad (43)$$

$$v_0 = \left[2g \left(z_1 + \frac{p_1}{\rho} \right) \right]^{1/2} \quad (44)$$

Accounting for losses at the point of discharge,

$$v_0 = C_v \sqrt{2gh} \quad (45)$$

where C_v , the coefficient of velocity, is determined from the coefficients of discharge and contraction

$$C_v = \frac{C_d}{C_c}$$

Table 4-2.7 Orifice Coefficients for Water

Illustration	Description	C_d	C_c	C_v
	Sharp-edged	0.62	0.63	0.98
	Round-edged	0.98	1.00	0.98
	Short tube (fluid separates from walls)	0.61	1.00	0.61
	Short tube (no separation)	0.82	1.00	0.82
	Short tube with rounded entrance	0.97	0.99	0.98
	Reentrant tube, length less than one-half of pipe diameter	0.54	0.55	0.99
	Reentrant tube, length 2 to 3 pipe diameters	0.72	1.00	0.72
Not shown	Smooth, well-tapered nozzle	0.98	0.99	0.99

Commonly used values of orifice coefficients for water are given in Table 4-2.7. The orifice discharge can then be expressed as

$$Q_o = C_d A_o \sqrt{2gh} \quad (46)$$

and the head loss due to turbulence at the orifice as

$$h_L = \left(\frac{1}{C_v^2} - 1 \right) \frac{v_0^2}{2g} \quad (47)$$

where

$$\left(\frac{1}{C_v^2} - 1 \right) = \text{minor loss } k\text{-factor}$$

For the general case of a tank of varying cross-sectional area being replenished with inflow, Q_{IN} , the time to empty from height z_1 to z_2 is given by

$$t = \int_{z_1}^{z_2} \frac{A_t dz}{c_d A_o \sqrt{2gh} - Q_{IN}} \quad (48)$$

where A_t is expressed as a function of z .

For a tank of constant cross section this simplifies to

$$t = \frac{2A_t(\sqrt{z_1} - \sqrt{z_2})}{C_d A_o \sqrt{2g}} \quad (49)$$

EXAMPLE 4:

A 15-ft-diameter tank discharges water at 50°F through a 2-in.-diameter sharp-edged orifice. If the initial water depth in the tank is 10 ft and the tank is continuously pressurized to 50 psig, how long will it take to empty the tank?

SOLUTION:

At 50°F (10°C),

$$\gamma = 62.4 \text{ lbm/ft}^3 \text{ (16.02 kg/m}^3\text{)}$$

For the orifice:

$$A_o = \frac{\pi D^2}{4} = 3.14 \text{ ft}^2 \text{ (0.29 m}^2\text{)}$$

$$C_d = 0.62 \text{ (sharp-edged orifice)}$$

For the tank:

$$A_t = \frac{\pi D^2}{4} = 176.7 \text{ ft}^2 \text{ (16.4 m}^2\text{)}$$

$$h_0 = 10 + \frac{50(144)}{62.4} = 125.38 \text{ ft (38.2 m)}$$

$$h_1 = 0 + \frac{50(144)}{62.4} = 115.38 \text{ ft (35.2 m)}$$

The total pressure head on the discharging fluid results from both an elevation and a static pressure head. Therefore,

$$t = \frac{2A_t[(z_0 = p_0/\gamma)^{1/2} - (z_1 + p_1/\gamma)^{1/2}]}{C_d A_o \sqrt{2g}}$$

$$t = 10.4 \text{ s}$$

Discharge stream coordinates are given by

$$x = v_0 t = v_0 \sqrt{\frac{2y}{g}} = 2C_v \sqrt{zy} \quad (50a)$$

$$y = \frac{gt^2}{2} \quad (50b)$$

For the simpler case of a hydrant discharging to atmosphere, the flow can be determined by an appropriate form of Equation 36,

$$Q = 29.8D^2 C_d \sqrt{p} \quad (51)$$

where

Q = discharge (gpm)

D = outlet diameter (in.)

p = pressure detected by pitot gage (psi)

C_d = coefficient based on hydrant outlet geometry (usually taken to be 0.90 for full flow across a standard 2½-in. outlet)

In the absence of a pitot gage, hydrant flows may be estimated by observing the trajectory of the discharge stream. The horizontal component of the velocity does not change appreciably over time, thus allowing calculation of the velocity based on the height of the outlet and the distance traveled by the stream. Figure 4-2.18 presents the basic parameters. The velocity determined in this manner is at the *vena contracta* and is given by

$$v = \frac{x}{\sqrt{2y/g}} \quad (52)$$

The discharge is simply the product of this velocity and the area of the *vena contracta*. The method is relatively inaccurate due to the obvious difficulty of measuring the

Figure 4-2.18. Determining discharge by the trajectory method.

required area and the distance x . It is a useful bounding guide, however, in the absence of precision measuring devices.

WATER HAMMER*

Water hammer in a pipeline is caused by a sudden stoppage of flow and is characterized by loud noise and vibration. The kinetic energy from the interrupted flow is transferred to the walls of the enclosing pipe or equipment, which expand under the increased pressure. Such pressures, or shock waves, can be severe enough to destroy the equipment and the pipeline itself.

Density changes due to pressure are assumed zero for nearly all hydraulic calculations, as water is considered incompressible for practical purposes even though it is about 100 times more compressible than steel. When shock waves arise in confined water, however, the compressibility of water becomes very significant, and water's elastic properties must be taken into account. The primary property of interest is the bulk modulus of elasticity, E , which is defined as the ratio of pressure change to the corresponding change of volume as determined by compression tests on volumes. (The bulk modulus is analogous to Young's modulus in solid mechanics, which is the ratio of linear stresses to linear strains as determined by tension tests.) The formula expressing the relationship between pressure and volume is

$$\Delta p = -E \frac{\Delta V}{V_0} \quad (53)$$

where the minus sign indicates that a positive change in pressure produces a decrease in volume. A modulus of compressibility, K , is also defined as the inverse of E .

Under normal conditions, water confined and flowing under pressure in a pipeline exerts pressure on the pipe walls according to the pressure-energy term of the energy equation. Any change in discharge within the system (due to valve closure, pump stoppage, etc.) results in a change of flow momentum. By virtue of the impulse-momentum relation, the momentum change will cause an impulse force to be created. This force in a pipeline is commonly referred to as water hammer.

The theory of water hammer, as developed by Zhukovsky, can be briefly illustrated as follows: a valve in a pipeline is closed instantaneously; the fluid impacts the closed gate and is decelerated to zero velocity, thereby creating a pressure shock. By Newton, pressure shocks in fluids of infinite extent travel at a velocity given by

$$c^* = \sqrt{\frac{KE}{\rho}} \quad (54)$$

where c^* is called the celerity (velocity) of the shock wave, KE is the kinetic energy of the fluid, and ρ is the fluid density. The pipe, however, is also elastic. Therefore, if the fluid in the pipe is compressed, the pipe will expand. The

*This discussion is patterned after the theory of water hammer as developed by N. J. Zhukovsky and as presented in Andrew L. Simon's *Practical Hydraulics*, 2nd ed.⁴

modulus of elasticity, E_c , of a system composed of fluid and pipe may be determined from the equation

$$\frac{1}{E_c} = \frac{1}{E} + \frac{D}{E_p w} \tag{55}$$

where

- D = pipe diameter
- w = thickness of the pipe wall
- E_p = modulus of elasticity of the pipe material

Table 4-2.8 gives the modulus of elasticity for common pipe materials. The celerity of a shock wave in a pipe system of finite extent can then be computed from

$$\frac{c}{c^*} = \frac{1}{\sqrt{1 + ED/(E_p w)}} \tag{56}$$

which is plotted in Figure 4-2.19. The graph indicates the considerable influence of pipe rigidity on the velocity of the shock.

The shock waves that travel upstream and downstream from the valve closure eventually reach points in the system that correspond to large stationary energy stores (e.g., reservoirs) or other sudden closure points, which may vary in their ability to absorb or reflect the shock wave. If the shock is absorbed into a larger energy field it will disappear, and it will do so in time

$$t = \frac{L}{c} \tag{57}$$

where L is the distance from the energy reservoir to the shock wave point of origin. At the instant of shock absorption the compressed fluid, no longer balanced, begins to flow backward, creating a relief pressure shock that travels back to the valve. The time period T that the initial shock or impulse pressure acts on the valve is, therefore, the time required for the pressure wave to travel away from and back to the valve:

$$T = 2t = \frac{2L}{c} \tag{58}$$

Table 4-2.8 Modulus of Elasticity E_p of Various Pipe Materials

Pipe Material	E_p		
	(psi)	(lb/ft ²)	(kg/m ²)
Lead	0.045×10^6	6.48×10^6	31.64×10^6
Lucite (at 73°F)	0.4×10^6	57.6×10^6	281.23×10^6
Rubber (vulcanized)	2×10^6	288×10^6	1406×10^6
Aluminum	10×10^6	1440×10^6	7030×10^6
Glass (silica)	10×10^6	1440×10^6	7030×10^6
Brass, bronze	13×10^6	1872×10^6	8489×10^6
Copper	14×10^6	2016×10^6	9842×10^6
Cast iron, gray	16×10^6	2304×10^6	$11,249 \times 10^6$
Cast iron, malleable	23×10^6	3312×10^6	$16,170 \times 10^6$
Steel	28×10^6	4023×10^6	$19,685 \times 10^6$

Figure 4-2.19. Celerity of pressure waves in pipes, c equals celerity in elastic pipe; c^* equals celerity in fluid of infinite extent.

At time T , all the fluid is moving backward at some velocity v . Since the valve is closed, there is no supply for this flow. A negative pressure shock is created at the valve. The shock travels to and back from the reservoir, as the flow is reversed. Such oscillations of pressure and periodic flow reversals persist until the kinetic energy is dissipated by friction. The process described will occur both upstream and downstream from the point of origin, though the initial shock will be positive upstream and negative downstream and the periodicities would not likely be equal.

The theoretical magnitude of the pressure shock at instantaneous valve closure can be determined directly from

$$p^* = \rho c \Delta v \tag{59}$$

and the pressure will oscillate in the pipe within the range

$$p = p_0 \pm p^* \tag{60}$$

In actuality, the time of closure of a valve is not zero but some finite time period which we may call T_c . The water hammer pressure increases gradually with the rate of closure of the valve. Depending on whether T_c is smaller or larger than T , we distinguish between quick and slow closure. For $T_c < T$, the shock pressure will attain its maximum value p^* . (In this sense, quick closure is equivalent to instantaneous closure.) For $T_c > T$, maximum pressure

will be somewhat less than p^* and may be calculated by the Allievi formula

$$p = p_0 \left(\frac{N}{2} + \sqrt{\frac{N^2}{4} + N} \right) \quad (61)$$

in which

$$N = \left(\frac{Lvp}{p_0 T_c} \right)^2 \quad (61a)$$

In general the calculation of water hammer pressure rises, regardless of method, will tend to underestimate the actual values. Real systems will tend to experience superimposition of positive or negative pressure waves due to complex piping configurations. Discontinuities introduced by a variety of auxiliary valving and metering equipment complicate the analysis considerably. Other methods are available for analyzing water hammer effects on systems that may not be reasonably handled by the above idealized method.⁸ Since water hammer can be extremely detrimental, often resulting in complete loss of the system, it is desirable to perform an analysis wherever such effects are of concern. Control over the development of damaging shock waves is achieved through use of slow-closing valves, pressure relief valves, or shock-absorbing devices.

Pumps

Pump Operating Characteristics

Pumps are mechanical devices that convert electrical or mechanical energy into hydraulic energy. There are many classes of pumps—for example, reciprocating, rotary, jet, ram, centrifugal—each class referring to different ways pumps move liquids. A common class of pump is the centrifugal and it is usually the only type we are concerned with in fire protection applications. Based on the way in which the impeller (the rotating component) imparts energy to the water, centrifugal pumps may be divided into several categories. Turbine or radial flow centrifugal pumps force water outward at right angles to the rotating axis. Mixed flow pumps force water in both radial and axial directions. Propeller pumps move water in the axial direction only. Any of these types may be single or multistage, where stage refers to the number of impellers on the pump's rotating shaft. The orientation of the shaft may be vertical or horizontal. The following discussion, while broadly applicable, is directed mainly to centrifugal pumps.

Figure 4-2.20 illustrates several of the terms commonly used to describe pump performance conditions. In general, pumping of liquids requires that the pressure at any point in the intake line be greater than the vapor

Figure 4-2.20. Pump head definitions.

pressure of the liquid to avoid loss of prime and the highly destructive phenomenon known as cavitation. The pressure gradient that causes a liquid to move through the intake line to the pump impeller is termed the net positive suction head (NPSH). In pump selection, it is essential to determine that the *available* NPSH of the system exceeds the *required* NPSH for the pump under consideration. Required NPSH depends upon many factors relating to pump geometry and construction and intake system operating conditions, but it is defined simply as the difference between net suction head and vapor pressure at a given flow, or the energy needed to fill the pump on the intake side and overcome intake system head losses. If the net suction head is less than the vapor pressure of the water, the water will vaporize in the pump, producing cavitation. Small vapor bubbles formed in the low-pressure region will collapse violently upon entering regions of high pressure, causing localized stress concentrations and vibrations, ultimately leading to mechanical failure.

The required net positive suction head ($NPSH_{req}$) for any pump can be obtained from the manufacturer. The available net positive suction head ($NPSH_{av}$) must be calculated for each system. Because the total energy of a system is constant, the available NPSH may be determined at any point in the system. The general expression at the pump centerline follows from Bernoulli as

$$NPSH_{av} = \frac{(p_{gauge} + p_{atm})}{\rho g} + z - h_L - \frac{p_{vp}}{\rho g} \quad (62)$$

where

h_L = friction head loss in intake system piping (in feet of water)

p_{vp} = vapor pressure (0.256 psia for water at 20°C)

Knowing the pressure and pipe friction loss terms, the pump can be set at a height, z , which will ensure that $NPSH_{av} > NPSH_{req}$.

Where a free surface exists on the intake side (such as at the surface of an intake reservoir) and the velocity at a point on the surface is negligible, the above expression simplifies to

$$NPSH_{av} = z - h_L + \frac{(p_{atm} - p_{vp})}{\rho g} \quad (63)$$

For pumps of relatively low heads and large discharge capacities (common in fire protection applications) the available NPSH may be less than zero (h_L is large). These pumps should be installed well below the reservoir water level to eliminate the possibility of cavitation. For this reason and also to avoid accidental loss of prime, authorities having jurisdiction generally require *positive suction* installation. In such instances the pump should be of the vertical shaft type so that the motor can be installed at an elevation above any possible flood level.

The useful work done by a pump is the product of the weight of the liquid pumped and the head developed by the pump. The work per unit time in this context is the hydraulic horsepower, commonly called the water horse-

power (WHP). For discharge, Q , in gpm, total dynamic head, h , in feet, and specific weight, γ , for water at 20°C (68°F),

$$WHP = \frac{Qh}{3960} \quad (64)$$

The power required to actually drive the pump is the brake horsepower (BHP). The difference between water horsepower and brake horsepower is the power lost within the pump due to mechanical and hydraulic friction. The ratio of WHP to BHP is the pump efficiency, η_p . Similarly, the ratio of BHP to electrical or engine horsepower (EHP) is the motor efficiency, η_m . The overall efficiency is, then, the pump efficiency multiplied by the motor efficiency:

$$\eta = (\eta_p)(\eta_m) = \frac{WHP}{BHP} \cdot \frac{BHP}{EHP} \quad (65)$$

Although WHP should be calculated using the specific weight of the fluid at known conditions of temperature and pressure, the variation for water is very small; it should be noted that pump motor sizes are chosen from standard available sizes in any case.

The interrelations of head, capacity, power, and efficiency for a given pump are known as the characteristics of the pump. They can be expressed graphically in the form of pump characteristic curves. Figure 4-2.21 shows a standard plot of the several variables at constant impeller speed (N). Note that the point of maximum operating efficiency on the head-capacity curve corresponds to the maximum value of the efficiency curve. The actual operating point of the pump, however, depends on the system demand (or system head) curve. The system head loss for any flow rate is the sum of the system friction head loss at that rate plus the total static head to be overcome in the system. Figure 4-2.22 illustrates the relationship. Recall from Figure 4-2.20 that the total static head is the difference in elevation between the discharge level and the suc-

Figure 4-2.21. Centrifugal pump characteristics.

Figure 4-2.22. Graphical determination of operating point.

tion level. System friction losses may be determined by calculations methods given in previous sections.

Pump Selection

Economical pump selection for fire protection applications requires consideration of the following factors:

1. The maximum discharge rate required under the most demanding design conditions
2. The total head-capacity relation (characteristic curve)
3. The suction head—in particular, the net positive suction head available
4. Pump speed and power source requirements
5. Pump spatial and environmental requirements
6. The maximum allowable system head downstream of the pump discharge

The usual design condition is that a system will be given or will be chosen from a very limited range of possibilities, and the proper pump must be selected. As shown in Figure 4-2.22, when the system demand curve and the pump head-capacity curve are superimposed, their intersection will determine the operating point of the pump. This point also locates the efficiency and, therefore, the power requirements. It is often economically desirable to select a pump such that its operating point is at or near its peak efficiency. In many fire protection applications, however, a pump may be called upon to operate very infrequently. Power consumption may, therefore, not be a significant factor relative to initial cost. Common practice in fire protection applications is to select a pump to operate at 150 percent of rated capacity at 65 percent of rated head (see NFPA 20⁸)—that is, an operating point farther out along the characteristic curve. A pump is chosen such that its operating point so defined meets or exceeds the system demand curve at that point.

If the pump is to be used as a *booster* to increase supply main pressure, care must be exercised to select a pump having a maximum discharge head at zero flow (also known as *churn head*), which, when added to the maximum main's supply head, does not exceed the maximum allowable working pressure on the system. The maximum allowable working pressure prescribed by NFPA 13, for example, is 175 psig.⁹

Centrifugal Pump Affinity Relations

The abstract concept of *pump specific speed* has been developed to simplify the description of pump performance characteristics. It consolidates the discharge, head, and speed (rpm) at optimum performance into a single number. For a single stage, single suction pump, specific speed may be calculated from

$$N_s = \frac{NQ^{1/2}}{H^{3/4}} \quad (66)$$

where Q (in gpm) is taken at pump rpm, N , and total dynamic head, H . The specific speed of a pump is not actually a speed for that pump in any physical sense; it is defined as the speed in revolutions per minute at which a homologous (geometrically similar) pump would run if constructed to deliver 1 gpm against 1 ft total head at its peak efficiency. For pump impeller designs of identical proportions but different sizes, the specific speed is a constant performance index. That is, the performance of any impeller can be predicted from knowledge of the performance of any other geometrically similar impeller.

Changing the impeller diameter results in changes in discharge, total head, and delivered power. These changes occur according to the follow relations:

$$\frac{Q_1}{Q_2} = \left(\frac{D_1}{D_2}\right)^3 \frac{n_1}{n_2} \quad (67a)$$

$$\frac{H_1}{H_2} = \left(\frac{D_1}{D_2}\right)^2 \left(\frac{n_1}{n_2}\right)^2 \quad (67b)$$

$$\frac{Q_1}{Q_2} = \left(\frac{H_1}{H_2}\right)^{1/2} \left(\frac{D_1}{D_2}\right)^2 \quad (67c)$$

$$\frac{\text{BHP}_1}{\text{BHP}_2} = \left(\frac{D_1}{D_2}\right)^5 \frac{\rho_1 n_1^3}{\rho_2 n_2^3} \quad (67d)$$

Since

$$\frac{N_1}{N_2} = \frac{D_1}{D_2} \quad (68)$$

a change in motor speed only will yield similar results. That is, a change in impeller size has the same effect on pump performance as a change in speed provided, of course, that there is no marked change in operating efficiency.

EXAMPLE 5:

A 6-in. (152.4-mm) pump operating at 1770 rpm discharges 1500 gpm (5678 l/m) of water at 40°F against a 120-ft (36.6-m) head.

- (a) What discharge capacity and total head can be expected from a homologous 8-in. (203-mm) pump operating at 1170 rpm?
- (b) If the pumps operate at an overall 80 percent efficiency, what is the 8-in. (203-mm) pump power requirement?

SOLUTION:

(a) From Equation 67b,

$$H_2 = \left[\frac{8^2(1170)^2}{(6)^2(1770)^2} \right] (120) = 93.2 \text{ ft (28.4 m)}$$

From Equation 67a,

$$Q_2 = \left[\frac{(8)^3(1170)}{(6)^3(1770)} \right] (1500) = 2350 \text{ gpm (8895.5 l/m)}$$

(b) From Equation 64,

$$\text{WHP} = \frac{2350(93.2)}{3960} = 55.3 \text{ HP}$$

Therefore,

$$\text{BHP} = \frac{55.3}{0.8} = 69.1 \text{ HP}$$

The motor chosen would be the next highest standard horsepower rating.

If more discharge or more head is required than a single pump can provide, two or more pumps may be combined to provide the necessary output. For example, when discharge is too little, pumps may be installed in parallel, sharing the same suction and inlet conditions. Figure 4-2.23 illustrates the principle. If a pump provides sufficient discharge but too little head, a second pump may be installed in series, the output of the first pump being fed directly into the suction of the second pump. Fig-

Figure 4-2.23. Two pumps combined in parallel.

Figure 4-2.24. Two pumps combined in series.

ure 4-2.24 depicts the series arrangement. A variety of compound arrangements are possible, depending on details of actual supply and demand, with economics being the prime arbiter.

Nomenclature

- A area
- C proportionality constant or flow coefficient, Hazen-Williams C-factor
- c celerity of a shock wave
- D pipe diameter
- d element diameter
- E velocity of approach factor, bulk modulus of elasticity
- f Darcy-Weisbach friction loss factor
- g gravitational acceleration constant, 9.8 m/s²
- H head of water
- h head
- h_c height of centroid
- h_L head loss
- I moment of inertia
- K proportionality constant or flow coefficient
- k proportionality constant or flow coefficient
- L length of conduit (in friction loss equations)
- l length or distance
- m mass

N	pump rpm
p	pressure
Q	volumetric discharge rate
Re	Reynolds number
S	slope of energy gradient
s	specific gravity
u	stream velocity at a given point in flow cross section
V	volume
v	average stream velocity
z	height above a reference datum (potential head)
α	kinetic energy correction factor
β	beta ratio
γ	specific weight
Δ	increment
ε	pipe wall absolute roughness
η	efficiency
μ	absolute (dynamic) viscosity
ν	kinematic viscosity
ρ	density
τ	fluid shear stress

CHAPTER 3

Automatic Sprinkler System Calculations

Russell P. Fleming

Introduction

Applications Where Water Is Appropriate

Water is the most commonly used fire extinguishing agent, mainly due to the fact that it is widely available and inexpensive. It also has very desirable fire extinguishing characteristics such as a high specific heat and high latent heat of vaporization. A single gallon of water can absorb 9280 Btus (2586.5 kJ) of heat as it increases from a 70°F (21°C) room temperature to become steam at 212°F (100°C).

Water is not the perfect extinguishing agent, however, and is considered inappropriate for the protection of certain water reactive materials. In some cases, the use of water can produce heat, flammable or toxic gases, or explosions. The quantities of such products must be considered, however, because application of sufficient water can overcome the reaction of minor amounts of these materials.

Another drawback of water is that it is more dense than most hydrocarbon fuels, and immiscible as well. Therefore, water will not provide an effective cover for burning hydrocarbons, or mix with them and dilute them to the point of not sustaining combustion. Instead, the hydrocarbons will float on top of the water, continuing to burn and possibly spread. To combat such fires, foam solutions can be introduced into the water to provide an effective cover and smother the fire. Applying water in a fine mist has also been successful.

However, even when water from sprinklers will not suppress the fire, its cooling ability can protect structural elements of a building by containing the fire until it can be extinguished by other means.

Types of Sprinkler Systems

Automatic sprinkler systems are considered to be the most effective and economical way to apply water to suppress a fire. There are four basic types of sprinkler systems:

1. A *wet pipe* system is by far the most common type of sprinkler system. It consists of a network of piping containing water under pressure. Automatic sprinklers are connected to the piping such that each sprinkler protects an assigned building area. The application of heat to any sprinkler will cause that single sprinkler to operate, permitting water to discharge over its area of protection.
2. A *dry pipe* system is similar to a wet system, except that water is held back from the piping network by a special dry pipe valve. The valve is kept closed by air or nitrogen pressure maintained in the piping. The operation of one or more sprinklers will allow the air pressure to escape, causing operation of the dry valve, which then permits water to flow into the piping to suppress the fire. Dry systems are used where the water in the piping would be subject to freezing.
3. A *deluge* system is one that does not use automatic sprinklers, but rather open sprinklers. A special deluge valve holds back the water from the piping, and is activated by a separate fire detection system. When activated, the deluge valve admits water to the piping network, and water flows simultaneously from all of the open sprinklers. Deluge systems are used for protection against rapidly spreading, high hazard fires.
4. A *preaction* system is similar to a deluge system except that automatic sprinklers are used, and a small air pressure is usually maintained in the piping network to ensure that the system is air tight. As with a deluge system, a separate detection system is used to activate a deluge valve, admitting water to the piping. However, because automatic sprinklers are used, the water is usually stopped from flowing unless heat from the fire has also activated one or more sprinklers. Some

Russell P. Fleming, P.E., is vice president of engineering, National Fire Sprinkler Association, Patterson, New York. Mr. Fleming has served as a member of more than a dozen NFPA technical committees, including the Committee on Automatic Sprinklers. He currently serves on the Board of Directors of NFPA.

special arrangements of preaction systems permit variations on detection system interaction with sprinkler operation. Preaction systems are generally used where there is special concern for accidental discharge of water, as in valuable computer areas.

These four basic types of systems differ in terms of the most fundamental aspect of how the water is put into the area of the fire. There are many other types of sprinkler systems, classified according to the hazard they protect (such as residential, in-rack, or exposure protection); additives to the system (such as antifreeze or foam); or special connections to the system (such as multipurpose piping). However, all sprinkler systems can still be categorized as one of the basic four types.

Applicable Standards

NFPA 13, *Standard for the Installation of Sprinkler Systems* (hereafter referred to as NFPA 13), is a design and installation standard for automatic sprinkler systems, referenced by most building codes in the United States and Canada.¹ This standard, in turn, references other NFPA standards for details as to water supply components, including NFPA 14, *Standard for the Installation of Standpipe and Hose Systems*; NFPA 20, *Standard for the Installation of Centrifugal Fire Pumps* (hereafter referred to as NFPA 20); NFPA 22, *Standard for Water Tanks for Private Fire Protection* (hereafter referred to as NFPA 22); and NFPA 24, *Standard for the Installation of Private Fire Service Mains and Their Appurtenances*.

For protection of warehouse storage, NFPA 13 traditionally referenced special storage standards that contained sprinkler system design criteria, including NFPA 231, *Standard for General Storage Materials* (hereafter referred to as NFPA 231); NFPA 231C, *Standard for Rack Storage of Materials* (hereafter referred to as NFPA 231C); NFPA 231D, *Standard for Rubber Tire Storage*; and NFPA 231F, *Standard for Roll Paper Storage*. However, beginning with the 1999 edition of NFPA 13 these standards were all merged into NFPA 13 to produce a consolidated sprinkler system design and installation standard.

Other NFPA standards contain design criteria for special types of occupancies or systems, including NFPA 13D, *Standard for the Installation of Sprinkler Systems in One- and Two-Family Dwellings and Manufactured Homes* (hereafter referred to as NFPA 13D); NFPA 15, *Standard for Water Spray Fixed Systems for Fire Protection*; NFPA 16, *Standard for the Installation of Foam-Water Sprinkler and Foam-Water Spray Systems*; NFPA 30, *Flammable and Combustible Liquids Code*; NFPA 30B, *Code for the Manufacture and Storage of Aerosol Products*; and NFPA 409, *Standard on Aircraft Hangars*.

Limits of Calculation in an Empirical Design Process

Engineering calculations are best performed in areas where an understanding exists as to relationships between parameters. This is not the case with the technology of automatic sprinkler systems. Calculation methods are widely used with regard to only one aspect of sprinkler systems: water flow through piping. There are only

very rudimentary calculation methods available with regard to the most fundamental aspect of sprinkler systems, i.e., the ability of water spray to suppress fires.

The reason that calculation methods are not used is simply the complexity of the mechanisms by which water suppresses fires. Water-based fire suppression has to this point not been thoroughly characterized to permit application of mathematical modeling techniques. As a result, the fire suppression aspects of sprinkler system design are empirical at best.

Some, but not all, of the current sprinkler system design criteria are based on full-scale testing, including the criteria originally developed for NFPA 231C and 13D, and parts of NFPA 13, such as the material on the use of large drop and ESRF (early suppression fast response) sprinklers. Most of the NFPA 13 protection criteria, however, are the result of evolution and application of experienced judgment. In the 1970s, the capabilities of pipe schedule systems, which had demonstrated a hundred years of satisfactory performance, were codified into a system of area/density curves. This permitted the introduction of hydraulic calculations to what had become a cookbook-type method of designing sprinkler systems. It allowed system designers to take advantage of strong water supplies to produce more economical systems. It also permitted the determination of specific flows and pressures available at various points of the system, opening the door to the use of "special sprinklers." Special sprinklers are approved for use on the basis of their ability to accomplish specific protection goals, but are not interchangeable since there is no standardization of minimum flows and pressures.

Because of this history, the calculation methods available to the fire protection engineer in standard sprinkler system design are only ancillary to the true function of a sprinkler system. The sections that follow in this chapter address hydraulic calculations of flow through piping, simple calculations commonly performed in determining water supply requirements, and optional calculations that may be performed with regard to hanging and bracing of system piping. The final section of this chapter deals with the performance of a system relative to a fire, and the material contained therein is totally outside the realm of standard practice. This material is not sufficiently complete to permit a full design approach, but only isolated bits of total system performance.

Hydraulic Calculations

Density-Based Sprinkler Demand

Occupancy hazard classification is the most critical aspect of the sprinkler system design process. If the hazard is underestimated, it is possible for fire to overpower the sprinklers, conceivably resulting in a large loss of property or life. Hazard classification is not an area in which calculation methods are presently in use, however. The proper classification of hazard requires experienced judgment and familiarity with relevant NFPA standards.

Once the hazard or commodity classification is determined and a sprinkler spacing and piping layout has

been proposed in conformance with the requirements of the standard, the system designer can begin a series of calculations to demonstrate that the delivery of a prescribed rate of water application will be accomplished for the maximum number of sprinklers that might be reasonably expected to operate. This number of sprinklers, which must be supplied regardless of the location of the fire within the building, is the basis of the concept of the remote design area. The designer needs to demonstrate that the shape and location of the sprinkler arrangement in the design area will be adequately supplied with water in the event of a fire.

Prior to locating the design area, there is the question of how many sprinklers are to be included. This question is primarily addressed by the occupancy hazard classification, but the designer also has some freedom to decide this matter.

Figure 7-2.3.1.2 of the 1999 edition of NFPA 13 and corresponding figures in NFPA 231 and 231C contain area/density curves from which the designer can select a design area and density appropriate for the occupancy hazard classification. Any point on or to the right of the curve in the figure(s) is acceptable. The designer may select a high density over a small area, or a low density over a large area. In either event, the fire is expected to be controlled by the sprinklers within that design area, without opening any additional sprinklers.

EXAMPLE 1:

Using the sample area/density curve shown in Figure 4-3.1, many different design criteria could be selected, ranging from a density of 0.1 gpm/ft² (3.7 mm/min) over 5000 ft² (500 m²) to 0.17 gpm/ft² (6.9 mm/min) over 1500 ft² (139 m²). Either of these two points, or any point to the right of the curve [such as 0.16 gpm/ft² (6.5 mm/min) over 3000 ft² (276 m²)] would be considered acceptable. A selection of 0.15 gpm/ft² (6.1 mm/min) over 2400 ft² (221 m²) is indicated.

Figure 4-3.1. Sample area/density curve.

Water is provided only for the number of sprinklers in the design area, since no water is needed for the sprinklers that are not expected to open. The actual number of sprinklers in the design area depends, of course, on the spacing of the sprinklers. NFPA 13 requires that the design area be divided by the maximum sprinkler spacing used, and that any fractional result be rounded up to the next whole sprinkler.

EXAMPLE 2:

Based on the point selected from the sample area/density curve above and the proposed maximum spacing of sprinklers, the number of sprinklers to be included in the design area can be determined. If sprinklers are spaced at 12 × 15 ft (3.66 × 4.57 m) so as to each protect an area of 180 ft² (16.72 m²), the design area of 2400 ft² (221 m²) would include

$$\frac{2400}{180} = 13.33 = 14 \text{ sprinklers}$$

The remote design area is required to have a rectangular shape, with the long side along the run of the branch lines. The length of the design area (needed to determine how many sprinklers along a branch line are contained within it) is found by multiplying the square root of the design area by a factor of 1.2. Again, any fractional result is rounded to the next whole sprinkler.

EXAMPLE 3:

If the 14 sprinklers from Example 2 were spaced 12 ft (3.66 m) along branch lines 15 ft (4.57 m) apart, the length of the rectangular area along the branch lines would be

$$\frac{1.2(2400)^{1/2}}{12} = \frac{1.2(49)}{12} = 4.9 = 5 \text{ sprinklers}$$

If the sprinklers were spaced 15 ft (4.57 m) along branch lines 12 ft (3.66 m) apart, the same length of the design area would include only 4 sprinklers.

NFPA 13 (1999) contains some exceptions to this method of locating a remote design area and determining the number of sprinklers to be supplied. Chapter 7 of the standard has special modifications to the design area based on factors such as the use of a dry system, the use of quick response sprinklers under flat smooth ceilings of limited height, and the existence of nonsprinklered combustible concealed spaces within the building. The chapter also contains a room design method, which can reduce the number of sprinklers expected to operate in a highly compartmented occupancy. Also, beginning in 1985, the standard adopted a four sprinkler design area for dwelling units and their adjacent corridors when residential sprinklers are installed in accordance with their listing requirements.

Figures in the appendix to Chapter 8 of NFPA 13 (1999 edition) show the normal documentation and the step-by-step calculation procedure for a sample sprinkler system. The starting point is the most remote sprinkler in the design area. For tree systems, in which each sprinkler is supplied from only one direction, the most remote sprinkler is generally the end sprinkler on the farthest branch line from the system riser. This sprinkler, and all

others as a result, must be provided with a sufficient flow of water to meet the density appropriate for the point selected on the area/density curve.

Where a sprinkler protects an irregular area, NFPA 13 prescribes that the area of coverage for the sprinkler must be based on the largest sides of its coverage. In other words, the area which a sprinkler protects for calculation purposes is equal to

$$\text{area of coverage} = S \times L$$

where S is twice the larger of the distances to the next sprinkler (or wall for an end sprinkler) in both the upstream and downstream directions, and L is twice the larger of the distances to adjacent branch lines (or wall in the case of the last branch line) on either side. This reflects the need to flow more water with increasing distance from the sprinkler, since increased flow tends to expand the effective spray umbrella of the sprinkler.

The minimum flow from a sprinkler must be the product of the area of coverage multiplied by the minimum required density

$$Q = \text{area of coverage} \times \text{density}$$

Most of the special listed sprinklers and residential sprinklers have a minimum flow requirement associated with their listings, which is often based on the spacing at which they are used. These minimum flow considerations override the minimum flow based on the area/density method.

EXAMPLE 4:

If a standard spray sprinkler protects an area extending to 7 ft (2.1 m) on the north side (half the distance to the next branch line), 5 ft (1.5 m) on the south side (to a wall), 6 ft (1.8 m) on the west side (half the distance to the next sprinkler on the branch line), and 4 ft (1.2 m) on the east side (to a wall), the minimum flow required for the sprinkler to achieve the density requirement selected in Example 1 can be found by completing two steps. The first step involves determining the area of coverage. In this case

$$\begin{aligned} S \times L &= 2(6 \text{ ft}) \times 2(7 \text{ ft}) = 12 \text{ ft} \times 14 \text{ ft} \\ &= 168 \text{ ft}^2 (15.6 \text{ m}^2) \end{aligned}$$

The second step involves multiplying this coverage area by the required density

$$\begin{aligned} Q &= A \times \rho = 168 \text{ ft}^2 \times 0.15 \text{ gpm/ft}^2 \\ &= 25.2 \text{ gpm} (95.4 \text{ lpm}) \end{aligned}$$

Pressure Requirements of the Most Remote Sprinkler

When flow through a sprinkler orifice takes place, the energy of the water changes from the potential energy of pressure to the kinetic energy of flow. A formula can be derived from the basic energy equations to determine

how much water will flow through an orifice based on the water pressure inside the piping at the orifice:

$$Q = 29.83c_d d^2 P^{1/2}$$

However, this formula contains a factor, c_d , which is a discharge coefficient characteristic of the orifice and which must be determined experimentally. For sprinklers, the product testing laboratories determine the orifice discharge coefficient at the time of listing of a particular model of sprinkler. To simplify things, all factors other than pressure are lumped into what is experimentally determined as the K -factor of a sprinkler, such that

$$Q = K \times P^{1/2}$$

where K has units of $\text{gpm}/(\text{psi})^{1/2}$ [$\text{lpm}/(\text{bar})^{1/2}$].

If the required minimum flow at the most remote sprinkler is known, determined by either the area/density method or the special sprinkler listing, the minimum pressure needed at the most remote sprinkler can easily be found.

$$\text{Since } Q = K(P)^{1/2}, \quad \text{then } P = (Q/K)^2$$

NFPA 13 sets a minimum pressure of 7 psi (0.48 bar) at the end sprinkler in any event, so that a proper spray umbrella is ensured.

EXAMPLE 5:

The pressure required at the sprinkler in Example 4 can be determined using the above formula if the K -factor is known. The K -factor to be used for a standard orifice (nominal 1/2-in.) sprinkler is 5.6.

$$P = \left(\frac{Q}{K}\right)^2 = \left(\frac{25.2}{5.6}\right)^2 = 20.2 \text{ psi} (1.4 \text{ bar})$$

Once the minimum pressure at the most remote sprinkler is determined, the hydraulic calculation method proceeds backward toward the source of supply. If the sprinkler spacing is regular, it can be assumed that all other sprinklers within the design area will be flowing at least as much water, and the minimum density is assured. If spacing is irregular or sprinklers with different K -factors are used, care must be taken that each sprinkler is provided with sufficient flow.

As the calculations proceed toward the system riser, the minimum pressure requirements increase, because additional pressures are needed at these points if elevation and friction losses are to be overcome while still maintaining the minimum needed pressure at the most remote sprinkler. These losses are determined as discussed below, and their values added to the total pressure requirements. Total flow requirements also increase backward toward the source of supply, until calculations get beyond the design area. Then there is no flow added other than hose stream allowances.

It should be noted that each sprinkler closer to the source of supply will show a successively greater flow rate, since a higher total pressure is available at that point in the system piping. This effect on the total water demand is

termed hydraulic increase, and is the reason why the total water demand of a system is not simply equal to the product of the minimum density and the design area. When calculations are complete, the system demand will be known, stated in the form of a specific flow at a specific pressure.

Pressure Losses through Piping, Fittings, and Valves

Friction losses resulting from water flow through piping can be estimated by several engineering approaches, but NFPA 13 specifies the use of the Hazen-Williams method. This approach is based on the formula developed empirically by Hazen and Williams:

$$p = \frac{4.52Q^{1.85}}{C^{1.85}d^{4.87}}$$

where

p = friction loss per ft of pipe in psi

Q = flow rate in gpm

d = internal pipe diameter in inches

C = Hazen-Williams coefficient

The choice of C is critical to the accuracy of the friction loss determination, and is therefore stipulated by NFPA 13. The values assigned for use are intended to simulate the expected interior roughness of aged pipe. (See Table 4-3.1.)

Rather than make the Hazen-Williams calculation for each section of piping, it has become standard practice, when doing hand calculations, to use a friction loss table, which contains all values of p for various values of Q and various pipe sizes. In many cases the tables are based on the use of Schedule 40 steel pipe for wet systems. The use of other pipe schedules, pipe materials, or system types may require the use of multiplying factors.

Once the value of friction loss per foot is determined using either the previous equation or friction loss tables, the total friction loss through a section of pipe is found by multiplying p by the length of pipe, L . Since NFPA 13 uses p to designate loss per foot, total friction loss in a length of pipe can be designated by p_f , where

$$p_f = p \times L$$

In the analysis of complex piping arrangements, it is sometimes convenient to lump the values of all factors in the Hazen-Williams equation (except flow) for a given piece of pipe into a constant, K , identified as a friction loss coefficient.

To avoid confusion with the nozzle coefficient K , this coefficient can be identified as FLC, friction loss coefficient.

$$FLC = \frac{(L \times 4.52)}{(C^{1.85}d^{4.87})}$$

The value of p_f is therefore equal to

$$p_f = FLC \times Q^{1.85}$$

EXAMPLE 6:

If the most remote sprinkler on a branch line requires a minimum flow of 25.2 gpm (92.1 lpm) (for a minimum pressure of 20.2 psi [1.4 bar]) as shown in Examples 4 and 5, and the second sprinkler on the line is connected by a 12-ft (3.6-m) length of 1 in. (25.4 mm) Schedule 40 steel pipe, with both sprinklers mounted directly in fittings on the pipe (no drops or sprigs), the minimum pressure required at the second sprinkler can be found by determining the friction loss caused by a flow of 25.2 gpm (92.1 lpm) through the piping to the end sprinkler. No fitting losses need to be considered if it is a straight run of pipe, since NFPA 13 permits the fitting directly attached to each sprinkler to be ignored.

Using the Hazen-Williams equation with values of 25.2 for Q , 120 for C , and 1.049 for d (the inside diameter of Schedule 40 steel 1-in. pipe) results in a value of $p = 0.20$ psi (0.012 bar) per foot of pipe. Multiplying by the 12-ft (3.6-m) length results in a total friction loss of $p_f = 2.4$ psi (0.17 bar). The total pressure required at the second sprinkler on the line is therefore 20.2 psi + 2.4 psi = 22.6 psi (1.6 bar). This will result in a flow from the second sprinkler of $Q = K(P)^{1/2} = 26.6$ gpm (100.7 lpm).

Minor losses through fittings and valves are not friction losses but energy losses, caused by turbulence in the water flow which increase as the velocity of flow increases. Nevertheless, it has become standard practice to simplify calculation of such losses through the use of "equivalent lengths," which are added to the actual pipe length in determining the pipe friction loss. NFPA 13 contains a table of equivalent pipe lengths for this purpose. (See Table 4-3.2.) As an example, if a 2-in. (50.8-mm) 90-degree long turn elbow is assigned an equivalent length of 3 ft (0.914 m), this means that the energy loss associated with turbulence through the elbow is expected to approximate the energy loss to friction through 0.914 m of 50.8 mm pipe. As with the friction loss tables, the equivalent pipe length chart is based on the use of steel pipe with a C -factor of 120, and the use of other piping materials requires multiplying factors. The equivalent pipe length for pipes having C values other than 120 should be adjusted using the following multiplication factors: 0.713 for a C value of 100; 1.16 for a C value of 130; 1.33 for a C value of 140; 1.51 for a C value of 150.

EXAMPLE 7:

If the 12-ft (3.6-m) length of 1-in. (25.4-mm) pipe in Example 6 had contained 4 elbows so as to avoid a building column, the pressure loss from those elbows could be approximated by adding an equivalent length of pipe to the friction loss calculation. Table 4-3.2 gives a value of 2 ft (0.610 m) as the appropriate equivalent length for standard elbows in 1 in. (25.4 mm) Schedule 40 steel pipe. For

Table 4-3.1 C Values for Pipes

Type of Pipe	Assigned C Factor
Steel pipe—dry and preaction systems	100
Steel pipe—wet and deluge systems	120
Galvanized steel pipe—all systems	120
Cement lined cast or ductile iron	140
Copper tube	150
Plastic (listed)	150

Table 4-3.2 Equivalent Pipe Length Chart (for C = 120)

Fittings and Valves	Fittings and Valves Expressed in Equivalent Feet of Pipe													
	¾ in.	1 in.	1¼ in.	1½ in.	2 in.	2½ in.	3 in.	3½ in.	4 in.	5 in.	6 in.	8 in.	10 in.	12 in.
45° Elbow	1	1	1	2	2	3	3	3	4	5	7	9	11	13
90° Standard Elbow	2	2	3	4	5	6	7	8	10	12	14	18	22	27

Butterfly Valve	—	—	—	—	6	7	10	—	12	9	10	12	19	21
Gate Valve	—	—	—	—	1	1	1	1	2	2	3	4	5	6
Swing Check ^a	—	5	7	9	11	14	16	19	22	27	32	45	55	65

For SI Units: 1 ft = 0.3048 m.

^aDue to the variations in design of swing check valves, the pipe equivalents indicated in the above chart are to be considered average.

4 elbows, the equivalent fitting length would be 8 ft (2.4 m). Added to the actual pipe length of 12 ft (3.6 m), the total equivalent length would be 20 ft (6 m). This results in a new value of $p_f = 20\text{-ft} \cdot 0.20\text{ psi/ft} = 4.0\text{ psi}$ (0.28 bar). The total pressure at the second sprinkler would then be equal to $20.2\text{ psi} + 4.0\text{ psi} = 24.2\text{ psi}$ (1.67 bar). The total flow from the second sprinkler in this case would be $Q = K(P)^{1/2} = 27.5\text{ gpm}$ (100.4 lpm).

Some types of standard valves, such as swing check valves, are included in the equivalent pipe length chart, Table 4-3.2. Equivalent lengths for pressure losses through system alarm, dry, and deluge valves are determined by the approval laboratories at the time of product listing.

Use of Velocity Pressures

The value of pressure, P , in the sprinkler orifice flow formula can be considered either the total pressure, P_t , or the normal pressure, P_n , since NFPA 13 permits the use of velocity pressures at the discretion of the designer. Total pressure, normal pressure, and velocity pressure, P_v , have the following relationship:

$$P_n = P_t - P_v$$

Total pressure is the counterpart of total energy or total head, and can be considered the pressure that would act against an orifice if all of the energy of the water in the pipe at that point were focused toward flow out of the orifice. This is the case where there is no flow past the orifice in the piping. Where flow does take place in the piping past an orifice, however, normal pressure is that portion of the total pressure which is actually acting normal to the direction of flow in the piping, and therefore acting in the direction of flow through the orifice. The amount by which normal pressure is less than total pressure is velocity pressure, which is acting in the direction of flow in the piping. Velocity pressure corresponds to velocity energy, which is the energy of motion. There is no factor in the above expression for elevation head, because the flow from an orifice can be considered to take place in a datum plane.

When velocity pressures are used in calculations, it is recognized that some of the energy of the water is in the form of velocity head, which is not acting normal to the pipe walls (where it would help push water out the orifice), but rather in the downstream direction. Thus, for every sprinkler (except the end sprinkler on a line), slightly less flow takes place than what would be calculated from the use of the formula $Q = K(P_t)^{1/2}$. (See Figure 4-3.2.)

NFPA 13 permits the velocity pressure effects to be ignored, however, since they are usually rather minor, and since ignoring the effects of velocity pressure tends to produce a more conservative design.

If velocity pressures are considered, normal pressure rather than total pressure is used when determining flow through any sprinkler except the end sprinkler on a branch line, and through any branch line except the end branch line on a cross main. The velocity pressure, P_v , which is subtracted from the total pressure in order to determine the normal pressure, is determined as

$$P_v = \frac{v^2}{2g} \times 0.433\text{ psi/ft} \text{ (0.098 bar/m)}$$

or

$$P_v = 0.001123Q^2/d^4$$

Figure 4-3.2. Velocity and normal pressures in piping.

where Q is the upstream flow through the piping to an orifice (or branch line) in gpm and d is the actual internal diameter of the upstream pipe in inches.

Because NFPA 13 mandates the use of the upstream flow, an iterative approach to determining the velocity pressure is necessary. The upstream flow cannot be known unless the flow from the sprinkler (or branch line) in question is known, and the flow from the sprinkler (or branch line) is affected by the velocity pressure resulting from the upstream flow.

EXAMPLE 8:

If the pipe on the upstream side of the second sprinkler in Example 6 were 3 in. Schedule 40 steel pipe with an inside diameter of 1.38 in. (35 mm), the flow from the second sprinkler would be considered to be 26.6 gpm (100.2 lpm) as determined at the end of Example 6, if velocity pressures were not included.

If velocity pressures were to be considered, an upstream flow would first be assumed. Since the end sprinkler had a minimum flow of 25.2 gpm (95.2 lpm) and the upstream flow would consist of the combined flow rates of the two sprinklers, an estimate of 52 gpm (196.8 lpm) might appear reasonable. Substituting this flow and the pipe diameter into the equation for velocity pressure gives

$$\begin{aligned} P_v &= \frac{0.001123Q^2}{d^4} \\ &= \frac{0.001123(52)^2}{(1.38)^4} \\ &= 0.8 \text{ psi (0.06 bar)} \end{aligned}$$

This means that the actual pressure acting on the orifice of the second sprinkler is equal to

$$\begin{aligned} P_n &= P_t - P_v \\ &= 22.6 \text{ psi} - 0.8 \text{ psi} \\ &= 21.8 \text{ psi (1.50 bar)} \end{aligned}$$

This would result in a flow from the second sprinkler of

$$\begin{aligned} Q &= K(P)^{1/2} \\ &= 26.1 \text{ gpm (98.7 lpm)} \end{aligned}$$

Combining this flow with the known flow from the end sprinkler results in a total upstream flow of 51.3 gpm (194.2 lpm). To determine if the initial guess was close enough, determine the velocity pressure that would result from an upstream flow of 51.3 gpm (194.2 lpm). This calculation also results in a velocity pressure of 0.8 psi (0.06 bar), and the process is therefore complete. It can be seen that the second sprinkler apparently flows 0.5 gpm (1.9 lpm) less through the consideration of velocity pressures.

Elevation Losses

Variation of pressure within a fluid at rest is related to the density or unit (specific) weight of the fluid. The unit weight of a fluid is equal to its density multiplied by the

acceleration of gravity. The unit weight of water is 62.4 lbs/ft³ (1000 kg/m³).

This means that one cubic foot of water at rest weighs 62.4 pounds (1000 kg). The cubic foot of water, or any other water column one foot high, thus results in a static pressure at its base of 62.4 pounds per square foot (304.66 kg/m²). Divided by 144 sq in. per sq ft (1.020 × 10⁴ kg/m³ bar), this is a pressure of 0.433 pounds per sq in. per ft (0.099 bar/m) of water column.

A column of water 10 ft (3.048 m) high similarly exerts a pressure of 10 ft × 62.4 lbs/ft² × 1 ft/144 in.² = 4.33 psi (3.048 m × 999.5 kg/m² ÷ 1.020 × 10⁴ kg/m² bar = 0.299 bar). The static pressure at the top of both columns of water is equal to zero (gauge pressure), or atmospheric pressure.

On this basis, additional pressure must be available within a sprinkler system water supply to overcome the pressure loss associated with elevation. This pressure is equal to 0.433 psi per foot (0.099 bar/m) of elevation of the sprinklers above the level where the water supply information is known.

Sometimes the additional pressure needed to overcome elevation is added at the point where the elevation change takes place within the system. If significant elevation changes take place within a portion of the system that is likely to be considered as a representative flowing orifice (such as a single branch line along a cross main that is equivalent to other lines in the remote design area), then it is considered more accurate to wait until calculations have been completed, and simply add an elevation pressure increase to account for the total height of the highest sprinklers above the supply point.

EXAMPLE 9:

The pressure that must be added to a system supply to compensate for the fact that the sprinklers are located 120 ft (36.6 m) above the supply can be found by multiplying the total elevation difference by 0.433 psi/ft (0.099 bar/m).

$$120 \text{ ft} \times 0.433 \text{ psi/ft} = 52 \text{ psi (3.62 bar)}$$

Loops and Grids

Hydraulic calculations become more complicated when piping is configured in loops or grids, such that water feeding any given sprinkler or branch line can be supplied through more than one route. A number of computer programs that handle the repetitive calculations have therefore been developed specifically for fire protection systems, and are being marketed commercially.

Determining the flow split that takes place in the various parts of any loop or grid is accomplished by applying the basic principles of conservation of mass and conservation of energy. For a single loop, it should be recognized that the energy loss across each of the two legs from one end of the system to the other must be equal. Otherwise, a circulation would take place within the loop itself. Also, mass is conserved by the fact that the sum of the two individual flows through the paths is equal to the total flow into (and out of) the loop. (See Figure 4-3.3.)

Figure 4-3.3. Example of a simple loop configuration.

Applying the Hazen-Williams formula to each leg of the loop

$$p_f = L_1 \frac{4.52Q_1^{1.85}}{C_1^{1.85}d_1^{4.87}} = L_2 \frac{4.52Q_2^{1.85}}{C_2^{1.85}d_2^{4.87}}$$

Substituting the term FLC for all terms except Q ,

$$p_f = \text{FLC}_1 Q_1^{1.85} = \text{FLC}_2 Q_2^{1.85}$$

This simplifies to become

$$\left(\frac{Q_1}{Q_2}\right)^{1.85} = \frac{\text{FLC}_2}{\text{FLC}_1}$$

Since Q_1 and Q_2 combine to create a total flow of Q , the flow through one leg can be determined as

$$Q_1 = \frac{Q}{[(\text{FLC}_1/\text{FLC}_2)^{0.54} + 1]}$$

For the simplest of looped systems, a single loop, hand calculations are not complex. Sometimes, seemingly complex piping systems can be simplified by substituting an "equivalent pipe" for two or more pipes in series or in parallel.

For pipes in series

$$\text{FLC}_e = \text{FLC}_1 + \text{FLC}_2 + \text{FLC}_3 + \dots$$

For pipes in parallel

$$\left(\frac{1}{\text{FLC}_e}\right)^{0.54} = \left(\frac{1}{\text{FLC}_1}\right)^{0.54} + \left(\frac{1}{\text{FLC}_2}\right)^{0.54} + \dots$$

For gridded systems, which involve flow through multiple loops, computers are generally used since it becomes necessary to solve a system of nonlinear equations. When hand calculations are performed, the Hardy Cross² method of balancing heads is generally employed. This method involves assuming a flow distribution within the piping network, then applying successive corrective flows until differences in pressure losses through the various routes are nearly equal.

The Hardy Cross solution procedure applied to sprinkler system piping is as follows:

1. Identify all loop circuits and the significant parameters associated with each line of the loop, such as pipe

length, diameter, and Hazen-Williams coefficient. Reduce the number of individual pipes where possible by finding the equivalent pipe for pipes in series or parallel.

2. Evaluate each parameter in the proper units. Minor losses through fittings should be converted to equivalent pipe lengths. A value of all parameters except flow for each pipe section should be calculated (FLC).
3. Assume a reasonable distribution of flows that satisfies continuity, proceeding loop by loop.
4. Compute the pressure (or head) loss due to friction, p_f , in each pipe using the FLC in the Hazen-Williams formula.
5. Sum the friction losses around each loop with due regard to sign. (Assume clockwise positive, for example.) Flows are correct when the sum of the losses, dp_f , is equal to zero.
6. If the sum of the losses is not zero for each loop, divide each pipe's friction loss by the presumed flow for the pipe, p_f/Q .
7. Calculate a correction flow for each loop as

$$dQ = \frac{-dp_f}{[1.85\sum(p_f/Q)]}$$

8. Add the correction flow values to each pipe in the loop as required, thereby increasing or decreasing the earlier assumed flows. For cases where a single pipe is in two loops, the algebraic difference between the two values of dQ must be applied as the correction to the assumed flow.
9. With a new set of assumed flows, repeat steps 4 through 7 until the values of dQ are sufficiently small.
10. As a final check, calculate the pressure loss by any route from the initial to the final junction. A second calculation along another route should give the same value within the range of accuracy expected.

NFPA 13 requires that pressures be shown to balance within 0.5 psi (0.03 bar) at hydraulic junction points. In other words, the designer (or computer program) must continue to make successive guesses as to how much flow takes place in each piece of pipe until the pressure loss from the design area back to the source of supply is approximately the same (within 0.5 psi [0.03 bar]) regardless of the path chosen.

EXAMPLE 10:

For the small two-loop grid shown in Figure 4-3.4, the total flow in and out is 100 gpm (378.5 lpm). It is necessary to determine the flow taking place through each pipe section. The system has already been simplified by finding the equivalent pipe for all pipes in series and in parallel. The following values of FLC have been calculated:

- Pipe 1 FLC = 0.001
- Pipe 2 FLC = 0.002
- Pipe 3 FLC = 0.003
- Pipe 4 FLC = 0.001
- Pipe 5 FLC = 0.004

Figure 4-3.4. Simplified system, pipe in series.

Under step 3 of the Hardy Cross procedure, flows that would satisfy conservation of mass are assumed. (See Figure 4-3.5.) Steps 4 through 9 are then carried out in a tabular approach. (See Table 4-3.3.)

Making these adjustments to again balance flows, a second set of iterations can be made. (See Table 4-3.4.) For pipe segment 3, the new flow is the algebraic sum of the original flow plus the flow corrections from both loops. (See Figures 4-3.6 and 4-3.7.)

In starting the third iteration, it can be seen that the pressure losses around both loops are balanced within 0.5 psi. (See Table 4-3.5.) Therefore, the flow split assumed after two iterations can be accepted. As a final check, step 10 of the above procedure calls for a calculation of the total pressure loss through two different routes, requiring that they balance within 0.5 psi (0.03 bar):

Figure 4-3.5. Original flow assumptions.

Route through pipes 1 and 5:

$$\begin{aligned} & FLC_1, (Q_1)^{1.85} + FLC_2(Q_2)^{1.85} \\ & = 0.001(54.0)^{1.85} + 0.004(35.9)^{1.85} \\ & = 1.6 + 3.0 = 4.6 \text{ psi (0.32 bar)} \end{aligned}$$

Route through Pipes 2 and 4:

$$\begin{aligned} & 0.002(46.0)^{1.85} + 0.001(64.1)^{1.85} = 2.4 + 2.2 \\ & = 4.6 \text{ psi (0.32 bar)} \end{aligned}$$

This is acceptable. Note that it required only two iterations to achieve a successful solution despite the fact that the initial flow assumption called for reverse flow in pipe 3. The initial assumption was for a clockwise flow of 5 gpm (18.9 lpm) in pipe 3, but the final solution shows a counterclockwise flow of 18.1 gpm (68.5 lpm).

Table 4-3.3 First Iteration

Water Supply Calculations

Determination of Available Supply Curve

Testing a public or private water supply permits an evaluation of the strength of the supply in terms of both quantity of flow and available pressures. The strength of a water supply is the key to whether it will adequately serve a sprinkler system.

Each test of a water supply must provide at least two pieces of information—a static pressure and a residual pressure at a known flow. The static pressure is the “no flow” condition, although it must be recognized that rarely is any public water supply in a true no flow condition. But this condition does represent a situation where the fire protection system is not creating an additional flow demand beyond that which is ordinarily placed on the system. The residual pressure reading is taken with an additional flow being taken from the system, preferably a flow that approximates the likely maximum system demand.

Between the two (or more) points, a representation of the water supply (termed a water supply curve) can be made. For the most part, this water supply curve is a fingerprint of the system supply and piping arrangements, since the static pressure tends to represent the effect of elevated tanks and operating pumps in the system, and the drop to the residual pressure represents the friction and minor losses through the piping network that result from the increased flow during the test.

The static pressure is read directly from a gauge attached to a hydrant. The residual pressure is read from the same gauge while a flow is taken from another hy-

drant, preferably downstream. A pitot tube is usually used in combination with observed characteristics of the nozzle through which flow is taken in order to determine the amount of flow. Chapter 7 of NFPA 13 provides more thorough information on this type of testing.

Figure A-8-3.2(d) of NFPA 13 (1999 edition) is an example of a plot of water supply information. The static pressure is plotted along the y-axis, reflecting a given pressure under zero flow conditions. The residual pressure at the known flow is also plotted, and a straight line is drawn between these two points. Note that the x-axis is not linear, but rather shows flow as a function of the 1.85 power. This corresponds to the exponent for flow in the Hazen-Williams equation. Using this semi-exponential graph paper demonstrates that the residual pressure effect is the result of friction loss through the system, and permits the water supply curve to be plotted as a straight line. Since the drop in residual pressure is proportional to flow to the 1.85 power, the available pressure at any flow can be read directly from the water supply curve.

For adequate design, the system demand point, including hose stream allowance, should lie below the water supply curve.

EXAMPLE 11:

If a water supply is determined by test to have a static pressure of 100 psi (6.9 bar) and a residual pressure of 80 psi (5.5 bar) at a flow of 1000 gpm (3785 lpm), the pressure available at a flow of 450 gpm (1703 lpm) can be approximated by plotting the two known data points on the hydraulic graph paper as shown in Figure 4-3.8. At a flow of 450 gpm (1703 lpm), a pressure of 90 psi (6.2 bar) is indicated.

Figure 4-3.8. Pressure available from 450 gpm flow water supply.

Pump Selection and Testing

Specific requirements for pumps used in sprinkler systems are contained in NFPA 20, which is cross-referenced by NFPA 13.

Fire pumps provide a means of making up for pressure deficiencies where an adequate volume of water is available at a suitable net positive suction pressure. Plumbing codes sometimes set a minimum allowable net positive suction pressure of 10 to 20 psi (0.69 to 1.38 bar). If insufficient water is available at such pressures, then it becomes necessary to use a stored water supply.

Listed fire pumps are available with either diesel or electric drivers, and with capacities ranging from 25 to 5000 gpm (95 to 18,927 lpm), although fire pumps are most commonly found with capacities ranging from 250 to 2500 gpm (946 to 9463 lpm) in increments of 250 up to 1500 gpm (946 up to 5678 lpm) and 500 gpm (1893 lpm) beyond that point. Each pump is specified with a rated flow and rated pressure. Rated pressures vary extensively, since manufacturers can control this feature with small changes to impeller design.

Pump affinity laws govern the relationship between impeller diameter, D , pump speed, N , flow, Q , pressure head, H , and brake horsepower, bhp. The first set of affinity laws assumes a constant impeller diameter.

$$\frac{Q_1}{Q_2} = \frac{N_1}{N_2} \quad \frac{H_1}{H_2} = \frac{N_1}{N_2} \quad \frac{\text{bhp}_1}{\text{bhp}_2} = \frac{N_1}{N_2}$$

These affinity laws are commonly used when correcting the output of a pump to its rated speed.

The second set of the affinity laws assumes constant speed with change in impeller diameter, D .

$$\frac{Q_1}{Q_2} = \frac{D_1}{D_2} \quad \frac{H_1}{H_2} = \frac{D_1}{D_2} \quad \frac{\text{bhp}_1}{\text{bhp}_2} = \frac{D_1}{D_2}$$

Pumps are selected to fit the system demands on the basis of three key points relative to their rated flow and rated pressure. (See Figure 4-3.9.) NFPA 20 specifies that each horizontal fire pump must meet these characteristics, and the approval laboratories ensure these points are met:

Figure 4-3.9. Pump performance curve.

1. A minimum of 100 percent of rated pressure at 100 percent of rated flow.
2. A minimum of 65 percent of rated pressure at 150 percent of rated flow.
3. A maximum of 140 percent of rated pressure at 0 percent of rated flow (churn).

Even before a specific fire pump has been tested, therefore, the pump specifier knows that a given pump can be expected to provide certain performance levels. It is usually possible to have more than one option when choosing pumps, since the designer is not limited to using a specific point on the pump performance curve.

There are limits to flexibility in pump selection, however. For example, it is not permitted to install a pump in a situation where it would be expected to operate with a flow exceeding 150 percent of rated capacity, since the performance is not a known factor, and indeed available pressure is usually quick to drop off beyond this point.

NFPA 20 gives the following guidance on what part of the pump curve to use:¹

A centrifugal fire pump should be selected in the range of operation from 90 percent to 150 percent of its rated capacity. The performance of the pump when applied at capacities over 140 percent of rated capacity may be adversely affected by the suction conditions. Application of the pump at capacities less than 90 percent of the rated capacity is not recommended.

The selection and application of the fire pump should not be confused with pump operating conditions. With proper suction conditions, the pump can operate at any point on its characteristic curve from shutoff to 150 percent of its rated capacity.

For design capacities below the rated capacity, the rated pressure should be used. For design capacities between 100 and 150 percent of rated capacity, the pressure

used should be found by the relationship made apparent by similar triangles.

$$\frac{0.35P}{0.5Q} = \frac{P' - 0.65P}{1.5Q - Q'}$$

where P and Q are the rated pressure and capacity, and P' is the minimum available pressure at capacity, Q' , where $Q < Q' < 1.5Q$.

EXAMPLE 12:

A pump is to be selected to meet a demand of 600 gpm (2271 lpm) at 85 psi (5.86 bar). To determine whether a pump rated for 500 gpm (1893 lpm) at 100 psi (6.90 bar) would be able to meet this point without having an actual pump performance curve to work from, the above formula can be applied, with $P = 100$, $Q = 500$, and $Q' = 600$.

Inserting these values gives

$$\begin{aligned} \frac{(0.35)(100)}{(0.5)(500)} &= \frac{[P' - (0.65)(100)]}{[(1.5)(500) - 600]} \\ \frac{35}{250} &= \frac{(P' - 65)}{(750 - 600)} \\ P' &= 65 + 21 = 86 \text{ psi (5.93 bar)} \end{aligned}$$

Since the value of P' so calculated is greater than the 85 psi (5.86 bar) required, the pump will be able to meet the demand point.

Tank Sizing

Tank selection and sizing are relatively easy compared to pump selection. The most basic question is whether to use an elevated storage (gravity) tank, a pressure tank, or a suction tank in combination with a pump. Following that is a choice of materials. NFPA 22 is the governing standard for water tanks for fire protection, and includes a description of the types of tanks as well as detailed design and connection requirements.

From a calculation standpoint, tanks must be sized to provide the minimum durations specified by NFPA 13 or other applicable standards for the system design. Required pressures must still be available when the tanks are at the worst possible water level condition (i.e., nearly empty).

If the tank is intended to provide the needed supply without the use of a pump, the energy for the system must be available from the height of a gravity tank or the air pressure of a pressure tank.

An important factor in gravity tank calculations is the requirement that the pressure available from elevation [calculated using 0.433 psi per foot (0.099 bar/m)] must be determined using the lowest expected level of water in the tank. This is normally the point at which the tank would be considered empty.

In sizing pressure tanks, the percentage of air in the tanks must be controlled so as to ensure that the last water leaving the tank will be at an adequate pressure. While a common rule of thumb has been that the tank should be one-third air at a minimum pressure of 75 psi (5.17 bar), this rule does not hold true for systems with high pres-

sure demands or where the tank is located a considerable distance below the level of the highest sprinkler.

For pipe schedule systems, two formulas have traditionally been used, based on whether the tank is located above the level of the highest sprinkler or some distance below.

For the tank above the highest sprinkler

$$P = \frac{30}{A} - 15$$

For the tank below the highest sprinkler

$$P = \left(\frac{30}{A} - 15 \right) + \left(\frac{0.434H}{A} \right)$$

where

A = proportion of air in the tank

P = air pressure carried in the tank in psi

H = height of the highest sprinkler above the tank bottom in feet

It can be seen that these formulas are based simply on the need to provide a minimum pressure of 15 psi (1.03 bar) to the system at the level of the highest sprinkler, and an assumption of 15 psi (1.03 bar) atmospheric pressure.

Using the same approximation for atmospheric pressure, a more generalized formula has come into use for hydraulically designed systems:

$$P_i = \frac{P_f + 15}{A} - 15$$

where

P_i = tank air pressure to be used

P_f = system pressure required per hydraulic calculations

A = proportion of air in the tank

EXAMPLE 13:

A pressure tank is to be used to provide a 30-min-water supply to a system with a hydraulically calculated demand of 140 gpm (530 lpm) at a pressure of 118 psi (8.14 bar). Since there are sprinklers located adjacent to the tank, it is important that air pressure in the tank not exceed 175 psi (12.0 bar). To determine the minimum size tank that can be used, it is important not only to consider the total amount of water needed, but also the amount of air necessary to keep the pressures within the stated limits.

The above equation for hydraulically designed systems can be used to solve for A .

$$\text{If } P_i = \left[\frac{(P_f + 15)}{A} \right] - 15$$

$$\text{then } A = \frac{(P_f + 15)}{(P_i + 15)}$$

$$A = \frac{(118 + 15)}{(175 + 15)} = \frac{133}{190} = 0.70$$

This means that the tank will need to be 70 percent air if the air pressure in the tank is to be kept to 175 psi (12.0 bar).

The minimum water supply required is $30 \text{ min} \times 140 \text{ gpm} = 4200 \text{ gallons (15,898 l)}$.

Thus, the minimum tank volume will be such that 4200 gallons (15,898 l) can be held in the remaining 30 percent of volume.

$$0.3V = 4200 \text{ gal} \quad V = \frac{4200}{0.3} = 14,000 \text{ gal tank (53,000 l)}$$

Hanging and Bracing Methods

Hangers and Hanger Supports

NFPA 13 contains a great deal of specific guidance relative to hanger spacing and sizing based on pipe sizes. It should also be recognized that the standard allows a performance-based approach. Different criteria exist for the hanger itself and the support from the building structure.

Any hanger and installation method is acceptable if certified by a registered professional engineer for the following:

1. Hangers are capable of supporting five times the weight of the water-filled pipe plus 250 pounds (114 kg) at each point of piping support.
2. Points of support are sufficient to support the sprinkler system.
3. Ferrous materials are used for hanger components.

The building structure itself must be capable of supporting the weight of the water-filled pipe plus 250 pounds (114 kg) applied at the point of hanging.

The 250 pound (114 kg) weight is intended to represent the extra loading that would occur if a relatively heavy individual were to hang on the piping.

Trapeze Hangers

Trapeze hangers are used where structural members are not located, so as to provide direct support of sprinkler lines or mains. This can occur when sprinkler lines or mains run parallel to structural members such as joists or trusses.

A special section of NFPA 13 addresses the sizing of trapeze hangers. Because they are considered part of the support structure, the criteria within NFPA 13 are based on the ability of the hangers to support the weight of 15 ft (5 m) of water-filled pipe plus 250 pounds (114 kg) applied at the point of hanging. An allowable stress of 15,000 psi (111 bar) is used for steel members. Two tables are provided in the standard, one of which presents required section moduli based on the span of the trapeze and the size and type of pipe to be supported, and the other of which presents the available section moduli of standard pipes and angles typically used as trapeze hangers.

In using the tables, the standard allows the effective span of the trapeze hanger to be reduced if the load is not at the midpoint of the span. The equivalent length of trapeze is determined from the formula

$$L = \frac{4ab}{(a+b)}$$

where L is the equivalent length, a is the distance from one support to the load, and b is the distance from the other support to the load.

EXAMPLE 14:

A trapeze hanger is required for a main running parallel to two beams spaced 10 ft (3.048 m) apart. If the main is located 1 ft 6 in. (0.457 m) from one of the beams, the equivalent span of trapeze hanger required can be determined by using the formula

$$L = \frac{4(1.5 \text{ ft})(8.5 \text{ ft})}{(1.5 \text{ ft} + 8.5 \text{ ft})} = 5.1 \text{ ft (1.554 m)}$$

Earthquake Braces

Protection for sprinkler systems in earthquake areas is provided in several ways. Flexibility and clearances are added to the system where necessary to avoid the development of stresses that could rupture the piping. Too much flexibility could also be dangerous, however, since the momentum of the unrestrained piping during shaking could result in breakage of the piping under its own weight or upon collision with other building components. Therefore, bracing is required for large piping (including all mains) and for the ends of branch lines.

Calculating loads for earthquake braces is based on the assumption that the normal hangers provided to the system are capable of handling vertical forces, and that horizontal forces can be conservatively approximated by a constant acceleration equal to one-half that of gravity.

$$a_h = 0.5g$$

NFPA 13 contains a table of factors that can be applied if building codes require the use of other horizontal acceleration values.

Since the braces can be called upon to act in both tension and compression, it is necessary not only to size the brace member to handle the expected force applied by the weight of the pipe in its zone of influence, but also to avoid a member that could fail as a long column under buckling.

The ability of the brace to resist buckling is determined through an application of Euler's formula with a maximum slenderness ratio of 300. This corresponds to the maximum slenderness ratio generally used under steel construction codes for secondary framing members. This is expressed as

$$\frac{\ell}{r} \leq 300$$

where ℓ = length of the brace and r = least radius of gyration for the brace.

The least radius of gyration for some common shapes is as follows:

pipe	$r = \frac{(r_o^2 + r_i^2)^{1/2}}{2}$
rod	$r = \frac{r}{2}$
flat	$r = 0.29h$

Special care must be taken in the design of earthquake braces so that the load applied to any brace does not exceed the capability of the fasteners of that brace to the piping system or the building structure, and that the braces are attached only to structural members capable of supporting the expected loads.

Performance Calculations

Sprinkler Response as a Detector

Automatic sprinklers serve a dual function as both heat detectors and water distribution nozzles. As such, the response of sprinklers can be estimated using the same methods as for response of heat detectors. (See Section 4, Chapter 1.) Care should be taken, however, since the use of such calculations for estimating sprinkler actuation times has not been fully established. Factors, such as sprinkler orientation, air flow deflection, radiation effects, heat of fusion of solder links, and convection within glass bulbs, are all considered to introduce minor errors into the calculation process. Heat conduction to the sprinkler frame and distance of the sensing mechanism below the ceiling have been demonstrated to be significant factors affecting response, but are ignored in some computer models.

Nevertheless, modeling of sprinkler response can be useful, particularly when used on a comparative basis. Beginning with the 1991 edition, an exception within Section 4-1.1 of NFPA 13 permitted variations from the rules on clearance between sprinklers and ceilings "... provided the use of tests or calculations demonstrate comparable sensitivity and performance."

EXAMPLE 15:

Nonmetallic piping extending 15 in. (0.38 m) below the concrete ceiling of a 10-ft- (3.048 m-) high basement 100 ft by 100 ft (30.48 × 30.48 m) in size makes it difficult to place standard upright sprinklers within the 12 in. (0.30 m) required by NFPA 13 for unobstructed construction. Using the LAVENT⁹ computer model, and assuming RTI values of 400 ft^{1/2}·s^{1/2} (221 m^{1/2}·s^{1/2}) for standard sprinklers and 100 ft^{1/2}·s^{1/2} (55 m^{1/2}·s^{1/2}) for quick-response sprinklers, it can be demonstrated that the comparable level of sensitivity can be maintained at a distance of 18 in. (0.457 m) below the ceiling. Temperature rating is assumed to be 165°F, and maximum lateral distance to a sprinkler is 8.2 ft (2.50 m) (10 ft × 13 ft [3.048 m × 3.962 m] spacing). Assuming the default fire (empty wood pallets stored 5 ft [1.52 m] high), for example, the time of actuation for the standard sprinkler is calculated to be 200 s, as compared to 172 s for the quick-response sprinkler. Since the noncombustible construction minimizes concern relative to the fire control performance for the structure, the sprinklers can be located below the piping obstructions.

Dry System Water Delivery Time

Total water delivery time consists of two parts. The first part is the trip time taken for the system air pressure to bleed down to the point where the system dry valve

opens to admit water to the piping. The second part is the transit time for the water to flow through the piping from the dry valve to the open sprinkler. In other words

$$\text{water delivery time} = \text{trip time} + \text{transit time}$$

where water delivery time commences with the opening of the first sprinkler.

NFPA 13 does not contain a maximum water delivery time requirement if system volume is held to no more than 750 gal (2839 l). Larger systems are permitted only if water delivery time is within 60 s. As such, the rule of thumb for dry system operation is that no more than a 60 s water delivery time should be tolerated, and that systems should be divided into smaller systems if necessary to achieve this 1-min response. Dry system response is simulated in field testing by the opening of an inspector's test connection. The test connection is required to be at the most remote point of the system from the dry valve, and is required to have an orifice opening of a size simulating a single sprinkler.

The water delivery time of the system is recorded as part of the dry pipe valve trip test that is conducted using the inspector's test connection. However, it is not a realistic indication of actual water delivery time for two reasons:

1. The first sprinkler to open on the system is likely to be closer to the system dry valve, reducing water transit time.
2. If additional sprinklers open, the trip time will be reduced since additional orifices are able to expel air. Water transit time may also be reduced since it is easier to expel the air ahead of the incoming water.

Factory Mutual Research Corporation (FMRC) researchers have shown³ that it is possible to calculate system trip time using the relation

$$t = 0.0352 \frac{V_T}{A_n T_0^{1/2}} \ln \left(\frac{p_{a0}}{p_a} \right)$$

where

t = time in seconds

V_T = dry volume of sprinkler system in cubic feet

T_0 = air temperature in Rankine degrees

A_n = flow area of open sprinklers in square feet

p_{a0} = initial air pressure (absolute)

p_a = trip pressure (absolute)

Calculating water transit time is more difficult, but may be accomplished using a mathematical model developed by FMRC researchers. The model requires the system to be divided into sections, and may therefore produce slightly different results, depending on user input.

Droplet Size and Motion

For geometrically similar sprinklers, the median droplet diameter in the sprinkler spray has been found to be inversely proportional to the $1/3$ power of water pressure and

directly proportional to the $^{2/3}$ power of sprinkler orifice diameter such that

$$d_m \propto \frac{D^{2/3}}{P^{1/3}} \propto \frac{D^2}{Q^{2/3}}$$

where

- d_m = mean droplet diameter
- D = orifice diameter
- P = pressure
- Q = rate of water flow

Total droplet surface area has been found to be proportional to the total water discharge rate divided by the median droplet diameter

$$A_S \propto \frac{Q}{d_m}$$

where A_S is the total droplet surface area.

Combining these relationships, it can be seen that

$$A_S \propto (Q^3 p D^{-2})^{1/3}$$

When a droplet with an initial velocity vector of \mathbf{U} is driven into a rising fire plume, the one-dimensional representation of its motion has been represented as⁴

$$\frac{m_1 d\mathbf{U}}{dt} = m_1 g - \frac{C_D \rho_g (\mathbf{U} + V)^2}{2S}$$

where

- \mathbf{U} = velocity of the water droplet
- V = velocity of the fire plume
- m = mass of the droplet
- ρ_g = density of the gas
- g = acceleration of gravity
- C_D = coefficient of drag
- S_f = frontal surface area of the droplet

The first term on the right side of the equation represents the force of gravity, while the second term represents the force of drag caused by gas resistance. The drag coefficient for particle motion has been found empirically to be a function of the Reynolds number (Re) as⁵

$$C_D = 18.5 \text{ Re}^{-0.6} \quad \text{for Re} < 600$$

$$C_D = 0.44 \quad \text{for Re} > 600$$

Spray Density and Cooling

The heat absorption rate of a sprinkler spray is expected to depend on the total surface area of the water droplets, A_S , and the temperature of the ceiling gas layer in excess of the droplet temperature, T . With water temperature close to ambient temperature, T can be considered excess gas temperature above ambient.

Chow⁶ has developed a model for estimating the evaporation heat loss due to a sprinkler water spray in a smoke layer. Sample calculations indicate that evaporation heat loss is only significant for droplet diameters less

than 0.5 mm. For the droplet velocities and smoke layer depths analyzed, it was found that the heat loss to evaporation would be small (10 to 25 percent), compared to the heat loss from convective cooling of the droplets.

Factory Mutual Research Corporation researchers⁷ have developed empirical correlations for the heat absorption rate of sprinkler spray in room fires, as well as convective heat loss through the room opening, such that

$$\dot{Q} = \dot{Q}_{\text{cool}} + \dot{Q}_c + \dot{Q}_l$$

where

- \dot{Q} = total heat release rate of the fire
- \dot{Q}_{cool} = heat absorption rate of the sprinkler spray
- \dot{Q}_c = convective heat loss rate through the room opening
- \dot{Q}_l = sum of the heat loss rate to the walls and ceiling, \dot{Q}_s , the heat loss rate to the floor, \dot{Q}_f , and the radiative heat loss rate through the opening, \dot{Q}_r

Test data indicated that

$$\dot{Q}_{\text{cool}}/\dot{Q} = 0.000039\Lambda^3 - 0.003\Lambda^2 + 0.082\Lambda$$

for $0 < \Lambda \leq 33 \text{ l}/(\text{min} \times \text{kW}^{1/2} \times \text{m}^{5/4})$

where Λ is a correlation factor incorporating heat losses to the room boundaries and through openings as well as to account for water droplet surface area.

$$\Lambda = (AH^{1/2}\dot{Q}_l)^{-1/2}(W^3PD^{-2})^{1/3}$$

for $P = \frac{p}{(17.2 \text{ kPa})}$ and $D = \frac{d}{0.0111 \text{ m}}$

where

- A = area of the room opening in meters
- H = height of the room opening in meters
- P = water pressure at the sprinkler in bar
- d = sprinkler nozzle diameter in meters
- W = water discharge in liters per minute

The above correlations apply to room geometry with length-to-width ratio of 1.2 to 2 and opening size of 1.70 to 2.97 m².

Suppression by Sprinkler Sprays

Researchers at the National Institute of Standards and Technology (NIST) have developed a "zeroth order" model of the effectiveness of sprinklers in reducing the heat release rate of furnishing fires.⁸ Based on measurements of wood crib fire suppression with pendant spray sprinklers, the model is claimed to be conservative. The model assumes that all fuels have the same degree of resistance to suppression as a wood crib, despite the fact that tests have shown furnishings with large burning surface areas can be extinguished easily compared to the deep-seated fires encountered with wood cribs.

The recommended equation, which relates to fire suppression for a 610-mm-high crib, has also been checked for validity with 305-mm crib results. The equation is

$$\dot{Q}(t - t_{\text{act}}) = \dot{Q}(t_{\text{act}}) \exp \left[\frac{-(t - t_{\text{act}})}{3.0(\dot{w}'')^{-1.85}} \right]$$

where

\dot{Q} = the heat release rate (kW)

t = any time following t_{act} of the sprinklers (s)

\dot{w}'' = the spray density (mm/s)

The NIST researchers claim the equation is appropriate for use where the fuel is not shielded from the water spray, and the application density is at least 0.07 mm/s [4.2 mm/min. (0.1 gpm/ft²)]. The method does not account for variations in spray densities or suppression capabilities of individual sprinklers.

The model must be used with caution, since it was developed on the basis of fully involved cribs. It does not consider the possibility that the fire could continue to grow in intensity following initial sprinkler discharge, and, for that reason, should be restricted to use in light hazard applications.

Sprinklers are assumed to operate within a room of a light hazard occupancy when the total heat release rate of the fire is 500 kW. The significance of an initial application rate of 0.3 gpm/ft² (0.205 mm/s) as compared to the minimum design density of 0.1 gpm/ft² (0.07 mm/s) can be evaluated by the expected fire size after 30 s. With the minimum density of 0.07 mm/s (0.1 gpm/ft²), the fire size is conservatively estimated as 465 kW after 30 s. With the higher density of 0.205 mm/s (0.3 gpm/ft²), the fire size is expected to be reduced to 293 kW after 30 s. Corresponding values after 60 s are 432 kW and 172 kW, respectively.

Nomenclature

C	coefficient of friction
FLC	friction loss coefficient
Q	flow (gpm)
\dot{w}''	spray density (mm/s)

CHAPTER 4

Foam Agents and AFFF System Design Considerations

Joseph L. Scheffey

Introduction

Foams have been developed almost entirely from experimental work. While the technologies are rather mature, no fundamental explanations of foam extinguishment performance have been developed based on first principles. As a result, foams are characterized by (1) fire tests for which there is no general international agreement and (2) physical and chemical properties which may or may not correlate with empirical results. This chapter reviews the important parameters associated with foam agents, test methods used to evaluate foams, and relevant data in the literature that can be used to evaluate designs for special hazards. Because of their superior performance in extinguishing hydrocarbon fuel fires, the emphasis is on film-forming foams and thin pool fires (e.g., from spills). Situations involving fuels “in depth” are not evaluated in detail here.

Fire-fighting foam consists of air-filled bubbles formed from aqueous solutions. The solutions are created by mixing a foam concentrate with water in the appropriate proportions (typically 1, 3, or 6 percent concentrate to water). The solution is then aerated to form the bubble structure. Some foams, notably those that are protein-based, form thick, viscous foam blankets on hydrocarbon fuel surfaces. Other foams, such as film-formers, are much less viscous and spread rapidly on the fuel surface. The film-formers are capable of producing a vapor-sealing film of surface-active water solution on most of the hydrocarbon fuels of interest.

Since the foam is lighter than the aqueous solution that drains from the bubble structure, and lighter than flammable or combustible liquids, it floats on the fuel surface. The floating foam produces an air-excluding

layer of aqueous agent, which suppresses and prevents combustion by halting fuel vaporization at the fuel surface. If the entire surface is covered with foam, the fuel vapor will be completely suppressed, and the fire will be extinguished. Low-expansion foams (i.e., foam volume: solution volume of $\leq 10:1$) are quite effective on two-dimensional (pool) flammable and combustible liquid fires, but not particularly effective on three-dimensional fuel fires. This is particularly true of three-dimensional fires involving a low flashpoint fuel. Typically, an auxiliary agent, such as dry chemical, is used with foam where a three-dimensional fire (running fuel or pressurized spray) is anticipated.

Description of Foam Agents

There are no universally agreed-on definitions of foam agents or terms associated with fire-fighting foam. For example, where foam is referenced in NFPA standards, definitions vary from document to document. Because foams vary in performance, in terms of application rates and quantities required for extinguishment, agent definitions can be cast to accentuate positive attributes, such as “rapid knockdown” or “superior burnback resistance.” Geyer et al. have described the composition of various foam agents, paraphrased as follows.¹

1. *Protein foam.* Protein foam is a “mechanical” foam produced by combining (proportioning) foam concentrate and water and discharging the resulting solution through a mixing chamber. The mixing chamber introduces (aspirates) air, which expands the solution to create foam bubbles. The liquid concentrate consists primarily of hydrolyzed proteins in combination with iron salts. Hoof and horn meal and hydrolyzed feather meal are examples of proteinaceous materials used in protein-foam concentrates. No aqueous film is formed on the fuel surface with this type of agent.

Joseph L. Scheffey, P.E., is director of Fire Protection RDT&E for Hughes Associates, Inc., Baltimore, Maryland.

2. *Fluoroprotein*. These agents are basically protein foams with fluorocarbon surface-active agents added. The varying degrees of performance are achieved by using different proportions of the base protein hydrolyzates and the fluorinated surfactants. While fluoroprotein foams generally have good fuel shedding capabilities and dry chemical compatibility, the solution that drains out from the expanded foam does not form a film on hydrocarbon fuels. However, the addition of the fluorinated surfactants may act to reduce the surface tension of the solution. This reduction may, in turn, decrease the viscosity of the expanded solution, thus promoting more rapid fire control when compared to protein foams.
3. *Aqueous film-forming foam (AFFF)*. These agents are synthetically formed by combining fluorine-free hydrocarbon foaming compounds with highly fluorinated surfactants. When mixed with water, the resulting solution achieves the optimum surface and interfacial tension characteristics needed to produce a film that will spread across a hydrocarbon fuel. The foam produced from this agent will extinguish in the same vapor-excluding fashion as other foams. Further, the solution that results from normal drainage or foam breakdown produces an aqueous "film" that spreads rapidly and is highly stable on the liquid hydrocarbon fuel surface. It is this film formation characteristic that is the significant distinguishing feature of AFFF.

These definitions are by no means all-inclusive. For example, film-forming fluoroprotein (FFFP) foam is an agent that is produced by increasing the quantity and quality of the surfactants added to a protein hydrolyzate. By doing this, the surface tension of the resulting solution, which drains from the expanded foam, is reduced to the point where it may spread across the surface of a liquid hydrocarbon fuel. An alcohol-resistant concentrate is formulated to produce a floating polymeric skin for foam buildup on water-miscible fuels. This polymeric skin protects the foam from breakdown by polar solvents, for example, acetone, methanol, and ethanol.

The descriptions show that there are distinct chemical differences between protein-based foams and AFFF. In general, the surfactants used in aqueous foams are long-chained compounds that have a hydrophobic or hydrophilic (i.e., water repelling or water attracting, respectively) group at one end.² The molecular structure of a typical AFFF fluorinated surfactant is shown in Figure 4-4.1.³ In this molecule, the perfluorooctyl group on

Perfluorooctylsulfonamide - N - Propyltrimethylammonium iodide

Figure 4-4.1. Typical AFFF fluorosurfactant molecule.³

the left is the hydrophobic group, while the propyltrimethylammonium group is the hydrophilic group. When these compounds are dissolved into solution with water, they will tend to group near the surface of the solution, aligned so that their hydrophobic ends are facing toward the air/solution interface. The advantage of this is that the perfluorooctyl group found in these compounds is also oleophobic (i.e., oil repelling) as well as hydrophobic.⁴

AFFF concentrates also contain hydrocarbon surfactants. These compounds are less hydrophobic than those containing the perfluorooctyl group. However, they do provide greater stability once the solution is expanded into a foam. As a result, the surface tension of the solution is reduced below that of water; the expanded foam produced from the solution is resistive to breakdown from heat, fuels, or dry chemical extinguishing agents; and the solution that drains out from the expanded foam is able to form a film on hydrocarbon fuels.

The importance of both the film formation and foam bubble characteristics of AFFF, resulting from the combination of fluorocarbon and hydrocarbon surfactants, was evaluated in early work by Tuve et al.⁵ When a highly expanded, stiff formulation of AFFF was used, these researchers found it difficult to obtain good fire extinguishment and vapor sealing characteristics. The foam resisted flow, and drainage of the aqueous solution (film) was slow. The drainage was corrected by expanding the foam to a lesser degree. This pioneering AFFF formulation, with an expansion ratio of 8:1 and 25 percent drainage time of 6 min, appeared to offer the best compromise in characteristics. It provided a readily flowable foam that sealed up against obstructions, promoted the rapid formation of a surface-active film barrier on the fuel, and provided a sufficiently stable foam to resist burnback.

Fire Extinguishment and Spreading Theory

As noted by Friedman in his review of suppression theory, the mechanisms of foam fire extinguishment on two-dimensional pool fires have not been developed.⁶ Usually, the fire extinguishment is described simply as a factor of the cessation of fuel vaporization at the fuel surface. As the fuel vapor decreases, the size of the combustion zone decreases. When the area is totally covered, extinguishment occurs. Cooling must occur to bring the vapor pressure of the fuel below that of its boiling point. Once the fuel is cooled, a layer of foam must then be applied either manually, or by spreading, to prevent combustion. Hanauska et al. have proposed fundamental extinguishment parameters, summarized in the following text.⁷ A similar foam extinguishment model has been proposed by Persson and Dahlberg.⁸

Foam Loss Mechanisms

Fire extinguishment by foams can be summarized as shown in Figure 4-4.2. Foam having a temperature, T_f ,

Figure 4-4.2. Illustration of the significant parameters affecting a foam's hydrocarbon fuel fire extinguishment capability.

and depth, h , spreads at a rate of V_s along a fuel of temperature, T_s , and vapor pressure, P_v . Fuel is volatilized by the fire at a rate of \dot{m}_{fuel} , which is a function of the radiative feedback, \dot{q}_{rad} . The foam is added by the discharge application, \dot{m}_{add} , and lost through evaporation, \dot{m}_{vap} , and drop-through, \dot{m}_{drop} .

The total mass loss of the foam is a function of the loss due to drop-through and the mass loss due to vaporization. The mass loss due to drop-through is at least partially dependent on the drainage of liquid from the foam. Evaporation of the liquid results primarily from radiant energy from the fire. Assuming that most of the radiation results in direct evaporation of the foam, the evaporation of foam can be characterized by

$$\dot{m}_{\text{vap}}'' = \frac{\dot{q}_{\text{rad}}''}{\Delta H_v} \quad (1)$$

where ΔH_v is the combined latent and sensible heats of vaporization. Using a rough estimate of \dot{q}_{rad}'' from large pool fires of 45–185 kW/m² yields an evaporation rate of 18 and 72 g·m²/s, assuming a heat of vaporization of 2563 kJ/kg. (See Section 2, Chapter 2.) To account for reflective and absorbed losses, Persson⁹ has proposed a calculation method

$$\dot{m}_{\text{vap}}'' = \dot{q}_{\text{rad}}'' k_e \quad (2)$$

where k_e is an experimentally derived constant using different fluxes from a radiant exposure. For \dot{q}_{rad}'' values of 45 and 185 kW/m², Equation 2 yields values for \dot{m}_{vap}'' of 11 and 46 g·m²/s, respectively. Since the estimated \dot{m}_{vap}'' values based on Equation 1 at the same heat fluxes were 18 and 72 g·m²/s, the experimental mass loss rate results are about 62 percent lower than the theoretical loss. The difference between values is attributable to neglect-

ing the reflected and absorbed losses in Equation 1. This indicates that about 48 percent of the radiant flux to the foam surface is either reflected from or absorbed into the foam blanket. The division between these two heat-transfer mechanisms is not clear and is an area for further study.

Foam loss can likewise be described theoretically, based on the downward force of gravity and the opposing forces due to surface tension and buoyancy. Alternately, a model mass loss due to drainage can be expressed as a time-averaged constant

$$\dot{m}_{\text{drain}} = k_d \quad (3)$$

where k_d is an experimentally determined drainage coefficient. From the data of Persson, the drainage coefficient can be estimated to be 17 to 25 g·m²/s.⁹ The drainage rate was found to be relatively independent of the radiant heat flux to the foam, but highly dependent on the expansion ratio. Foams with lower expansion ratios will drain faster. For example, decreasing the expansion ratio by about half (11.3 to 5.3) increased the drainage rate by a factor of about 2 (55 to 105 g/min). Decreasing the expansion ratio changes fundamental parameters of the foam, which allows it to drain faster.

Experimental work on the foam model, particularly with regard to the effects of incident heat flux on the foam blanket, are continuing in the United States and Europe. Lattimer et al.¹⁰ designed a test apparatus that was used to measure the behavior of foam when exposed to irradiance levels of 0–50 kW/m². The apparatus provided data on evaporation rate, drainage rate, foam destruction rate, foam temperature, heat penetration, and time to fuel ignition. The performance of a single AFFF formulation was characterized.

Evaporation rates were measured primarily to be a function of irradiance, making it possible to predict evaporation using the irradiance from the fire and an effective heat of vaporization. The AFFF foam evaluated in this study was determined to have an effective heat of vaporization of 4.87 ± 0.75 MJ/kg. This result is slightly higher than that found by Ikasson and Persson,¹¹ 4.0 MJ/kg. Different AFFF formulations may explain this difference.

Foam drainage rate was measured to be insensitive to the irradiance level or the presence of a fuel layer below the foam. This was consistent with the findings of the Swedish researchers. For foams with expansion ratios ranging from 6.0–9.7, drain rate was determined to be a function of foam mass per unit area. A single curve was developed to characterize the drain rate for all foams with a thickness equal to or less than 75 mm. The drainage rate was measured to be constant down to a foam mass per unit area of 3.0 kg/m² and decreased linearly to zero by 1.5 kg/m². The steady-state drain-rate level decreased from 40 g·m²/s to 28 g·m²/s by increasing the expansion ratios from 6.0 to 9.7, respectively.

The drainage rate of low-expansion ratio foams (3.3) was as much as 4–10 times higher than levels measured at higher expansion ratios. The high level was attributed to the fluidity of the foam, which is affected by solution density in foam, breaking and coalescing of bubbles, and so-

lution viscosity. Measurements of foam fluidity for different AFFF foam expansion ratios and temperatures are necessary to further understand these trends in the data at low expansion ratios.

Foam depletion rate was measured primarily to be a function of the irradiance level incident on the foam. As irradiance increased, the foam depletion rate increased. Foam depletion rate was independent of the initial foam height and expansion ratio.

Heat penetration through the foam was measured to be a function of foam height and foam mass. For all of the different tests where heat penetration was measured, the data indicate that heat begins penetrating through the foam when the foam becomes approximately 50 ± 7 mm thick and has a foam mass of 4.2 ± 1.2 kg/m².

Ignition time in tests with JP-5 fuel layers was measured to be a function of both irradiance and initial foam height. Increases in irradiance and decreases in initial foam height were determined to decrease the time to ignition. This result was found to be independent of expansion ratio and initial fuel temperature. At ignition, nearly all of the AFFF (less than 0.8 kg/m²) had been lost from the fuel surface.

Additional small-scale testing needs to be performed to quantify the foam losses and foam spread characteristics of other foam concentrates. Foam loss and spread data are expected to be concentrate dependent, and these data are necessary to further validate the performance of the foam extinguishment model.

Foam drainage is a complicated phenomenon that is highly time dependent. Besides the forces associated with the bubble structure, drainage is dependent on the continual changing geometries of the cells and other variable conditions, such as collapsing cells. Even though all aspects of this problem cannot be fully detailed, simplified models have been created that predict the drainage rate for foams. Kraynik has developed one such model that considers the drainage from a column of persistent foam.¹² The model contains no empirical parameters and assumes the foam is dry with very thin walls such that the liquid contained in the cell walls is negligible. In relaxing the assumptions, this basic model might ultimately be used to assess the effect of various fundamental parameters on foam drainage.

Foam Spread over Liquid Fuels

In order to predict the extinguishment of a liquid pool fire by fire-fighting foam, it is necessary to describe the process of spreading the foam over the liquid fuel surface. This process of foam spread on a liquid fuel is similar to the spread of a less dense liquid (such as oil) on a more dense liquid (such as water). This phenomenological approach to the spread of foam on a liquid pool fire is appropriate to the extent that foam can be treated as a liquid. Kraynik characterizes foams macroscopically as being Bingham fluids with a finite shear stress and non-newtonian viscosity.¹³ That is, foam displays an infinite viscosity up to some initial shear rate above which it displays a shear-rate dependent viscosity.

Since fuels typically have low viscosities (especially compared to foam viscosities at relatively low shear rates), it may be appropriate to model foam spread across a fuel surface using models developed for oil spread on water. These models assume that the oil spreads as a fluid with a viscosity much higher than the water on which it is spreading. The process of oil spread on water has been described in detail by Fay,¹⁴ and Fay and Hoult.¹⁵ Their phenomenologically based model describes three regimes of spread characterized by combinations of spreading forces and retarding forces. The first regime is the gravity-inertia regime, where the outward spread of the oil is driven by a gravity force and retarded by the inertia required to accelerate the oil. The second regime is the gravity-viscous regime, where the gravity-induced spreading is retarded by viscous dissipation in the water. Since the oil is much more viscous than the water, they assume that there is slug flow in the oil and that the viscous drag force is dominated by the velocity gradient in the water. The third regime is characterized by a surface-tension spreading force opposed by the viscous retarding force. By setting the spreading and retarding forces equal in each of the regimes, they developed equations to estimate the length of the spread as a function of time.

By treating the spread of foam on fuel as similar to the spread of oil on water, the equations developed by Fay and Hoult might be used to describe the spread of a foam blanket over a fuel pool as a function of time.¹⁴ Since foam generally has a much higher viscosity than the fuel on which it is spreading, the assumption of slug flow made for the oil by Fay and Hoult should be reasonably valid for foam spread on fuel as well.¹⁴ The equations are

$$\begin{aligned} \text{gravity-inertia regime:} & \quad l = (\Delta g V t^2)^{1/4} \\ \text{gravity-viscous regime:} & \quad l = \left(\frac{\Delta g V^2 t^{3/2}}{\nu^{1/2}} \right)^{1/6} \\ \text{surface-tension-viscous} & \quad l = \left(\frac{\sigma^2 t^3}{\rho^2 \nu} \right)^{1/4} \\ \text{regime:} & \end{aligned} \quad (4)$$

where

l = length of spread (cm)

$\Delta = (\rho_{\text{fuel}} - \rho_{\text{foam}}) / \rho_{\text{fuel}}$

g = acceleration of gravity (981 cm/s²)

V = foam volume (cm³)

t = time (s)

ν = kinematic viscosity of fuel (cm²/s)

σ = spreading coefficient (dynes/cm)

ρ = density of fuel or foam (g/cm³)

Equation 4 represents an untested theoretical model of foam spread. The equation includes the parameters that are known or suspected to affect foam spread. They are presented here as an initial effort to understand foam flow based on first principles. They are not yet developed

for engineering use. The following discussion expands on this theory.

The transition from gravity-dominated spread to surface-tension-dominated spread can be shown to occur at a critical thickness of the foam layer, h_c , given by

$$h_c = \left(\frac{\sigma}{g\Delta\rho_{\text{foam}}} \right)^{1/2} \quad (5)$$

The transition from inertia to viscous-dominated retarding force occurs when the foam thickness, h , is equal to the viscous boundary layer thickness, δ , of the fuel, with

$$h = \frac{V}{l^2} \quad (6)$$

$$\delta = (vt)^{1/2}$$

The equations for length of spread can be used to generate preliminary estimates of the spread distance and area coverage for the placement of a volume of foam on a fuel surface. The equations are only estimates because they consider a force balance between just the dominant forces for each regime. All forces are actually present in each regime. Also, the densities of both fluids are considered to be very nearly equal for the development of the equation for the gravity-viscous regime. This is the case for oil spread on water, but may not be the case for foam on fuel.

Using approximations for fuel and foam characteristics, it can be shown that a positive spreading coefficient does not begin to affect the spread of foam until the foam layer has become very thin. For the placement of a volume of foam on a fuel, this may not occur until after significant time has passed, relative to the time scale for knockdown desired in many fire protection situations.

The equations for foam spread on fuel include many of the parameters known to be important to foam spread. However, the equations are independent of the foam viscosity. Observations indicate that low-viscosity nonrigid foams, such as AFFF, spread faster than high-viscosity rigid protein foams. The inclusion in the model of a term to account for this is desirable.

The equations for spread length so far have assumed that the foam spreads over the fuel as plug flow, with no relative movement within the foam itself. It is easy to conceive that the foam has the capability to flow over itself. The relative movement within the foam is equivalent to the foam flowing over a solid surface. The total foam flow might ultimately be modeled as the combination of the foam plug over the fuel and the flow within the foam layer itself.

According to Cann et al., several regimes exist for spread of a liquid on a solid that are similar to those described for spread of a liquid on a liquid.¹⁶ Most of this spread occurs in a gravity-viscous force regime, where the spread is given by

$$l = \frac{kt}{\mu} \quad (7)$$

where k is an empirically determined constant, and μ is the foam viscosity.

Thus, the spread of foam over fuel can be characterized by two scenarios: (1) high-viscosity liquid spreading over a low-viscosity liquid and (2) a liquid spreading over a "solid." The spread of foam can be described by modifying Equation 4, as follows:

$$\begin{aligned} \text{gravity-inertia regime:} \quad l &= (\Delta g V t^2)^{1/4} + \frac{kt}{\mu} \\ \text{gravity-viscous regime:} \quad l &= \left(\frac{\Delta g V^2 t^{3/2}}{v^{1/2}} \right)^{1/6} + \frac{kt}{\mu} \quad (8) \\ \text{surface-tension regime:} \quad l &= \left(\frac{\sigma^2 t^3}{\rho^2 v} \right)^{1/4} + \frac{kt}{\mu} \end{aligned}$$

Kraynik describes foams as being characterized by a yield stress and shear thinning viscosity.¹³ Thus, the foam viscosity in the equations above is not a constant but is a function of the shear rate. The stress in the foam is a result of the gravity-induced pressure gradient. As the foam flows out and becomes thin, the stress will be reduced. When the stress falls below the yield stress, the viscosity will become infinite and the second term, kt/μ , in the spread length equations will go to zero. The foam will flow simply as plug flow. Above the yield stress, the foam will have a finite viscosity, but this viscosity will be dependent on the yield stress.

An AFFF agent that is very free flowing will have a relatively small yield stress and will retain the second term in the spread length equations until it has flowed out to a very thin layer. A protein foam that is relatively stiff will have a large yield stress, and the second term will go to zero before the foam has spread very far. Above the yield stress, the viscosity of the AFFF will be lower than that of a protein foam, and the second term will provide a greater contribution to foam spread. The rheological properties described appear to have a significant impact on foam spread; however, the properties are not a part of any current specification and are rarely measured.

Foam Extinguishment Modeling

At present, modeling of foam extinguishment cannot be performed because of the large number of remaining uncertainties. A model would have to take into account the addition of foam to the fuel surface, the spread of foam on the fuel surface, and the foam loss mechanisms of evaporation and drop-through. The foam spread length equations can be used to estimate the area of foam coverage at a specific time and for a specific quantity of foam. Modeling at this time is limited because of the lack of established values for k_e (Equation 2) and k_d (Equation 3). Also, the yield stress and viscosity relationships for fire-fighting foams have not been quantified. Experimental work is needed to complete this modeling effort. Also, the actual method of application (e.g., from a handline nozzle or fixed device such as a sprinkler) must ultimately be

taken into account. Even so, preliminary calculations using this methodology are encouraging and support continued development.⁷

Surface Tension and Spreading Coefficient

Film-forming foams are defined by the ability of the aqueous solution draining from the foam to spread spontaneously across the surface of a hydrocarbon fuel. The fundamental relationship used to describe the spreading coefficient is

$$S_{a/b} = \gamma_b - \gamma_a - \gamma_l \quad (9)$$

where

$S_{a/b}$ = spreading coefficient (dynes/cm)

γ_b = surface tension of the lower liquid phase of a hydrocarbon fuel (dynes/cm)

γ_a = surface tension of the upper layer of liquid using AFFF solution (dynes/cm)

γ_l = interfacial tension between liquids *a* and *b* (dynes/cm)

Surface tension and interfacial tension can be measured using methods such as those described in ASTM-D-1331, *Standard Test Methods for Surface and Interfacial Tension of Solutions of Surface-Active Agents*. Reagent-grade cyclohexane is typically used as a reference fuel. A du Nouy tensiometer, having a torsion balance with a 4- or 6-cm-circumference platinum-iridium ring, is lowered into the liquid and slowly pulled out until the liquid detaches from the ring's surface. The force recorded at the point where this separation occurs is the surface tension (dynes/cm) of the pure liquid. Similarly, the interfacial tension is the measurement of tension when the ring is pulled through the boundary layer between two liquids.

The Naval Research Laboratory developed some of the earliest quantitative data on the spreading coefficient of AFFF on hydrocarbons, as shown in Tables 4-4.1 and 4-4.2.¹⁷ As fuel temperature increases, the surface tensions of both the fuel and solution decrease. The spreading coefficient may go to zero or go negative.^{17,18}

While it has been shown that film-forming foams are superior fire extinguishing agents compared to other foams, there are no one-to-one correlations between bench-scale surface-tension/spreading coefficient data and fire control, extinguishment, and burnback resistance times. Both Scheffey et al.¹⁹ and Geyer²⁰ have demonstrated that there is no direct correlation between fire extinguishment and spreading coefficient. As such, spreading coefficient data alone cannot be used as a relative predictor of fire performance.

Since the surface tensions of most AFFFs are approximately equal, there must be a balance between the surface tension of the fuel and the interfacial tension of the two liquids to create a positive spreading coefficient. It can be seen then that, while both the surface tension of the solution and the interfacial tension between the liquids have an impact on the spreading coefficient, the interfa-

Table 4-4.1 Surface Tension of Hydrocarbon Liquids and Fuels¹⁷

^bSample 2

cial tension is usually the determining factor. For fuels, such as avgas or *n*-heptane, which have surface tensions in the range of 19 to 20 dynes/cm, either the foam surface tension or the interfacial tension, or both, must be reduced. Normally, the changes resulting from a modification of the formulation will be more significant for the interfacial-tension value than they will be for the foam surface-tension value. Still, a relationship between the two values does exist.⁴ Therefore, in reducing the sum of the values to obtain a positive spreading coefficient, a delicate balance must be maintained.

Maintaining this balance and achieving a positive spreading coefficient is accomplished by controlling the amount and type of fluorinated surfactants used to formulate the agent. This at first seems beneficial, since a positive number on a low surface-tension fuel will ensure an even larger value with higher surface-tension fuels (e.g., JP-5 or motor gasoline). But, in reducing the interfacial tension, the agent may lose some of its fuel-shedding capabilities. The effects of adding too much fluorosurfactant to an aqueous solution and the result on foam bubble stability are described by Rosen⁴ and Aubert et al.² This could be a problem that manifests itself only during actual fire testing. The type and amount of fluorosurfactants also affect the spreading coefficient.¹⁹

Despite the lack of one-to-one correlations between surface-tension spreading coefficient data and fire control, extinguishment, and burnback results, these criteria are useful in categorizing film-forming agents. The spreading coefficient test is used throughout the world as a standard indicator of aqueous film-forming foams. Although undocumented, it is believed that film formation results in improved viscosity (or associated mechanisms that improve spreading), ultimately resulting in superior extinguishing performance.

Table 4-4.2 Interfacial Tensions, Spreading Coefficients, and Film Formation Observations for Various Surfactant Solution-Hydrocarbon Liquid Combinations¹⁷

Surfactant Solution	Hydrocarbon Liquid	Interfacial Tension (dynes/cm)	Spreading Coefficient (dynes/cm)	Film Formed

Assessment of Fire Extinguishing and Burnback Performance

Standard Test Methods

Since a theory of foam spreading has not been developed, performance of foams is measured using fire tests. The use of bench-scale burning fuel trays (e.g., less than 1 m diameter) results in varying fuel burning rates. This was observed by Chiesa and Alger when they attempted to use a 15-cm by 45-cm pan for foam performance evaluation.²¹ Data from their experiments are shown in Figure 4-4.3, which correlates control times observed when foam samples were tested using bench-scale apparatus (laboratory) and 4.6-m² (50-ft²) fire tests (field method). Equal control times correspond to a 45-degree line. Since the majority of the points fall below this line, the laboratory test is more severe (about 35 percent) than the field test.

Fire test methods used by regulatory authorities for certification are usually on the order of 2.6 to 9.3 m² (28 to 100 ft²). Foams must also meet additional test parameters related to storage, proportioning, and equipment factors.

Underwriters Laboratories Standard 162: Underwriters Laboratories (UL) 162, *Standard for Foam Equipment and Liquid Concentrates*, is the principle test standard for the listing of foam concentrates and equipment in the United States. Test procedures outlined in this standard have been developed to evaluate specific agent/proportioner/discharge device combinations. When a foam concentrate is submitted for testing, it must be accompanied by the discharge device and proportioning equipment with which it is to be listed. Listed products, including the agent, discharge device, and proportioner, are then described in the *UL Fire Protection Equipment Directory*.

Listed with a system, foam liquid concentrates are associated with discharge devices classified as Type I, II, or III. Type I devices deliver foam gently onto the flammable liquid fuel surface, for example, a foam trough along the inside of a tank wall. These devices are no longer evaluated in UL 162. Type II discharge devices deliver foam onto the liquid surface in a manner that results in submergence of the foam below the fuel surface, and restricted agitation at the fuel surface. Examples include subsurface injection systems, tank wall-mounted foam chambers, and applications where foam is bounced off the wall of a tank. Type III discharge devices deliver foam

Figure 4-4.3. Correlation of control times observed in laboratory and field tests of foam.²¹

directly onto the liquid surface and cause general agitation at the fuel surface, for example, by using hand-held nozzles. The flammable liquid fire tests in UL 162 include methods for sprinklers, subsurface injection, and topside discharge devices, including nozzles.

Class B fire test requirements for Types II and III discharge devices and sprinklers are shown in Table 4-4.3. Commercial grade *n*-heptane is placed in a square test pan. The area of the pan is a minimum of 4.6 m² (50 ft²). The application rates (“densities” in UL 162, *Standard for*

Foam Equipment and Liquid Concentrates) for various concentrates are outlined in Table 4-4.3.

In the test fire, the fuel is ignited and allowed to burn for 60 s. Foam is then discharged for the duration specified in Table 4-4.3. The foam blanket resulting from the foam discharge must spread over and completely cover the fuel surface, and the fire must be completely extinguished before the end of the foam discharge period.

After all the foam is discharged, the foam blanket formed on top of the fuel is left undisturbed for the period specified in Table 4-4.3. During the time the foam blanket is left undisturbed, a lighted torch is passed approximately 25.4 mm (1 in.) above the entire foam blanket in an attempt to reignite the fuel. The fuel must not reignite, candle, flame, or flash over while the torch is being passed over the fuel. However, candling, flaming, or flashover that self-extinguishes is acceptable, provided that the phenomenon does not remain in one area for more than 30 s.

After the attempts to reignite the fuel with the lighted torch are completed, a 305-mm- (12-in.-) diameter section of stovepipe is lowered into the foam blanket. The portion of the foam blanket that is enclosed by the stovepipe is removed with as little disturbance as possible to the blanket outside the stovepipe. The cleared fuel area inside the stovepipe is ignited and allowed to burn for 1 min. The stovepipe is then slowly removed from the pan while the fuel continues to burn. After the stovepipe is removed, the foam blanket must either restrict the spread of fire for 5 min to an area not larger than 0.9 m² (10 ft²), or flow over and reclose the burning area.

When the UL 162 test is passed, the agent, proportioning device, and discharge device become listed. The

^aFilm-forming fluoroprotein is to be tested at application densities of 2.5 and 1.6 Lpm/m² (0.06 and 0.04 gpm/ft²).

^bApplication rate may vary among polar groups, as specified by the manufacturer.

^c0.01 or 1.67 times test application rate, whichever is greater.

^d0.16 or 1.6 times test application rate, whichever is greater.

Source: UL 162, *Standard for Foam Equipment and Liquid Concentrates*, March 1994.

fact that foam concentrate has a UL label does not mean it has been tested under all potential end-use conditions. The *UL Fire Protection Equipment Directory* must be referenced to determine with what equipment the concentrate has been tested and approved.

UL 162, *Standard for Foam Equipment and Liquid Concentrates*, is not an agent specification; therefore, there are no requirements for physical properties, such as film formation and sealability and corrosion resistance. Neither are there any provisions to test, on a large scale, the degree of dry chemical compatibility of an agent, or the effects of aging or mixing with agents of another manufacturer. Requirements for a positive spreading coefficient (greater than zero using cyclohexane) for film-forming foams recently have been implemented.²²

U.S. military specification: The U.S. Military Specification, MIL-F-24385, is the AFFF procurement specification for the U.S. military and federal government. The U.S. military, in all likelihood, is the largest user of foam in the world. It is important to recognize that MIL-F-24385 is a procurement specification as well as a performance specification. Hence, there are requirements for packaging, initial qualification inspection, and quality conformance inspection, in addition to fire performance criteria. Equipment designs unique to the military, in particular U.S. Navy ships, also impact on the specification requirements (e.g., use of seawater solutions and misproportioning-related fire tests). These requirements have been developed based on research and testing at the Naval Research Laboratory and actual operational experience with protein and film-forming foams.

Table 4-4.4 summarizes the important fire extinguishment, burnback resistance, film formation, and foam quality requirements established by MIL-F-24385. The fire tests are conducted using 2.6 m² (28 ft²) and 4.6 m² (50 ft²) circular fire test pans. There are specific requirements to conduct a fire test of the agent after it has been subjected to an accelerated aging process (simulating prolonged storage) and after intentionally misproportioning the concentrate with water. In particular, the requirement to conduct a fire test of the agent at one-half of its design concentration is one of the most difficult tests. The 2.6-m² (28 ft²) half-strength fire test must be extinguished in 45 s, only 15 s greater than allowed when the full-strength solution is used.

The physical and chemical properties evaluated for MIL-F-24385 agents are outlined in Table 4-4.5, along with the rationale for each test. These procedures have been developed based on experience and specific military requirements. For example, MIL-F-24385 requires that the agent be compatible with dry chemical agents. Dry chemical agents may be used as “secondary” agents in aviation and shipboard machinery space fires, for example, to combat three-dimensional fuel fires, where AFFF alone may have limited effectiveness. MIL-F-24385 requires that an agent’s compatibility with potassium bicarbonate dry chemical agent (PKP) be demonstrated. The burnback time of the foam in the presence of the dry chemical is measured. Also, the concentrate of one manufacturer

must be compatible with concentrates of the same type furnished by other manufacturers, as determined by fire tests and accelerated aging tests.

Standards outside the United States: The number of standards developed for foams outside the United States is quite substantial. A brief review of the literature yielded over 17 different standards and test methods.²³ Developments in the European community are reviewed here to provide examples of differences in test standards.

The International Civil Aviation Organization (ICAO) develops crash fire-fighting and rescue documents for its member bodies. The ICAO *Airport Services Guide*, Part 1, “Rescue and Firefighting,” describes airport levels of protection to be provided and extinguishing

Table 4-4.5 Physical/Chemical Properties and Procurement Requirements of the AFFF Mil Spec

Requirement	Rationale
Refractive index	Enable use of refractometer to measure solution concentrations in field; this is most common method recommended in NF PA 412 ^a
Viscosity	Ensures accurate proportioning when proportioning pumps are used; for example, balance pressure proportioner or positive displacement injection pumps
pH	Ensures concentrate will be neither excessively basic or acidic; intention is to prevent corrosion in plumbing systems
Corrosivity	Limits corrosion of, and deposit buildup on, metallic components (various metals for 28 days)
Total halides/chlorides	Limits corrosion of, and deposit buildup on, metallic components
Environmental impact	Biodegradability, fish kill, BOD/COD ^b
Accelerated aging	Film formation capabilities, fire performance, foam quality; ensures a long shelf life
Seawater compatibility	Ensures satisfactory fire performance when mixed with brackish or saltwater
Interagent compatibility	Allows premixed or storage tanks to be topped off with different manufacturers' agents, without affecting fire performance
Reduced- and over-concentration Fire test	Ensures satisfactory fire performance when agents are proportioned inaccurately
Compatibility with dry chemical (PKP) agents	Ensures satisfactory fire performance when used in conjunction with supplementary agents
Torque to remove cap	Able to remove without wrench
Packaging requirements	Strength, color, size, stackable, minimum pour, and vent-opening tamperproof seal; ensures uniformity of containers and ease of handling
Initial qualification inspection	Establish initial conformance with requirements
Quality conformance inspection (each lot)	Ensures continued conformance with requirements

^aNFPA 412, *Standard for Evaluating Aircraft Rescue and Fire-Fighting Foam Equipment*, 1998 edition.

^bBOD/COD: Biological oxygen demand/chemical oxygen demand

agent characteristics. Minimum usable amounts of extinguishing agents are based on two levels of performance: Level A and Level B. The amounts of water specified for foam production are predicted on an application rate of 8.2 lpm/m² (0.20 gpm/ft²) for Level A, and 5.5 lpm/m² (0.13 gpm/ft²) for Level B. Agents that meet performance

Level B require less agent for fire extinguishment. ICAO foam test criteria are described in Table 4-4.6. Foams meeting performance Level B have an extinguishment application density of 2.5 l/m² (0.061 gal/ft²). There are no surface-tension, interfacial-tension, and spreading coefficient requirements.

The International Organization for Standardization (ISO) has issued a draft specification for low-expansion foams, EN 1568-3.²⁴ The specification includes definitions for protein, fluoroprotein, synthetic, alcohol resistant, AFFF, and FFFP concentrates. A positive spreading coefficient is required for film-forming foams when cyclohexane is used as the test fuel. There are toxicity, corrosion, sedimentation, viscosity, expansion, and drainage criteria. The fire test uses a 2.4-m- (8-ft-) diameter circular pan with heptane as the fuel. The UNI 86 foam nozzle is used for either a "forceful" or "gentle" application method at a flow rate of 11.4 lpm (3 gpm). The application rate is 2.4 lpm/m² (0.06 gpm/ft²). For the greatest performance level, a 3-min extinguishment time is required. This extinguishment time results in an extinguishment application density of 7.6 l/m² (0.19 gal/ft²).

The proposed ISO/EN requirements for extinguishing and burnback are summarized in Table 4-4.7. There are three levels of extinguishment performance and four levels of burnback performance. For extinguishing performance, Class I is the highest class and Class III the lowest class. For burnback resistance, Level A is the highest level and Level D the lowest level.

Typical performance classes and levels for different concentrates are provided. Typical anticipated performance for AFFF is noted as Level IC, and Level IB for alcohol-type AFFF. For a fluoroprotein foam, performance is expected to be Level IIA for both alcohol-type and hydrocarbon-only concentrates.

Table 4-4.6 ICAO Foam Test Requirements

Fire Tests	Performance Level A	Performance Level B
1. Nozzle (air aspirated)		
(a) Branch pipe	UNI 86 foam nozzle	UNI 86 foam nozzle
(b) Nozzle pressure	700 kPa (100 psi)	700 kPa (100 psi)
(c) Application rate	4.1 lpm/m ² (0.10 gpm/ft ²)	2.5 lpm/m ² (0.06 gpm/ft ²)
(d) Discharge rate	11.4 lpm (3.0 gpm)	11.4 lpm (3.0 gpm)
2. Fire size	≅ 2.8 m ² (≅ 30 ft ²) (circular)	≅ 4.5 m ² (≅ 48 ft ²) (circular)
3. Fuel (on water surface)	Kerosene	Kerosene
4. Preburn time	60 s	60 s
5. Fire performance		
(a) Extinguishing time	≤60 s	≤60 s
(b) Total application time	120 s	120 s
(c) 25% reignition time	≥5 min	≥5 min

Table 4-4.7 Maximum Exinction Times and Minimum Burnback Times from Proposed ISO/EN Specification

Extinguishing Performance Class	Burnback Resistance Level	Gentle Application Test		Forceful Application Test

	C	5	10	Not tested	Not tested
	D	5	5	Not tested	Not tested

Comparison of small-scale tests: Table 4-4.8 outlines the large number of variables associated with foam performance and testing. These include factors such as foam bubble stability and fluidity, actual fire test parameters (e.g., fuel, foam application method and rate), and environmental effects. Even the fundamental methods of measuring foam performance (i.e., knockdown, control, and extinguishment) vary. For example, Johnson reported that FFFP fails the proposed ISO/EN gentle application tests because small flames persist along a small area of the tray rim.²⁵ As a result, the foam committees have proposed re-defining extinction to include flames.

Given the variations and lack of fundamental foam spreading theory, it follows that tests and specifications for various foams and international standards have different requirements. The differences are reflected in Table 4-4.9, which compares four key parameters of MIL-F-24385, UL 162, ICAO, and ISO/EN standards for manual application (e.g., handline or turret nozzles). There is no uniform agreement among test fuel, application rate, the allowance to move the nozzle, and the extinguishment application density for AFFF. There is a factor of six difference between the lowest permitted extinguishment application density (MIL-F-24385) and the highest (ISO/EN). This significant difference is attributed, at least in part, to the fixed nozzle requirement in the ISO/EN specification.

No study has been performed to correlate test methods; given the significant differences in performance characteristics and requirements, it is unlikely that correlation between these test methods could be established, even when considering AFFF only. An AFFF that meets the ICAO standard could not be said to meet MIL-F-24385 without actual test data. The problem of correlating differences in small-scale tests was demonstrated by UL in a comparison of UL, MIL-F-24385, O-F-555B (U.S. government protein foam specification), and United Kingdom test methods.²⁶ In those tests, differences between different classes of agents (protein vs. AFFF) and between agents within a class (e.g., AFFF) were demonstrated. No correlations between test standards could be established.

The problem of correlation is compounded when a single test method is used in an attempt to assess different classes of foam (e.g., protein and AFFF). Attempts to use a single test method are problematic because of the inherent difference between these foams. That is, protein foams require air aspiration so that the foam floats on the fuel surface. This stiff, "drier" foam is viscous and does not inherently spread well without outside forces (e.g., nozzle stream force). AFFF, because of its film-formation characteristics, does not require the degree of aspiration that protein foams require. This heavier, "wetter" foam is inherently less viscous, which contributes to improved spreading and fluidity on fuel surfaces. This is related, at least in part, to the degree of aspiration of the foam. A more exact description of foam aspiration is appropriate. Thomas has described two levels of foam aspiration: (1) primary aspirated and (2) secondary aspirated.²⁷ Primary aspirated foam occurs when a foam solution is applied by means of a special nozzle designed to mix air with the solution within the nozzle. The consequence is foam bubbles of general uniformity. *Air-aspirated* foam refers to this primary aspirated foam. Secondary aspirated foam results when a foam solution is applied using a nozzle that does not mix air with the solution within the nozzle. Air is, however, drawn into the solution in-flight or at impact at the fire. Secondary aspirated foam is more commonly referred to as *non-air-aspirated* foam.

The correlation between foam solution viscosity and extinguishment time has been shown by Fiala, but the entire foam spreading and extinguishment theory has yet to be demonstrated based on first principles.²⁸ Thus, the test standards reference bench-scale methods that measure a factor of foam fluidity (e.g., spreading coefficient), but fail to recognize the total foam spreading system, including viscous effects. Fundamental understanding of foam mechanisms would promote the development of bench- and small-scale test apparatuses that potentially have greater direct correlation for predicting large-scale results.

There has been some criticism of the human element involved in many of the test methods. The human factor occurs when an operator is allowed to apply foam from a

hand-held nozzle onto the burning test fire. Personnel are also called upon in some tests to qualitatively assess the percentage of fire involvement in the test pan during the burnback procedure. Using a fixed nozzle during a specification test eliminates the human element during extinguishment. For sprinkler applications, using a fixed nozzle is entirely appropriate and should yield results comparable to actual installations. For applications where movement is actually involved (e.g., fire-fighting hand-

lines, crash-rescue truck turrets, and movable monitors on ships and at petrochemical facilities), the extinguishment densities in the fixed test application will generally exceed the densities found in actual applications in the field. (See Table 4-4.9 for differences in extinguishing densities for manual versus fixed applications.) Removal of the human element is certainly advisable from a test repeatability standpoint. However, removing the human element from approval fire tests has proved difficult. Both

Table 4-4.9 Examples of Extinguishment Application Densities of Various Test Standards

Test Standard	Fuel	Application Rate [lpm/m ² (gpm/ft ²)]	Nozzle Movement Permitted	Extinguishment Application Density [l/m ² (gal/ft ²)]
MIL SPEC	Motor gasoline	1.6 (0.04)	Yes	1.34 (0.033)

ISO/EN— Forceful	Heptane	2.5 (0.06)	No	7.6 (0.19)

U.S. and Canadian military authorities have investigated the use of fixed nozzles. Both organizations concluded that tests with human operators resulted in better correlation with large fires and overall repeatability.

Quantitative methods for evaluating burnback performance have been described by Scheffey et al.¹⁹ and been adopted in ISO/EN and Scandinavian (NORDTEST) test methods. These methods involve the use of radiometers to establish a heat flux during full test-pan involvement. After extinguishment, the radiometers measure the increasing flux as the burnback fire grows. This increasing flux due to burnback is compared against the original flux. A cutoff is established so that the maximum burnback time is the time for the burnback flux to reach some percentage (e.g., 25 percent) of the original full-burning flux.

Critical Application Rates and Correlations between Small- and Large-Scale Tests

The previous section described the application rate differences in standard test methods between AFFF, fluoroprotein, and protein foams. These application rate differences were established based on full-scale testing. For sprinklers, much of the fundamental application rate differences were established during testing conducted by Factory Mutual Research Corporation (FMRC). (See section on foam-water sprinkler systems.) For manual applications, tests in the aviation fire protection field provide the basis for the fundamental application rates. The application rates specified in test standards are usually rates lower than those used in actual practice. (See Table 4-4.3.) There are two reasons for this: (1) a factor of safety is used when specifying rates in actual practice and (2) differences between individual foam agents are more readily apparent at critical application rates. To demonstrate how application rates are developed and how specification tests correlate with large-scale results, an example from aviation fire tests will be used. This example is based on a review of foam fire test standards performed by Scheffey et al. for the Federal Aviation Administration (FAA).²³

Tests were conducted by the FAA to determine application rates for a single-agent attack to achieve fire control (e.g., 90 percent extinguishment of a fire area) within 1

min under a wide variety of simulated accident conditions. Two factors are important in addition to the application rate required for 1-min fire control: (1) the critical application rate, below which fires will not be extinguished independent of the amount of time an agent is applied; and (2) application density, which is the amount of foam per unit area to control or extinguish a fire.

Minimum application rates were originally developed by Geyer in tests of protein and AFFF agents.²⁹ These tests involved “modeling” tests with JP-4 pool fires of 21-, 30-, and 43-m (70-, 100-, and 140-ft) diameter. Large-scale verification tests with a B-47 aircraft and simulated shielded fires (requiring the use of secondary agents) were conducted with 34- and 43-m (110- and 140-ft) JP-4 pool fires. All tests were conducted with air-aspirating nozzles. The protein foam conformed to the U.S. government specification, O-F-555b, while the AFFFs used were in nominal conformance with MIL-F-24385 for AFFF. These tests were being performed at the time when the seawater-compatible version of MIL-F-24385 had just been adopted based on large-scale tests.

Figure 4-4.4 illustrates the results of the modeling experiments. The results show that, for a fire control time of 60 s, the application rate for AFFF was on the order of 1.6 to 2.4 lpm/m² (0.04 to 0.06 gpm/ft²), while the application rate for protein foam was 3.3 to 4.1 lpm/m² (0.08 to 0.10 gpm/ft²). The data indicated that the application rate curves become asymptotic at rates of 4.1 lpm/m² (0.1 gpm/ft²) and 8.2 lpm/m² (0.2 gpm/ft²) for AFFF and protein foam, respectively. Above these rates, fire control times are not appreciably improved. Likewise, critical application rates for fire control are indicated when control times increase dramatically. The single test with a fluoroprotein agent indicated that this agent, as expected, fell between AFFF and protein foam.

Large-scale auxiliary agent tests were conducted to identify increases in foam required when obstructed fires

Figure 4-4.4. Fire control time as a function of solution application rate using protein foam and AFFF on JP-4 pool fires.²⁹

with an actual fuselage were added to the scenario. The results indicated that fire control times increased by a factor of 1 to 1.9 for AFFF and 1.5 to 2.9 for protein foams. It was estimated that the most effective foam solution application rates were 4.9 to 5.7 lpm/m² (0.12 to 0.14 gpm/ft²) for AFFF and 7.5 to 9 lpm/m² (0.18 to 0.22 gpm/ft²) for protein foam. This is the original basis of the recommendations adopted by ICAO of 5.5 lpm/m² (0.13 gpm/ft²) for AFFF and 8.2 lpm/m² (0.20 gpm/ft²) for protein foam. A rate of 7.5 lpm/m² (0.18 gpm/ft²) was subsequently established for fluoroprotein foam. These application rate values are still used by FAA, NFPA, and ICAO to establish minimum agent supplies at airports.

Tests of AFFF alone were conducted by Geyer.³⁰ These agents, selected from the U.S. Qualified Products List (MIL-F-24385 requirements), were tested on JP-4, JP-5, and aviation gasoline (avgas) fires. Air-aspirating nozzles were used with different AFFF agents. Example results are shown in Figure 4-4.5. Similar data were collected by holding the JP-4 fuel fire size constant at 743 m² (8000 ft²) and varying the flow rates to develop application rate comparisons. These data are shown in Figure 4-4.6.

Additional tests were conducted by Geyer et al. to verify the continuation of the reduction of water when AFFF agents were substituted for protein foam in aviation situations.¹ In 25-, 31-, and 44-m- (82.4-, 101-, and 143-ft-) diameter Jet A pool fires, AFFF, fluoroprotein, and protein foams were discharged with air-aspirating and non-air-aspirating nozzles. The data, summarized in Figure 4-4.7, validated the continued allowance of a 30 percent reduction in water requirement at certified U.S. airports when AFFF is substituted for protein foam.

Although some test criteria in standardized methods do not necessarily correlate directly with actual fire and

Figure 4-4.5. Fire control and extinguishing times as functions of the foam solution application rate using AFFF at 250 gpm (946 lpm), 400 gpm (1514 lpm), and 800 gpm (3028 lpm) on JP-4, JP-5, and avgas fires.³⁰

Figure 4-4.7. Fire control time as a function of solution application rate for AFFF, fluoroprotein, and protein foams for Jet A pool fires.¹

burnback performance, small-scale test data for AFFF formulated to the U.S. military specification (MIL-F-24385) has been shown to correlate with large-scale fire test results. This is based on a comprehensive review of small- and large-scale test data.²³ In these data, a key variable

was controlled; that is, all AFFF agents were formulated to meet MIL-F-24385. Ninety percent fire control times were used as the most accurate measure of fire knock-down performance, which were reported in all tests. The use of 90 percent control times eliminates the variability of total extinguishment, which might be dependent on test-bed-edge effects or running fuel fire scenarios. Data for tests using air-aspirated or non-air-aspirated nozzles were combined. Low-flashpoint [less than 0°C (32°F)] fuels were evaluated. The evaluation included only tests where manual application was used, eliminating the variable of fixed versus manual application.

The effects of application rate on control and extinguishment times, as demonstrated in Figures 4-4.4 through 4-4.7, were reconfirmed as shown in Figure 4-4.8. Control time increases exponentially as application rate decreases, particularly below 4.1 lpm/m² (0.10 gpm/ft²). Variability of the data is shown by the first standard deviation.

The scaling of small fires with large fires is shown in Figures 4-4.9 and 4-4.10, which relate the time needed to control the burning fuel surface as a function of fire size. The time needed to control a unit of burning area [s/ft² (s/m²)], designated as the specific control time, is plotted as a function of fire size. For low [1.2 to 2.5 lpm/m² (0.03 to 0.06 gpm/ft²)] and intermediate [2.8 to 4.1 lpm/m² (0.07 to 0.10 gpm/ft²)] application rates, the specific control times decrease linearly as a function of fire area. These data are in agreement with data from Fiala, which also indicate decreasing specific extinguishment control times as a function of burning area for increasing application rates of AFFF.²⁸ Also, Fiala showed that, for a constant application rate, AFFFs have lower specific extinguishment times as a function of burning area than those of protein and fluoroprotein foams. Obviously, this linear relationship must change at very large areas; otherwise, the specific control/extinguishment time would go to zero. This is evidenced in Figure 4-4.9, where the curve flattens at the high-area end of the plot.

Figure 4-4.8. AFFF control time as a function of application rate.²³

Figure 4-4.9. Specific control times for AFFF at low application rates.²³

Figure 4-4.10. Specific control times for AFFF at intermediate application rates.²³

Figures 4-4.9 and 4-4.10 show that higher specific control times are required for MIL-F-24385 test fires [2.6 and 4.7 m² (50 and 20 ft²) compared to large fires. This is readily apparent as actual/control extinguishment times for the small fires are on the same order as results from large fires. FAA and NFPA criteria for minimum quantities of agent are also shown in Figures 4-4.9 and 4-4.10. These criteria are expressed in terms of specific control time as a function of area by using the required control time of 60 s and the practical critical fire areas for airports serving different sizes of aircraft. The data indicate that specific control times with MIL-F-24385 agents are roughly equivalent or less than the specific control times established by NFPA and FAA requirements for large fire areas. This relationship is true even with the AFFF discharged at rates 25 to 75 percent below the minimum NFPA/FAA discharge rate of 5.5 lpm/m² (0.13 gpm/ft²). From these data, it can be concluded that a scaling relationship exists between MIL-F-24385 small-scale tests and

actual large-scale crash rescue and fire-fighting applications. The MIL-F-24385 tests are more challenging than the larger tests in terms of specific control time, but this challenging test produces an agent that can meet NFPA and FAA requirements at less than the design application rate. This factor of safety accounts for variables in actual aviation crash situations, for example, running fuel fires, debris that may shield fires, and cross winds that may limit foam stream reach.

Aviation Fire Protection Considerations

Historical Basis for Foam Requirements

The underlying principle in aviation fire protection is to temporarily maintain the integrity of an aircraft fuselage after a mishap to allow passenger escape or rescue. When an aircraft is involved in a fuel spill fire, the aluminum skin will burn through in about 1 min. If the fuselage is intact, the sidewall insulation will maintain a survivable temperature inside the cabin until the windows melt out in approximately 3 min. At that time, the cabin temperature rapidly increases beyond survivable levels.

Aircraft rescue and fire-fighting (ARFF) vehicles are designed to reach an incident scene on the airport property in 2 to 3 min, depending on the standard enforced by the authority having jurisdiction (AHJ). Having reached the scene in this time frame, agent must be applied to control a fire in 1 min or less. The 1-min critical time for fire control is recognized by FAA, NFPA, and ICAO.

Minimum agent requirements on ARFF vehicles are established using the 1-min critical control time plus the anticipated spill area for the largest aircraft using the airport. A "theoretical critical fire area" has been developed, based on tests, and is defined as the area adjacent to the fuselage, extending in all directions to the point beyond which a large fuel fire would not melt an aluminum fuselage regardless of the duration of the exposure. A function of the size of an aircraft, the theoretical critical fire area was amended to a "practical critical fire area" after evaluation of actual aircraft fire incidents. The practical critical area, two-thirds the size of the theoretical critical area, is widely recognized by the aviation fire safety community, including FAA, NFPA, and ICAO. Vehicles must be equipped with sufficient agent and discharge devices to control a fire in the practical critical area within 1 min. Vehicles must also be equipped with secondary agent (dry chemical or Halon 1211) for use in combating three-dimensional fuel fires.

Agent Quantities and Standards

The previous text on critical application rates described the rationale used to develop design application rates used in aviation fire protection. These rates are 5.5 lpm/m² (0.13 gpm/ft²) for AFFF, 7.5 lpm/m² (0.18 gpm/ft²) for fluoroprotein foam, and 8.2 lpm/m² (0.28 gpm/ft²) for protein foam. Using these rates, the practical critical fire area and the 60-s control time criteria,

minimum agent quantities are established for airports serving different size aircraft. These criteria are contained in NFPA 403, *Standard for Aircraft Rescue and Fire-Fighting Services at Airports*, and the FAA Advisory Circular 150/5210-6C, "Aircraft Fire and Rescue Facilities and Extinguishing Agents." ICAO uses similar criteria. NFPA 403 recently adopted the 4.6 m² (50 ft²) fire extinguishment and burnback criteria from MIL-F-24385 for AFFF agents. UL test criteria are acceptable for protein and fluoroprotein foams. Most airports in the United States use AFFF as the primary fire-fighting agent. Recognizing the limitations of its test methods for aviation applications, UL has deleted references to crash rescue fire fighting from the scope of UL 162, *Standard for Foam Equipment and Liquid Concentrates*. NFPA 403 recognizes that the standards for foam that it references are widely recognized throughout North America, but may not be recognized in other areas of the world. In particular, the ICAO test method has significantly different test parameters, including test fuel, application rate, and extinguishment density. The NFPA notes that it is incumbent on the national authority having jurisdiction to determine that alternative test methods meet the level of performance established by NFPA 403 test criteria.

NFPA 412, *Standard for Evaluating Aircraft Rescue and Fire-Fighting Foam Equipment*, provides field test methods to determine the adequacy of foam equipment on crash rescue vehicles. It includes criteria for foam expansion and drainage, and methods to determine foam solution concentration.

Expansion and drainage: Foam expansion and drainage requirements of the current version of NFPA 412, *Standard for Evaluating Aircraft Rescue and Fire-Fighting Foam Equipment*, are shown in Table 4-4.10.

NFPA 412 references a 1600-ml foam sample collector, which was originally adopted by ICAO and ISO/EN. This single method is used to obtain expansion and drainage measurements for all types of foams in hope that similar success could be obtained in using a single fire test method for all foams. The multiple categories of foam test classification in Table 4-4.7 for the ISO/EN method show how difficult this has been to achieve. Given the different methods of foam flow over a fuel surface, it may not be practical to use a common fire test method predicated on the current means of testing. Further development of fundamental foam-extinguishing principles is recommended.

Table 4-4.10 Foam Quality Requirements from NFPA 412

Agent	Minimum Expansion Ratio	Minimum Solution 25% Drainage Time (min)
AFFF or FFFP		
Air aspirated	5:1	2.25
Non-air-aspirated	3:1	0.75
Protein	8:1	10
Fluoroprotein	6:1	10

The 1600-ml expansion and drainage test method replaced two other methods where a 1000-ml cylinder or 1400-ml pan was used as the collection device. MIL-F-24385 still uses the 1000-ml collection method. This situation, plus other different test methods, makes direct comparison of expansion and drainage data difficult. Tests performed by Underwriters Laboratories (UL) identified differences among the three test methods based on expansion and drainage results.³¹ UL found that expansion ratios remained the same but that drainage was quicker using the 1600-ml method compared to the 1000-ml method for film-forming foams. Drainage time increased (i.e., doubled) for the protein foams when the 1600-ml method was used compared to the 1400-ml pan method.

No direct correlations have been established between expansion, drainage, and fire-extinguishing performance. There is a relationship between foam drainage and burnback. Longer drainage times generally result in longer burnback times.

The expansion and drainage data in Table 4-4.10 indicate the inherent differences between air-aspirated and non-air-aspirated film-forming foams. The data in Figure 4-4.7 showed that non-air-aspirated AFFF was more effective at critical application rates than air-aspirated AFFF. This conclusion was verified by Jablonski in tests with U.S. Air Force crash trucks as shown in Figure 4-4.11.³² Even so, there continues to be debate over aspirated and non-air-aspirated foam for manual applications involving aviation fuel spills.

Under certain conditions, non-air-aspirated AFFF is not as effective as air-aspirated AFFF. The results of the foam tests in the United Kingdom^{33,34} and the results from DiMaio et al.³⁵ described situations where air-aspirated AFFF resulted in better fire extinguishment performance than non-air-aspirated foam.

Figure 4-4.11. Effects of AFFF aspiration on JP-4 pool fire control times.³²

Given that one-to-one correlation between expansion, drainage, and fire-extinguishing performance is difficult to identify, there appears to be a lower limit where non-air-aspirated AFFF becomes ineffective. This has not been quantified, but it is speculated that poor performance occurs when AFFF expansion ratio is less than 2.5 to 3.0, and drainage is difficult to measure, that is, nearly instantaneous. This is based in part on unpublished data from the Naval Research Laboratory on shipboard bilge AFFF sprinklers³⁶ and the results of the U.K. tests.^{33,34} The importance of this lower limit of foam aspiration is recognized in NFPA 412 criteria.

Foam concentration determination: The most common method of determining foam concentration in the field is by use of a hand-held refractometer. The refractive index, n , is defined as

$$n = \frac{\sin i}{\sin r} \tag{10}$$

where

$\sin i$ = angle of incidence

$\sin r$ = angle of refraction

This is depicted graphically in Figure 4-4.12.

Manufacturers report that the glycols in AFFF formulations create the necessary refractive characteristics to determine concentration. However, they also report that glycol has a potential detrimental impact on overall agent performance. Elimination of this compound might improve (slightly) the performance of AFFF, but the glycol is also needed as a fundamental component of agent mixing.

The refractive index of water at 20°C (68°F) is 1.333 (air has a refractive index of 1.0002926). Since the refractive index of a solution is proportional to the inverse of the solution density, and density is proportional to temperature, then

$$n \propto \frac{1}{T} \tag{11}$$

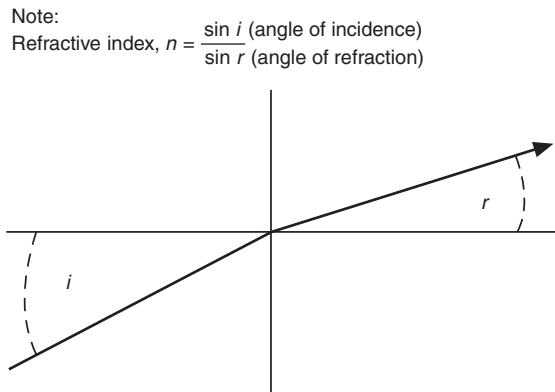

Figure 4-4.12. Refractive index of solutions.

Figure 4-4.13. Effects of temperature on refractive index.³⁷

where T is the temperature. This relationship is illustrated in Figure 4-4.13. Any refractive index measurements must be made considering temperature. Some hand-held measurement devices are temperature compensated. It is good procedure to conduct concentration measurements at a constant temperature.

Other scales may be used. For example, the Brix scale is used as a measure of sucrose weight percent concentration. Units with this scale, commonly found in the food product industry, can be used to measure foam concentration. A typical range of a bench or hand-held refractometer is 1.3000 to 1.7000.

NFPA 412, *Standard for Evaluating Aircraft Rescue and Fire-Fighting Foam Equipment*, describes a method to determine foam concentration using the refractive method. In NFPA 412, the preparation of three standard solutions is recommended: one at the nominal concentration, one at one-third more than the nominal concentration, and one at one-third less than the nominal concentration. A plot of the refractive scale reading against the known foam concentration is made on graph paper. This plot establishes a "calibration" curve against which foam samples from a vehicle or system can be judged. Since refractive index is linear, a calibration curve can be created by

$$\text{AFFF \%}_{\text{sample}} = \frac{n_{\text{foam}} - n_{\text{water}}}{n_{\text{concentrate}} - n_{\text{water}}} \times 100 \quad (12)$$

This method is used by the U.S. Navy for checking proportioning system accuracy onboard ships.

The limitations of the refractive index technique are described by Timms and Hagggar.³⁷ The accuracy of the refractometer can become poor due to the focusing and setting of the refracted light junction on the cross hairs of the viewing window, and the reading of the graduated scale to four decimal places (where the scale is graduated only to three places). This effect is illustrated in Figure 4-4.14, where a calibration curve for a 1 percent AFFF concentrate was established using a straight line through the 50

Figure 4-4.14. Refractive indices of 1 percent AFFF solutions in tap water.

percent concentration point and the "water" reading by one of the experimenters. Note that the error between readings by the two experimenters at 1 percent concentration exceeds 25 percent. In this example, differences in the baseline water reading will create substantial error in the calibration curve. These differences are exaggerated with 1 percent concentrates. At 3 percent or 6 percent, the experimental error in reading the refractometer, for field testing, is generally accepted as adequate.

Alternative methods for measuring AFFF concentration include total fluorine content, optical absorption methods, and electrical conductivity. Since neither the total fluorine content method nor optical absorption method is suited to field use, the conductivity method has been proposed. Since foams contain electrolytes, their conductance, G , can be measured and described as

$$G = \frac{1}{R} \text{ (mhos)} \quad (13)$$

where R = resistance (ohms). Conductivity, σ , is conductance per unit length:

$$\begin{aligned} \sigma &= G / \text{unit length} \\ &= \text{mhos/cm} \\ &= \text{siemens/cm} \end{aligned}$$

Since conductivity is directly proportional to temperature, conductivity increases with temperature. (See Figure 4-4.15.) Temperature compensation is appropriate when using this method.

Timms and Hagggar showed the influence of the substrate water on both refractive index and conductivity.³⁷ (See Figures 4-4.16 and 4-4.17.) It is important to note the difference of the characteristic curve for a salt solution. AFFF actually reduces the conductivity of this highly conductive water. Note also that, while conductance may exhibit straight-line characteristics in the area of interest (0 to 10 percent), the overall curves from 0 to 100 percent are nonlinear.

Figure 4-4.15. Effects of temperature on the conductance of AFFF solutions.³⁷

Figure 4-4.17. Effect of substrate water on conductivity of AFFF solutions.³⁷

Figure 4-4.16. Effect of substrate water on refractive index of AFFF solutions.³⁷

Table 4-4.11 Sensitivity of Refractive Index and Conductivity Methods for Determining Foam Concentration³⁷

	Refractive Index	Conductance (mS)
3%	1.3337	0.318
6%	1.3343	0.558
Difference	0.0006	0.240
"Sensitivity"	0.0005 (0.5 in 1000)	0.43 (430 in 1000)

Table 4-4.12 Accuracy of Foam Test Measurements³⁷

Solution	Refractive Index	Electrical Conductance	Actual
A	4.5% ± 0.8%	3.5% ± 0.1%	3.50 ± 0.01%
B	5.1% ± 0.8%	5.5% ± 0.1%	5.50 ± 0.01%
C	8.7% ± 0.8%	8.5% ± 0.1%	8.50 ± 0.01%

The "sensitivity" of the two methods (i.e., refractive index and conductivity) was shown by these researchers by comparing the difference between readings for solutions of 3 percent and 6 percent divided by the reading at 6 percent. The sensitivities for tap water show that the conductivity method is more sensitive than the refractive index measure. (See Table 4-4.11.) In repeated readings of refractive index and conductivity, the foam concentration accuracy using conductivity was ± 0.1 percent, where the accuracy of the refractive index method was ± 0.8 percent. (See Table 4-4.12.)

The electrical conductivity method is now recognized in NFPA standards. NFPA 412 cautions against the use of this method for seawater applications. The electrical conductivity method, used for process control in the chemical

industry, has recently been adapted for use as a proportioning controller for AFFF systems.

Aircraft Hangar Protection

The two objectives of aircraft hangar protection are (1) protect aircraft and (2) prevent collapse of the hangar roof structure, which is usually unprotected steel. The protection of the aircraft is the principle concern, since its value is generally many times that of the structure. This concern is particularly true for advanced military aircraft. Historically, these protection systems have been deluge-type sprinkler systems with open-head nozzles. They are activated by rapid-response detection systems.

Before the development of foam, water-deluge systems were used. The original foam-water sprinkler systems used protein foam. With the development of AFFF, research was performed to determine appropriate application rates and types of discharge devices. The research work, performed primarily by Factory Mutual Research Corporation (FMRC), provides the basis not only for current aircraft hangar protection criteria, but also for other sprinkler suppression system criteria.

Overhead sprinkler protection: Before the advent of foam, hangars were protected by conventional spray sprinklers using water. Water-deluge systems having discharge rates on the order of 10.4 lpm/m² (0.25 gpm/ft²) were used in conjunction with sloped floors and drains to protect aircraft. Even with these systems, activated by detection systems, burnthrough protection of aircraft fuselages (e.g., 1 min) could not be ensured. Ceiling temperatures in an 18.3-m- (60-ft-) high space on the order of 427 to 816°C (800 to 1500°F) have been recorded for fuel spill fires where this protection was provided. For a 121-m² (1300-ft²) JP-4 fuel fire, 927°C (1700°F) ceiling temperatures have been recorded within 30 s of ignition prior to deluge system discharge.

Protein foam systems, discharging at a rate of 8.2 lpm/m² (0.20 gpm/ft²), were an improvement on the water systems. Air-aspirating sprinklers were required to make effective protein foam. Because of the high centerline velocities of a pool fire plume, the foam flow from the perimeter toward the center of the fire was thought to be the dominant suppression mechanism.³⁸

With the development of AFFF, FMRC conducted a series of tests for the U.S. military to establish appropriate design parameters. In a series of baseline comparison tests, FMRC compared AFFF with protein foam. The tests consisted of 83.6-m² (900-ft²) JP-4 pool fires in an 18.3-m- (60-ft-) high space. Air-aspirating, standard upright, and

old-style upright sprinklers were evaluated at application rates of 4.1 to 8.2 lpm/m² (0.10 to 0.20 gpm/ft²). In one test, a low-level turret nozzle discharging AFFF was used in conjunction with sprinklers discharging water. Table 4-4.13 summarizes the results of the AFFF tests. A comparison of Tests 4 and 5 with Test 3 indicates improved results from the use of standard sprinklers compared to foam-water sprinklers. At application rates of 6.6 lpm/m² (0.16 gpm/ft²), the standard sprinklers were 1.3 to 1.6 times as effective in achieving extinguishment compared to air-aspirating foam-water sprinklers. At an application rate of 8.2 lpm/m² (0.20 gpm/ft²), the extinguishment times with AFFF from foam-water sprinklers were comparable to results from protein foam tests. Rapid suppression with the turret nozzle [at 8.3 lpm/m² (0.22 gpm/ft²)] combined with an overhead water system was demonstrated in Test 7. No adverse effects were evident from the water discharged from the overhead sprinklers after the foam ran out.

The superior performance of the standard sprinklers was attributed to more effective plume penetration by higher density foam particles. The maximum centerline velocities measured were 23.2 m/s (76 ft/s), with 15.2 m/s (50 ft/s) at the centerline of the fire. The fire plumes tended to bend due to air currents within the test building. Since the terminal velocity of the foam agents was estimated to be on the order of 9.1 m/s (30 ft/s) maximum, the droplets near the centerline never reached the fire. This result supports the theory that extinguishment occurs from the outside perimeter inward. Since foam droplets from standard sprinklers are about twice as dense as air-aspirated particles, the terminal velocities are greater. Greater velocities allow greater penetration of the fire plume. The same mechanisms explain why air-aspirated AFFF provides similar performance to protein foam. When the AFFF is air aspirated, there is no longer any advantage of increased droplet terminal velocity.

Table 4-4.13 Hangar Deluge System Tests by Factory Mutual Research Corporation³⁸

Test Conditions	Test No. 2	Test No. 3	Test No. 4	Test No. 5	Test No. 6	Test No. 7 (turret nozzle)
Type of Head	Foam-water	Foam-water	Standard	Standard	Standard	Old-style sprinkler
Spacing [m ² head ⁻¹ (ft ² head ⁻¹)]	7.4 (80)	9.3 (100)	12.1 (130)	12.1 (130)	9.3 (100)	9.3 (100)
Application rate [lpm/m ² (gpm/ft ²)]	8.2 (0.20)	6.6 (0.16)	6.6 (0.16)	6.6 (0.16)	5.2 to 4.4 (0.125 to 0.105)	6.6 (0.16) (water system)
End head pressure [kPa (psi)]	193 (28)	193 (28)	97 (14)	97 (14)	35 (5)	55 (8) (water system)
25% Drainage time (min)	2.5	2.1	0.5–0.8	1.0–1.3	0.5–0.7	No data recorded

Expansion ratio	4.3 : 1	3.4 : 1	2.2 : 1	1 : 25	2.2 : 1	12 : 1
Extinguishment time (min : s)	2 : 22	2 : 15	1 : 45	2.3 : 1	3 : 05	≈0 : 33

Table 4-4.14 Estimated Particle Diameter vs. Terminal Velocity⁴⁰

Particle Diameter [mm (in.)]	Terminal Velocity [m/s (ft/s)]			
	Water	Foam		
		Expansion Ratio 2:1	Expansion Ratio 5:1	Expansion Ratio 10:1
12.7 (0.5)	See note ^a	10.1 (33)	6.7 (22)	4.6 (15)
6.3 (0.25)	10.4 (34)	7.3 (24)	4.6 (15)	3.4 (11)
2.5 (0.1)	6.7 (22)	4.6 (15)	2.7 (9)	—

^aThe breakup of water drops greater than about 6.3-mm (0.25-in.) diameter is highly probable due to instability.

Additional work by FMRC established estimates for the terminal velocity of foam, as shown in Table 4-4.14.^{39,40} Plume theory was used to estimate roughly that velocity on the order of 18.3 m/s (60 ft/s) could be expected in an 18.3-m- (60-ft-) high space with an 83.6-m² (900-ft²) JP-4 fire. This estimate was in good agreement with the experimental results. Based on an average foam particle diameter of 6.3 mm (0.25 in.), a maximum terminal velocity of 7.3 m/s (24 ft/s) could be expected. For a JP-4 pool fire, this translates into a 0.7-m²- (8-ft²-) maximum fire size before plume penetration is not possible.

The practical significance of AFFF discharged through non-air-aspirating sprinklers was demonstrated by Breen et al.⁴⁰ Air-aspirating sprinklers require 207-kPa (30-psi) nozzle pressure to be effective. Standard sprinklers can discharge effective AFFF solution at pressures as low as 69 kPa (10 psi). This had important retrofit considerations where foam proportioning system losses could be made up through reduced sprinkler pressures.

Additional tests were conducted with closed-head sprinklers in an 18.3-m- (60-ft-) high hangar.⁴¹ Potential

cost benefits would have resulted from reduced hardware costs and unwanted discharges from deluge systems. These tests demonstrated that this concept was not feasible for the hangar scenario because of the large number of sprinklers that opened during the 83.6-m² (900-ft²) fire tests.

The superior performance of standard sprinklers compared to air-aspirating sprinklers is reflected in the criteria of NFPA 409, *Standard on Aircraft Hangars*. If standard sprinklers are used with AFFF, the design application rate for overhead deluge systems may be reduced to 6.6 lpm/m² (0.16 gpm/ft²) from 8.2 lpm/m² (0.20 gpm/ft²) required for air-aspirated sprinklers. This decrease represents a 20 percent reduction in foam required when standard sprinklers are used.

Low-level application of AFFF: With the increase in wingspan areas of large aircraft, it was recognized that significant damage could occur before extinguishment of the pool fire underneath the wing. Using overhead sprinklers only, FMRC demonstrated the times required for the foam to spread and extinguish fires. (See Table 4-4.13.) The concept of low-level application of foam, using monitors or turret nozzles, was developed to reduce extinguishment time where shielded fires may occur. This concept was later extended to include side-mounted nozzles and discharge outlets, and flush-mounted nozzles installed in a floor or deck.

These systems are effective because AFFF solution droplets do not have to penetrate the fire plume. They also typically deliver, at spot locations, high densities of foam. A high density allows the foam to gain a "bite" or toehold on the fire. Low-level AFFF systems have been used successfully for over two decades on U.S. Navy air-capable ships, protecting flight decks and special hazard areas.

Table 4-4.15 summarizes fire test data for low-level application of AFFF. As seen, control and extinguishment times are quite rapid. NFPA 409, *Standard on Aircraft*

^aSpray height and diameter at the pressure/flow used in the test

^bAn unplanned 69-kPa (10-psi) pressure drop in FMRC Test 4 caused a 4.6-m (15 ft) reduction in nozzle range, resulting in 90 percent control and extinguishment times 3 to 4 times those observed in Tests 3 and 6.

^cNo wing obstruction over fire test area

^dThe overhead deluge system discharging ordinary water was accidentally activated 12 sec later than the turret nozzle (5 sec before control was attained). The contribution, if any, of the overhead deluge system toward complete extinguishment was judged to be quite small compared to the turret nozzle.

^eWind-affected results

^fDeck pool fire area was obstructed with simulated weapons carts.

Hangars, criterion of 4.1 lpm/m² (0.10 gpm/ft²) for low-level applications is based on a fire control time of 30 s and extinguishment in 60 s. Data indicate that a JP-5 pool fire can be 90 percent controlled in 60 to 90 s and 99 percent extinguished in 2 min when an application rate of 2.4 lpm/m² (0.06 gpm/ft²) is used. The system can be effective at rates as low as 1.6 lpm/m² (0.04 gpm/ft²). For low-flash-point fuels (e.g., avgas), control time increases. Control and extinguishment times can be reduced by increasing the application rates on JP-5 fuel fires. Based on these results, the U.S. Navy adopted an AFFF application rate of 2.4 lpm/m² (0.06 gpm/ft²) for protecting aircraft carrier flight decks.⁴⁶

While they may help control a three-dimensional (spill) fire, low-level application systems cannot be assumed to suppress totally a running fuel fire. Running fuel fires at a spill rate of 189 lpm (50 gpm) are typically used in U.S. Navy flight-deck suppression tests using the flush-deck system. The running fuel fire, shielded by simulated aircraft debris, requires aggressive handline attack for extinguishment.⁴⁷

Obstructions, such as parked vehicles, may block low-level nozzles. Testing for a flight-deck weapons staging area showed that a side-mounted low-level system could be effective even when nozzles are obstructed.⁴⁵ In these tests, 5 of the 12 deck-edge nozzles were obstructed to simulate vehicle tires blocking edge-mounted nozzles. Even with 40 percent reduction, the fire was controlled and extinguished in less than 1 min (compared to 15 to 30 s when unobstructed).

Cost of installation, maintainability, and reliability are factors when considering a low-level application system. Reliability issues with turrets/monitors have been identified by both FMRC and the U.S. Navy. The flush-deck system adopted by the U.S. Navy took considerable effort before a high degree of reliability and maintainability could be achieved. This open deluge nozzle, originally installed as a water washdown nozzle, incorporates a ball-check feature in the nozzle orifice to prevent debris from clogging the nozzle. Clean-out traps are installed in system piping for maintenance. Pop-up nozzles have been proposed as an alternative to flush-deck nozzles. These nozzles have their own reliability and maintainability issues. Unless there are very high costs associated with the loss of an aircraft, in-floor or flush-deck nozzles are generally cost-prohibitive for commercial aviation facilities. For high risk/cost applications, in-floor nozzles may be justified. This may be the case for advanced military aircraft; for example, research has been performed on an inverted deluge system that not only can suppress a pool fire, but also can cool exterior combustible components of the airframe. Initial installations have suffered from design and installation problems.⁴⁸ Lack of experience with these types of systems was the significant single cause of problems with these systems. Acceptance testing and maintenance were found to be lacking.

Side-mounted nozzles are the most reliable systems, consisting of open-pipe or -spray nozzles. The spreading rate of foam from an aspirated open-pipe system increases control and suppression time. Open-spray nozzles can be very effective, but their reach is limited.

New hangar fire protection design concepts: Issues related to asset protection, reliability of fixed systems, and environmental impact led the U.S. Navy to reevaluate their approach to hangar fire protection systems. A goal was established to install reliable and easily maintained fire protection systems that prevent damage to the hangar structure and to aircraft not directly involved in an initial spill fire ignition. This goal resulted in a multidiscipline study to address all associated technical issues.

All military service branches in North America have been plagued with false activation involving foam-water-deluge sprinkler systems over aircraft with open cockpits. These false activations have been caused by numerous sources including lightning strikes that introduced transient voltage spikes into the fire alarm system; water hammers in aging underground water distribution systems; accidental releases by maintenance personnel; deliberate acts of vandalism; accidental activation of manual pull stations; failure of pressure relief valves at pumping stations; roof-water leakage into overhead heat detection systems; and false activation of fire detection systems. This prompted the pursuit of alternative fire protection designs that would provide the desired level of protection.

Alternative designs included the use of closed-head AFFF overhead sprinkler systems and greater reliance on low-level monitor nozzle AFFF systems as the primary extinguishing component as described in the previous section. Low-level systems were originally designed to provide supplementary protection for the area shadowed from the overhead system by large wing areas. In pursuing these alternative designs, technical and operational issues and limitations of both existing and proposed new systems were identified:

- Thermally activated systems may result in unacceptably high damage to assets prior to fire control/extinguishment, particularly in very high bay hangar ceilings (see Reference 49).
- While it is readily accepted that conventional hangar fire protection systems were not designed to extinguish a three-dimensional fire, some fire protection engineers believed that AFFF extinguishing systems could be designed to control a spill fire and limit the area of the fire to only those aircraft intimate with the initial ignition source.
- Different aviation fuels are now commonly being used, e.g., JP-5 and JP-8 are now the predominant fuels, compared to the lower flashpoint JP-4 previously used.
- Low-level AFFF monitor nozzle systems are
 - Relatively inefficient in terms of pattern distribution
 - Unreliable
 - Susceptible to blockage by equipment
 - Commonly found out of service in the field
- Any new AFFF low-level nozzle should be designed for minimal overspray and should not be significantly impacted by water discharge from any water-only protection system.
- Optical fire detectors are
 - Prone to false alarms
 - Currently tested, listed, and approved using fuels that are not typical in aviation

—Subjected to few if any sources of false alarms in currently recognized approval standards

A concept was developed by the U.S. Navy to meet the desired performance goals. This concept included the following:

- Use of low-level AFFF deluge nozzles, having minimal overspray, to control/extinguish liquid fuel pool spill fires
- Operation of the low-level AFFF system using improved optical detectors designed to
 - Be highly immune to false alarms
 - Rapidly detect JP-5 fuel spill fires
- Installation of a quick-responding, closed-head, wet-pipe sprinkler system in the hangar ceiling
- Implementation of lessons learned from all military hangar design experiences in a comprehensive new, improved design

Most of the research and development associated with the process has been completed and is described in References 49 to 54. Two aspects of U.S. Navy research and development are germane to the performance of AFFF. The first involves the performance of AFFF when subjected to water spray from sprinklers. The second is a developmental effort initiated to design a reliable, low-profile AFFF nozzle that could be installed in the floors of hangars.

Twenty-three full-scale fire tests were conducted to evaluate the effects of overhead water sprinklers on AFFF foam blankets.⁵¹ One AFFF application rate [4.0 lpm/m² (0.1 gpm/ft²)] and two sprinkler application rates [6.5 and 10.2 lpm/m² (0.16 and 0.25 gpm/ft²)] were included in this evaluation. The tests were conducted on a range of spill fires. The spill fires were produced using either JP-5 or JP-8 aviation fuels and were evaluated on a concrete pad with similar drainage characteristics typical of navy hangars. The spill fires continued to burn (i.e., were shielded) during water/foam application. The heating effect on the burnback resistance of foam, with and without sprinkler water application, was evaluated.

The results show that the use of water sprinklers in conjunction with a low level AFFF fire suppression system [with an application rate of 4.0 lpm/m² (0.1 gpm/ft²)] had minimal effects on the ability of the system to suppress the fire and resist burnback. In all tests, the low-level AFFF system was capable of quickly extinguishing the test fire (control ~30 s and extinguishment ~1 min) independent of the sprinkler application rate. The time required for the fire to burnback across the fuel surface was apparently a function of the drainage characteristics of the hangar and was only slightly affected by the application of water through the overhead sprinklers. The tests also show that the flashpoint of the fuel has an effect on the control, extinguishment, and burnback resistance capabilities of the system. Although the burnback times for the lower flashpoint fuels were faster than the higher flashpoint fuels, the duration of protection was not significantly altered. These tests show that overhead water sprinklers have minimal effect on AFFF foam blankets, in-

dependent of the test fuel, particular fire, and sprinkler application rate. A combined low-level AFFF extinguishing system operating in conjunction with an overhead water sprinkler system provided adequate burnback protection during AFFF discharge, but this protection may be lost shortly (a few minutes) after the end of AFFF discharge.

The new low-level fire-extinguishing system was designed to discharge AFFF adequately across a hangar floor, to be less likely to be affected by obstructions, and to reduce the likelihood of damage to exposed aircraft electronic equipment.⁵³ To achieve these objectives, the nozzle was designed to

- Produce a nominal AFFF application rate of 4.0 lpm/m² (0.1 gpm/ft²)
- Operate at a nominal pressure of 2.8 bar (40 psi)
- Provide coverage to a distance of 7.6 m (25 ft) from a hangar floor drainage trench (centerline of two parallel trenches spaced 15.2 m (50 ft) apart)
- Spray AFFF so that the pattern height does not exceed 0.3 m (1 ft) above the deck

The nominal AFFF application rate of 4.0 lpm/m² (gpm/ft²) was selected based on current design practices as described in the previous two sections of the chapter. The nozzle operating pressure was selected based on standard, commercially available pump performance curves and preliminary estimates of friction loss for the system.

Over 50 nozzles were evaluated for this application.⁵³ Testing of these nozzles indicated that, while a limited number of commercially available nozzles could meet the design requirements, manufacturing, installation, and operation of these nozzles under normal hangar conditions was not feasible. Existing pop-up nozzles were not designed for the high flow rates or spray characteristics required of this application. As a result of these deficiencies, a prototype nozzle was developed. The prototype concept was subsequently developed into a commercially available nozzle. Foam pattern, distribution, and flow tests were conducted by Underwriters Laboratories Inc. on a nozzle with a flow coefficient of 22.6 *k* (gpm/psi^{1/2}).

There is no universal agreement on the proper approach to military hangar fire protection in North America. For example, the U.S. Air Force recognizes the use of high-expansion foam. A number of these systems have recently been installed. The Canadian Ministry of Defense (MoD) is investigating the possible use of compressed-air foam. Additionally, the U.S. Army has evaluated the use of early-suppression fast-response (ESFR) closed-head water sprinkler protection for helicopter hangars.⁵⁵ FMRC concluded that both 93°C- (200°F-) temperature-rated ESFR sprinklers discharging at 345 kPa (50 psig) [41 lpm/m² (1.0 gpm/ft²)] and 517 kPa (75 psig) [49 lpm/m² (1.2 gpm/ft²)] and 141°C- (286°F-) temperature-rated, *k* = 5.6 (gpm/psi^{1/2}) quick-response sprinklers at 345 kPa (50 psig) [16 lpm/m² (0.40 gpm/ft²)] can provide adequate fire protection for the hangar against a 61-m² (200-ft²), 473-l (125-gal) JP-4 aviation fuel-pan fire. For some tests, fuel depletion was necessary for the fire to be controlled.

Foam-Water Sprinkler Systems

This chapter has dealt with foam characteristics, foam concentrate, test standards, and manual application techniques. In particular, applications in the aviation industry were described. The text on aircraft hangar protection introduced the concept of fixed foam protection systems. In particular, much of the foam-water sprinkler system test data was originally developed for aircraft hangars. Herein, additional foam-water sprinkler system design criteria are described. Again, emphasis is placed on AFFF systems since they are more effective for extinguishment than protein or fluoroprotein systems.

Codes, Standards, and Regulations

Overhead foam-water sprinkler systems, as specified in the NFPA standards, are generally designed to serve dual purposes: (1) to control and/or suppress a fuel spill fire and (2) when the foam runs out, to cool materials with water. Since the systems are designed to provide protection for flammable/combustible liquid hazards and ordinary combustibles, the specified application rates reflect this dual-protection approach. Table 4-4.3 shows the fundamental application rates used by Underwriters Laboratories on hydrocarbon fuel fires to evaluate sprinklers. The fire must be extinguished within 5 min for AFFF discharged at 4.1 lpm/m² (0.10 gpm/ft²) for standard sprinklers and 6.6 lpm/m² (0.16 gpm/ft²) for agents discharged from foam-water sprinklers (air aspirating). However, since most deluge and closed-head sprinkler systems are installed in industrial occupancies, they must meet highly protected risk (HPR) insurance requirements. As a result, the NFPA standard for deluge and closed-head AFFF systems (NFPA 16, *Standard on the Installation of Deluge Foam-Water Sprinkler and Foam-Water Spray Systems*) requires 6.6-lpm/m² (0.16-gpm/ft²) minimum water application. This water application rate also provides a safety factor over the 4.1 lpm/m² (0.10 gpm/ft²) rate at which AFFF discharged from sprinklers is effective on pool fires. The safety factor is reflected in Table 4-4.3 under the column heading Minimum Application Rate.

Table 4-4.16 summarizes current requirements from NFPA standards and guidelines. NFPA 11, *Standard for Low-Expansion Foam*, is geared toward petroleum and chemical industry protection. Previous requirements from NFPA 11 allowed 4.1 lpm/m² (0.10 gpm/ft²) for loading racks, for example, tank truck loading facilities. The latest requirements for NFPA 11 eliminate this design criterion and reference NFPA 16 requirements, which require 6.6 lpm/m² (0.16 gpm/ft²). In special situations, 4.1 lpm/m² (0.10 gpm/ft²) is permitted by NFPA 11, but only where there is low-level or manual application for a hydrocarbon fuel spill. NFPA 16 is consistent in requiring 6.6 lpm/m² (0.16 gpm/ft²); it references other NFPA standards for special exceptions, for example, NFPA 409, *Standard on Aircraft Hangars*, and NFPA 30, *Flammable and Combustible Liquids Code*. NFPA 409 requirements were previously discussed. Section 4, Chapter 5 provides an example for calculating foam quantities based on design application rates and areas to be protected.

With the publication of the 1998 edition of NFPA 11, marine foam application is now addressed. Foam appli-

Table 4-4.16 NFPA Standards Related to AFFF Sprinkler Systems

Standard ^a	Minimum AFFF Application Rate [lpm/m ² (gpm/ft ²)]	Duration (min)
NFPA 11, (1998) <i>Low-Expansion Foam</i>	Indoor storage tank greater than 37 m ² (400 ft ²)	30
	6.6 (0.16)	
	Loading rack monitors	15
	4.1 (0.10)	
	Diked areas	Fixed low level (Class II hydrocarbon)
4.1 (0.10)		
Monitor		20
Undiked areas for AFFF handlines	6.6 (0.16)	15
	4.1 (0.10)	
NFPA 16, <i>Standard for the Installation of Foam-Water Sprinkler and Foam-Water Spray Systems</i> (1999)	6.6 (0.16)	10 min; 7 min if above minimum design
NFPA 409, <i>Standard on Aircraft Hangars</i> (1995)	Overhead deluge	10 min; 7 min if above minimum design
	8.2 (0.20) for aspirated AFFF	
	6.6 (0.16) for non-air-aspirated AFFF	
Supplemental low level (for shielded wing areas)	4.1 (0.10)	10 min

Table 4-4.17 Foam Application Rate for Marine Hydrocarbon Hazards (NFPA 11)

Type of Hazard	Calculation of Rate
Deck spill	6.50 lpm/m ² (0.16 gpm/ft ²) or 10% of the cargo block area
Largest tank	9.78 lpm/m ² (0.24 gpm/ft ²) of the single largest tank area
Largest monitor	3.0 lpm/m ² (0.074 gpm/ft ²) of the area protected by the largest monitor (not less than 1250 lpm)

cation rates are required to be not less than the greatest of that required for deck spills, the largest tank, or the largest monitor solution flow rate as shown in Table 4-4.17 for hydrocarbon fuels and Table 4-4.18 for polar solvents. For polar solvents, standardized fire tests are used to determine the minimum foam design application

Table 4-4.18 *Foam Application Rate for Marine Polar Solvent Hazards (NFPA 11)*

Type of Hazard	Calculation of Rate
Deck spill	Rate for most hazardous polar solvent \times 10% of the cargo block area
Most demanding tank	150% of the highest required foam application rate for the single largest tank
Largest monitor	45% of the highest required foam application rate applied over the area protected by the monitor (not less than 1250 lpm)

rate for the most difficult extinguishment case. Foam concentrates for hydrocarbon fuels must be approved using a 9.29-m² (100-ft²) fire test similar to UL 162. The fixed-nozzle gasoline fire test has an extinguishment application density of 12.2 l/m² (0.30 gal/ft²).

Model building and fire codes in the United States are in the process of adopting AFFF protection criteria for the storage of flammable and combustible liquids. Criteria of insuring authorities [e.g., Industrial Risk Insurers (IRI) and Factory Mutual (FM)] are similar to the NFPA requirements. Insurance authority guidelines should be referenced for specific projects, since there are differences in protection criteria.

Protection of Stored Flammable and Combustible Liquids

Flammable and combustible liquids are stored in containers ranging in size from less than one quart to several hundred gallons. These liquids may be stored for display in a retail outlet or “super store,” or stored for distribution in a general-purpose warehouse housing many different combustibles, or stored in “liquid” warehouses containing large quantities of the liquid. NFPA 30, *Flammable and Combustible Liquids Code*, is the applicable NFPA protection document. This code includes requirements for tank storage, piping systems, containers, and operations. Criteria for suppression system protection is addressed in the sections dealing with container storage.

The protection of flammable and combustible liquids is a function of many factors, including the liquid properties, the ignition (which can be a factor of the storage occupancy), the packaging system (e.g., stored in cardboard cartons), the container design and material (e.g., steel, plastic, glass, fiberboard), and the arrangement of storage (e.g., rack versus pallet, storage height, aisle width, and mixture of other combustibles in the array). Based on these factors, a suppression system is provided to control or suppress the anticipated fire and protect the structure. The system may be designed to (1) control a fire so that the fire department can ultimately extinguish or suppress the burning material or (2) suppress the fire. Variables in suppression system design include sprinkler application rate,

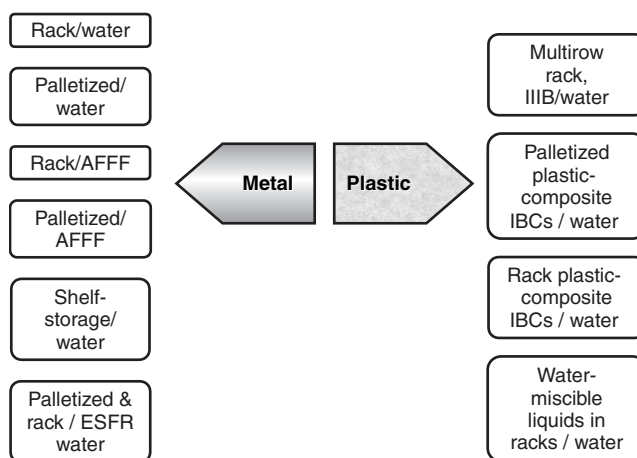

agent, orifice size, spacing, response time index (RTI), temperature rating, and provision of in-rack protection.

The basis of protection criteria in NFPA 30 is now well documented. Fire test references and associated citations in technical literature are now included with all protection tables.⁵⁶ The basis of the protection criteria can now be directly linked to test data or engineering extrapolations of the data. Material in Appendix E of NFPA 30 provides guidance and an example test protocol for evaluating protection of liquids stored in the containers. This includes consideration of the source of the fire, which may be a “point” ignition (i.e., small ignition) or a large spill/three-dimensional fire. Depending on other variables, such as container type and packaging material, one of these scenarios may be more difficult to protect. Appendix E of NFPA 30 provides detailed guidance on this subject.

Stored liquids may be protected using water sprinklers, foam, or other approved methods. Figure 4-4.18 shows a conceptual grouping of water and AFFF protection methods as a function of container type and storage method for water protection of liquids. The reader should consult Reference 56. The basis of AFFF protection is described in the following sections.

Protection of drum and tank storage: Some of the earliest work using AFFF sprinklers involved the protection of 208-l (55-gal) drums. In work conducted at Factory Mutual Research Corporation, sponsored by Allendale Insurance, Factory Insurance Association (FIA), and the 3M Company, the effectiveness of standard sprinklers supplied with AFFF for controlling drum fires was determined.⁵⁷ Five fire tests were conducted in simulated flammable liquid-drum storage using two types of storage arrangements. Three tests were conducted with two-, three-, and four-high palletized drum storage, respectively. Two tests were conducted with five-tier high-rack storage of palletized drums.

In all tests, a heptane fuel supply simulated leakage from the upper level of storage. Except for one rack-storage

**Figure 4-4.18.** *Grouping of NFPA 30 protection criteria for liquids.*

test that used a 57-lpm (15-gpm) spill rate, fuel spillage was 7.6 lpm (2 gpm). Ceiling protection employed high-temperature sprinklers at discharge rates of either 12.3 or 24.6 lpm/m² (0.30 or 0.60 gpm/ft²). In-rack supplemental protection for the rack-storage tests was provided at three levels, with ordinary temperature sprinklers each discharging 113 lpm (30 gpm). The success of each test was based on storage stability, that is, no pile collapse, and limitation of drum pressure to 104 kPa (15 psig).

AFFF was effective in controlling spill fires on the floor. The exception was in areas not reached by the discharge from operating sprinklers, where the flow of foam was blocked by pallets. Protection was not effective on the three-dimensional spill fires. Fire exposure and resultant pressure development within drums were more severe with increased clearances between storage and sprinklers due to greater delays in sprinkler operation.

Generally, results were considered good in the rack-storage tests, where in-rack sprinklers were provided in each tier. For palletized storage, the AFFF protection controlled the floor fire although pallets hindered the spread of foam. Ceiling sprinklers alone did not adequately protect palletized storage where an elevated spill resulted in a three-dimensional fire within the pile.

The results of these tests were used, along with engineering judgment, to develop AFFF protection criteria in NFPA 30, *Flammable and Combustible Liquids Code*. AFFF protection of 12.3 lpm/m² (0.30 gpm/ft²) at the ceiling for rack protection of metal drum/tank storage up to 7.6 m (25 ft) high. In-rack protection (e.g., sprinklers in alternating tiers or every tier) is a function of the liquid (flash-point), container style (relieving vs. nonrelieving), and capacity of the container.

The results of the original Factory Mutual (FM) drum tests were extended in a series of tests conducted by Southwest Research Institute.⁵⁸ The objective was to test the effectiveness of relieving-style steel drums and varying degrees of overhead sprinkler protection to mitigate fire hazards associated with the storage of flammable liquids. Nylon plugs inserted in the 5.1-cm (2.0-in.) pour hole and 1.3-cm (0.5-in.) vent hole were designed to melt under fire conditions, allowing the drum to vent any built-up pressure. Heptane, a Class IB flammable liquid, was used as the stored commodity.

Tests were designed to model credible, worst-case loss scenarios involving the 208-l (55-gal) storage of the commodity. The fire modeled the accidental puncture of a full drum, and either an immediate or a delayed ignition source. Sprinkler suppression of the fire was monitored for the duration of the spill, and until flames were either under control or completely extinguished. Commodity was stacked in a 3 × 3 palletized array, to varying heights (2, 3, or 4 high), and protected with varying sprinkler types and densities.

The relieving-style closures were successful at mitigating the hazards associated with overpressurizing drums during a fire. The installed suppression systems were capable of either extinguishing or controlling the fire for the duration of the spill. A summary of the successful protection configurations for the commodity tested is provided in Table 4-4.19.

Table 4-4.19 Summary of Heptane-Palletized Drum Storage Tests⁵⁸

Test	Commodity	Protection (nominal application rates)
2 and 3	3 × 3, 2 high	3% AFFF at 12.3 lpm/m ² (0.30 gpm/ft ²)
5	3 × 3, 2 high	ELO water-based at 24.6 lpm/m ² (0.60 gpm/ft ²)
7	3 × 3, 3 high	ELO, 3% AFFF at 18.5 lpm/m ² (0.45 gpm/ft ²)
8	3 × 3, 4 high	ELO, 3% AFFF at 24.6 lpm/m ² (0.60 gpm/ft ²)

The fuel spill rate (7.6 vs. 56.8 lpm) was found to have a substantial impact on the fire exposure of the drums. When taken in conjunction with the effect of the ignition scenario, the fuel spill rate had a strong influence on the number of initial heads operating and on the duration of the fire exposure. The ignition of the fuel source also played a role in the number of heads actuated during a test. The immediate ignition of fuel (simulating a spill onto an existing ignition source) resulted in a slower growing fire, actuating fewer sprinkler heads. Alternately, an ignition scenario where a 7.6-l spill was allowed to develop prior to ignition resulted in the actuation of four heads within the first minute of fire exposure. A comparable test with the immediate ignition scenario resulted in only two heads operating in a time in excess of 2 min and 30 s. The involvement of fewer sprinkler heads and the prolonged fire exposure implied that the immediate ignition provided a more challenging scenario.

The AFFF system used in the test program was successful in generating a good blanket of foam within 1 to 2 min of actuation (depending on the number of initial heads actuated). The foam quality was such that it was free to flow over drum heads, providing cooling to the tops and sides of drums, and forming a blanket at the floor to suppress pool fires. The foam system (in Tests 6 through 8) was also effective at limiting the fire at the fuel introduction point, periodically extinguishing the source. In general, by the time fuel flow to the array was complete, the foam system had suppressed all pool fires, leaving only small pallet fires for manual suppression.

An initial survey of closure obstruction versus venting phenomenon indicated that there was little or no effect on the obstruction of a plug and its ability to vent. This is indicated by the low number of drums that exhibited bulging during tests. The bulging of a drum indicates an unusual buildup of pressure. This phenomenon was not consistent, even in drums where both closures were obstructed. It was also noted that even partial venting of either opening was sufficient in reducing the pressure within the drum.

Drum deformation was recorded on a subjective basis. Typical deformation involved bulging of the head of the drum by 1.2 to 2.5 cm (0.5 to 1.0 in.). In some cases, deformations were seen on the order of 7.6 to 10.2 cm (3 to 4 in.) with some unfurling of the head chime.

It is difficult to attribute the level of deformation with a corresponding internal pressure. Several drums were deformed to a degree consistent with hydrostatic pressures of 207 to 241 kPa (30 to 35 psi); however, no pressures of this magnitude were recorded. A possible reason for higher levels of deformation at lower pressures may lie in the exposed temperatures of the drums. Several drums were subjected to uneven heating. The uneven heating phenomenon is present where a drum is located directly above a pallet containing venting drums. This scenario sets the subject drum over an isolated flame source, heating it from below.

The results of these tests have been included in the NFPA 30 protection criteria tables for palletized steel drum storage up to four high when protected using AFFF. The use of listed relieving devices is recommended; the exact details of this listing procedure are being developed.

Liquid spill and container storage: Table 4-4.20 summarizes early closed-head AFFF sprinkler testing on a flammable liquid spill.⁵⁹ In a 9.1-m- (30-ft-) high ceiling room, *n*-heptane was discharged in a simulated spill to create a three-dimensional spill and a two-dimensional pool fire. Fuel spill rate was varied up to 113 lpm (30 gpm). AFFF application rates were 4.5 to 12.3 lpm/m² (0.11 to 0.30 gpm/ft²). The primary variables were the temperature rating of the sprinkler and the application rate. Non-air-aspirating sprinklers were used. The data show that high-temperature-rated sprinklers activated at

about the same time as ordinary temperature sprinklers, controlled the fire in comparable times (roughly 2 min control time), and resulted in significantly fewer sprinklers operating (7 versus 32). An increase in application rate when the high-temperature sprinklers were used resulted in fewer heads operating, but did not decrease overall control and extinguishment time. Fires were controlled, but not totally extinguished as a result of the three-dimensional spill fire. These tests showed the advantage of using high-temperature-rated sprinklers in AFFF closed-head suppression systems.

In response to the concerns related to flammable liquid warehouse protection, the National Fire Protection Research Foundation (NFPRF) initiated the International Foam-Water Sprinkler Research Project. The objectives were to document the performance of foam-water sprinkler systems designed for real-world storage and ignition scenarios and provide a design basis and minimum design parameters for foam-water sprinkler systems. Five tasks were performed, including a literature search, range-finding tests, and large-scale tests involving palletized and rack storage of liquids.

The literature search identified over 1100 sources of information related to flammable liquid fires and foam protection, but a dearth of data related to water and foam-water sprinkler suppression of liquid storage fires.⁶⁰ The range-finding tests indicated that the Class IB flammable liquids (heptane) provided a greater challenge than water-miscible fuels (e.g., isopropanol).⁶¹ Breach of steel containers exposed to a flammable liquid pool fire without sprinkler protection occurred over a range of times between 2 and 7.5 min, depending on the particular type of container. Plastic containers were quickly breached and discharged their contents to the exposing pool fire.

Large-scale tests were conducted under an 8.2-m- (27-ft-) high ceiling at the Underwriters Laboratories fire test facility in Northbrook, Illinois.⁶² A series of 14 fire tests involving the protection of 3.8- and 18.9-l- (1- and 5-gal-) metal and 18.9-l (5-gal) plastic containers filled with heptane (Class IB flammable liquid) were conducted. The use of closed-head foam-water sprinkler systems for the protection of these fuel packages was investigated. Quantities of fuel used in the fire tests varied from 605 to 7260 l (160 to 1920 gal); fuel storage densities ranged from 160 to 1907 l/m² (3.9 to 46.5 gal/ft²); and storage heights ranged from 4.3 to 42.7 m (1.3 to 13 ft). Each fire test was initiated using a 37.8-l (10-gal) flammable liquid (heptane) spill, recognizing the larger spill ignition scenarios observed in large-loss fires.

Fire tests involving palletized storage of 3.8-l (1-gal) metal F-style containers of heptane, packaged four containers in a corrugated cardboard carton, were conducted. The results indicated that the 37.8-l (10-gal) flammable liquid spill fire could be suppressed by a closed-head foam-water sprinkler system at a 16.4 lpm/m² (0.40 gpm/ft²) design application rate for storage heights up to 3.3 m (10.7 ft) under the 8.2-m (27-ft) ceiling prior to any container breach or fuel loss. Fires involving 18.9-l (5-gal) metal containers of heptane could be suppressed by a closed-head foam-water sprinkler system application rate of 12.3 lpm/m² (0.30 gpm/ft²) for a palletized storage height

Table 4-4.20 Closed-Head Sprinkler Tests⁵⁹

Sprinkler Temperature Rating [°C (°F)]	Nominal Application Rate [lpm/m ² (gpm/ft ²)]	Total Heads Opened	Sprinkler Operation and Control Times (min :s)
71 (160)	4.5 (0.11)	34	First sprinkler—0:27 Final sprinkler—1:01 3:50 Control time
71 (160)	7.4 (0.18)	32	First sprinkler—0:22 Final sprinkler—1:08 1:00 to 1:20 for knockdown 2:20 Control time
138 (280)	7.4 (0.18)	7	First sprinkler—0:33 Final sprinkler—0:531 1:50 Control time
138 (280)	7.4 (0.18)	15	First sprinkler—0:28 Final sprinkler—1:44 2:20 Control time
138 (280)	7.4 (0.18)	17 to 19	First sprinkler—0:22 to 0:24 Final sprinkler—1:03 to 1:13 2:00 Control time
141 (286)	12.3 (0.30)	10	First sprinkler—0:24 Final sprinkler—1:10 2:25 Control time

of up to 3.6 m (12 ft). Plastic pour spouts in the 18.9-l (5-gal) tight-head metal containers safety vented and prevented container breaching.

Fires involving 18.9-l (5-gal) plastic containers of heptane could not be suppressed by a preprimed, closed-head foam-water sprinkler system with an application rate of 12.3 lpm/m² (0.30 gpm/ft²), where containers were stacked one high [483 mm (19 in.)], due to container breaching and flammable liquid spillage prior to foam-water discharge.

Rack-storage tests also conducted in the NFPRF International Foam-Water Sprinkler Research Project did not lead to conclusive results.⁶³

Based on the results of the NFPRF foam-water sprinkler testing, the FMRC original AFFF drum testing, and engineering judgment/extrapolation, the NFPA 30 Technical Committee adopted protection criteria for palletized and rack storage of liquids in metal containers when protected by AFFF. Variables that affect the specific level of protection include container size, class of liquid stored, inclusion of exterior packaging material, and storage height. Ceiling application rates are on the order of 12.3 to 16.4 lpm/m² (0.30 to 0.40 gpm/ft²). Protection criteria shown in Table 4-4.21 are recommended for palletized storage of small containers that are nonrelieving style (i.e., do not readily vent when exposed to fire). Additional criteria are included in NFPA 30 for foam protection of palletized relieving-style containers based on extrapolation of the NFPRF data and engineering judgment. Where the hazard involves a water-miscible fuel, an alcohol-type foam should be used. The application rate should be at least as great as the rate established by foam listing requirements. AFFF solution should be discharged when four sprinklers are operating.

AFFF protection of flammable and combustible liquids should be used where large spills of low flashpoint fuels are a realistic scenario. Other protection options are available and have recently been adopted or are currently being con-

sidered by NFPA 30 and the model building/fire prevention codes. Designers of warehouse protection should have a thorough knowledge of these criteria and the available test data (including water-only protection) when considering design options for the protection of stored combustible and flammable liquids. Reference 56 and NFPA 30 provide detailed data and guidance for water-only protection. Additional guidance for warehouse protection is available from the Center for Chemical Process Safety.⁶⁴

Foam Environmental Considerations

There has been increasing concern about the consequences of the discharge of foam in the environment. This concern affects the users of foam, the manufacturers of foam agents, the fire safety authority having jurisdiction, and environmental authorities. Quantitative data and methods to evaluate environmental impact are not widely published or well developed. The issue is not a new or unique development but has received increased notice as a result of increased attention to environmental impact of fire-fighting agents.

Factors related to the impact of fire-fighting foam on the environment include

1. Discharge of foam solutions and fuel-contaminated foam solutions to waterways and the potential toxicity to aquatic life
2. Effects on water treatment facilities
3. Persistence and biodegradability of chemicals in foam concentrates and solutions
4. Combustion products of fuel/foam solutions

Perspective on the Use of Foam Agents

In order to assess the impact of foam on the environment, the likely scenarios under which AFFF may be discharged should be considered. Based on these scenarios, the overall impact can be assessed and, where appropriate, potential mitigation strategies can then be developed. Likely scenarios include uncontrolled fires, potential hazardous situations, fire-fighting training evolutions, and fixed or mobile vehicle suppression system discharge testing.

Uncontrolled fires: There are many fires for which foam may be used, including flammable liquid storage, process industry protection, aviation protection, and marine applications. For most fires, the elimination of foam as a suppression agent results in the potential for dramatically increased environmental impact. This impact results from the potential increase in hydrocarbon fuel effluent to the environment (due to smoke from uncontrolled burning and fuel/fire-fighting water effluent). Consider the example shown in Figure 4-4.19. A 929-m² (10,000-ft²) section of a warehouse containing combustible and flammable liquids may be protected using traditional water sprinklers discharging at a rate of 12.3 lpm/m² (0.30 gpm/ft²). If these sprinklers fail to control a large spill fire, the fire may develop and spread past the design area of the sprinklers. The example assumes the fire is contained within the fire wall; this may not always be the case for high-challenge fires. If the fire department aggressively combats the fire, a

Table 4-4.21 *AFFF Sprinkler Protection Requirements in NFPA 30 for Solid-Pile and Palletized Storage of Flammable and Combustible Liquids in Non-Relieving-Style Metal Containers of 18.9-l (5-gal) Capacity or Less*

Package Type	Cartoned	Uncartoned

Figure 4-4.19. Example of potential effluent from flammable liquid warehouse fire.

rough estimate of fire-fighting water that may be used is 15 to 50 times the minimum anticipated agent required for suppression.^{6,65,66} A rough estimate of the potential fuel-contaminated effluent (neglecting the actual quantities of hydrocarbon liquid) is shown in Figure 4-4.19. In the alternative situation, a properly specified foam-water sprinkler system designed for a high degree of reliability can control or suppress the fire. Using application rates and discharge times based on recent tests and building code requirements, the anticipated fuel/foam/water effluent for this scenario can be estimated. (See Figure 4-4.19.) The use of the foam-water system reduces the potential effluent by a factor of nearly 500 compared to the "unsuccessful" water sprinkler scenario where handlines are used. This reduction neglects the impact of smoke discharged to the atmosphere during the uncontrolled burning in the water-only scenario.

In some cases, it may be possible to collect the effluent from an uncontrolled fire. In other situations, it may not be possible. Any foam solution that has been used in fire suppression is likely to be contaminated with fuel and diluted with water.

Potential hazardous situations: Potential hazardous situations may result from a fuel spill where there is a

likely ignition source. In this situation, foam may be applied for ignition prevention. The potential impact of ignition and resulting uncontrolled fire must be assessed against the potential additional environmental impact by discharging foam for ignition prevention. The potential environmental effects from an uncontrolled fire should be considered as described in the previous text. Another consideration is the assessment of any additional impact of foam when applied to a fuel spill. For example, would the resulting fuel with foam have any greater impact on the environment than the fuel alone? If so, how is this impact quantitatively determined?

Training evolutions: Fire-fighting training is usually conducted under conditions conducive to collection of fuel, water, and foam. A separation process might be used to recover fuel. Water/foam solution may then be treated or reused. Alternatively, simulated hydrocarbon fuel spill scenarios might be used, with a simulated foam agent. Propane-fired burners are typically used. The disadvantage of these systems is the potential loss of realism of the simulated fire/agent interaction. These techniques may potentially reduce training effectiveness. Quantitative comparisons have not been performed to assess these differences.

System discharge testing: Facilities protected by foam systems may have containment systems that can hold effluent. Requirements for these containment systems are becoming more widespread in model building and fire codes. An alternative to discharge testing with foam is the use of a simulant that can be measured using concentration determination methods. For example, salt solutions can be used as the "concentrate" to test AFFF systems, with the simulant concentration measured using the conductivity method. Simulators may be more difficult to use for protein-based systems, where viscosity factors influence proportioning system accuracy.

Methods of Assessment

Biodegradability: The primary component of AFFF solution is water. Examples of other components are non-fluorinated surfactants, glycol ethers, and fluorinated surfactants. Freeze-resistant concentrate may contain ethylene or propylene glycol. Alcohol-type foams contain xanthan or similar gums. The fluorinated surfactants are particularly resistant to biodegradation. Further, the less-effective protein-based foams were largely assumed to be nonpolluting because of their "natural" organic base. An early review of the available literature by Factory Mutual Research Corporation indicated that both types of agents, that is, AFFF and protein-based, present inherent environmental issues and that effluents containing either should be processed in some form of sewage treatment facility or diluted prior to discharge into a stream.³⁹

A conventional method used to determine the biodegradability of a material is comparison of the chemical oxygen demand (COD) of the material with its biological oxygen demand (BOD). This method is particularly important for waste treatment facilities where the stability of the treatment process may be upset. The method typically used is specified in "Standard Methods for the Examination of Water and Wastewater."⁶⁷ BOD measures the amount of oxygen consumed by microorganisms in breaking down a hydrocarbon. COD measures the maximum amount of oxygen that could theoretically be consumed by microorganisms. Therefore, a BOD/COD ratio is representative of the ability of microorganisms to biodegrade the components in a foam. The higher the BOD/COD ratio, the more biodegradable the foam. Results reported for BOD/COD of AFFF range from 0.60 to 0.99. MIL-F-24385 requires a maximum COD of 500,000 mg/l and a minimum 20-day BOD/COD ratio of 0.65 for 6 percent concentrate. AFFF agents have been reported to have higher BOD and COD values than protein foams.³⁹ AFFF solutions are high-BOD materials compared to the normal influent to treatment plants. Large quantities can "shock load" wastewater treatment facilities.

The fluorochemical-based surfactants in AFFF have a carbon-fluorine chain that apparently does not break down in either the BOD or the COD test. The AFFF might then appear to be completely "biodegradable," even though the carbon-fluorine chain remains.

If nonbiodegradability concerns are based on the persistence of the fluorochemical surfactants, then the environmental impact tests currently used to assess foams do

not address this concern. There is speculation that the undegradable material is biologically inert, but no published data confirms this. Since the fluorinated surfactants are required to create surface-tension reduction of the solution, replacement with less persistent chemicals is problematic. There is a need for a more thorough understanding and testing related to the environmental impact of fluorosurfactants and possible alternatives.

The persistence of fluorosurfactants in soil has recently been quantified in a study of fire-training facilities.⁶⁸ In a study of training sites having long-term use, perfluorocarboxylates were detected using gas chromatography/mass spectrometry. These chemicals were detected at sites that were inactive for a period of 7 to 10 years. The results are consistent with the view that biodegradation of the long chain perfluorocarbon is unlikely. The influence of the perfluorinated compounds on the biotransformation and transport of other cocontaminants (e.g., training fuel) and other site characterization parameters (e.g., dissolved organic carbon and inorganics) is unknown.

Methods for detecting AFFF in aqueous solutions have been investigated.⁶⁹ A Fourier Transform Infrared Spectroscopy (FTIR) method and drain-time test were found to be effective in evaluating the level of AFFF contamination in wastewater and soil. The drain-time method was proposed as a simple, easy-to-use field test. Using these methods, procedures were developed to estimate AFFF contamination levels in wastewater and soil. Analysis of wastewater and soil for AFFF contamination was broken into two groups: nonbiodegraded samples and biodegraded samples. Nonbiodegraded samples were screened for AFFF, then analyzed further if deemed necessary. Samples were initially screened using the drain-time test. Samples with no drain time contain less than a 1:240 dilution of AFFF (5 ppm of fluorosurfactant). If the sample had a drain time, it was recommended that the FTIR analysis be performed on the sample. In solutions with fluorosurfactants, FTIR analysis can provide a quantitative level of AFFF in the sample if the fluorosurfactant source solution is available to develop a calibration curve. Otherwise, FTIR provides a qualitative estimate of the AFFF level in the solution.

Biodegraded wastewater samples were difficult to analyze because the hydrocarbon surfactants and a portion of the fluorosurfactant molecule are degraded. With these foam-making constituents degraded, the drain-time test results were found to be unreliable. However, the fluorine-carbon tail of the fluorosurfactant is not biodegraded, making FTIR analysis on biodegraded samples possible. With biodegraded samples, FTIR analysis can provide a qualitative measure of AFFF levels.

Toxicity: In sufficient concentrations, foams may affect aquatic life. A number of fish toxicity studies have been performed. In tests using fathead minnows, the U.S. Air Force found that these fish could live in a simulated effluent stream containing 250-ppm AFFF without fatality for up to 8 days. LC₅₀ values (i.e., the concentration causing deaths of 50 percent of the fish exposed) at 96 and 24 hr were 398 and 650 ppm, respectively.⁷⁰ MIL-F-24385

requires AFFF toxicity testing in accordance with ASTM E-729, using dynamic procedures with killifish. LC₅₀ of 1000 mg/l for 6 percent concentrate is permitted.

Alone, these values may be considered as having a low degree of fish toxicity using environmental regulation rating scales. Localized concentrations in ponds or streams may exceed the values cited, if there is limited water movement.

Published data do not exist for the phytotoxicity of foam solutions; however, there have been no published reports of plant kills resulting from foam solution discharges.

Manufacturers report that thermal decomposition products from AFFF do not present a health hazard during fire fighting. Again, there are no data published in the literature. Manufacturers' product environmental data for AFFF include references to a test where a layer of AFFF was burned in a pan of gasoline inside an enclosure. Two measurements of hydrogen fluoride recorded above the sample were 0.23 and 0.16 ppm.⁷¹

Foaming and emulsification of fuels: The surfactants in AFFF solutions can cause foaming in treatment aeration ponds. This foaming process may suspend high BOD solids in the foam. If these are carried over to the outfall of the treatment facility, nutrient loading in the outfall waterway may result. Foam aeration may also cause foam bubble backup in sewer lines.

In uncontrolled fires, spills, and live fire-training scenarios, foams may contain suspended fuels. The fuel may become emulsified in the foam-water solution.

A bench-scale study has been conducted to evaluate the potential inhibitory effects of untreated AFFF wastewater on the biological nutrient removal process.⁷² In this study, bench-scale reactors simulating the nitrification process were loaded at various AFFF concentrations, and the influence on process performance was evaluated. The results indicated that AFFF in concentrations between 10 ppm and 60 ppm did not show any inhibition to biological nitrification, and effluent did not exhibit any pass-through toxicity. These range-finding tests did indicate that nitrification inhibition did occur above 60 ppm AFFF. Some reductions in percent COD removal were observed as AFFF concentrations were increased.

Mitigation Strategies

Foam discharges are more easily handled where there is an in-place collection capability. This situation may be available at warehouses, tank farms, and fire-fighting training facilities. Where these facilities are not available, temporary diking is an alternative where time and resources permit.

Investigations have been conducted to develop foam/water separators using aeration and agitation techniques. To date, these techniques have not been optimized.

Discharge to water treatment facilities is recommended by many foam vendors when the solution is uncontaminated by fuel. Metering or dilution may be required to prevent levels of foam that will upset treatment facility reactions or cause excessive foaming. The use of defoamers to reduce aeration has been suggested.

Where fuels contaminate foam solutions, fuel/water separators might be used to skim off the hydrocarbon fuel. AFFF solutions have a tendency to form emulsions with fuels, potentially reducing the effectiveness of fuel/water separators. An alternative is to hold the solution in a pond or tank until the emulsion breaks and the separation process can be used. Agitation should be avoided to prevent the emulsion from reforming. In some situations (e.g., training), the fuel and treated water have been reused. Many fire-training facilities collect foam solution for ultimate discharge to water treatment facilities.

To ensure that unbalanced conditions do not occur in water treatment facilities, foam discharge should be carefully monitored. Different ranges of discharge rates have been suggested. This is an area requiring further investigation. Manufacturers of the foam solution should be consulted in conjunction with the wastewater treatment operator.

The entire area of environmental aspects of foam discharge requires additional evaluation and development of generally recognized guidance. Until generally recognized guidance is promulgated, users must rely on manufacturers' data and guidance. In all situations, discussions with the operator of the wastewater treatment facility and the environmental regulatory authorities are appropriate. Work is continuing in an effort to identify appropriate policy and criteria covering foam discharge for facilities having foam suppression systems. These efforts are focusing on identifying applicable codes and standards, analyzing environmental impact, and evaluating containment options.

Nomenclature

AFFF% _{sample}	percentage of AFFF present in the sample
BOD	biological oxygen demand (mg/l)
γ_a	surface tension of liquid <i>a</i> (dynes/cm)
γ_b	surface tension of liquid <i>b</i> (dynes/cm)
γ_l	interfacial tension between liquids <i>a</i> and <i>b</i> (dynes/cm)
COD	chemical oxygen demand (mg/l)
ΔH_v	combined latent and sensible heads of vaporization (kJ/kg)
δ	viscous boundary layer thickness (cm)
<i>G</i>	conductance (mhos)
<i>g</i>	acceleration of gravity (cm/s ²)
<i>h</i>	foam thickness
<i>h_c</i>	critical thickness of the foam layer
<i>i</i>	angle of incidence
<i>k</i>	foam spreading coefficient, dimensionless or nozzle coefficient (lpm/kPa ^{1/2})
<i>k_d</i>	foam drainage coefficient, dimensionless
<i>k_e</i>	foam evaporation coefficient, dimensionless
<i>l</i>	length of foam spread
<i>n</i>	refractive index, dimensionless
μ	viscosity (cm ² /s)

\dot{m}_{add}	foam addition rate
\dot{m}_{fuel}	fuel mass loss rate
\dot{m}_{drain}	foam mass loss due to drainage
\dot{m}_{drop}	foam loss rate due to drop-out
\dot{m}_{vap}	foam mass loss rate due to vaporization
ν	kinetic viscosity (cm^2/s)
n_{water}	refractive index of water, dimensionless
n_{foam}	refractive index of foam solution, dimensionless
$n_{\text{concentrate}}$	refractive index of foam concentrate, dimensionless
P_v	vapor pressure of fuel
ρ_{fuel}	fuel density (g/cm^3)
ρ_{foam}	foam density (g/cm^3)
\dot{q}''	rate of heat transfer
\dot{q}_{rad}	rate of heat transfer due to radiation
\dot{q}_{rad}''	radiative heat release rate from pool fire
R	resistance (ohms)
r	angle of refraction
σ	spreading coefficient (dynes/cm) or conductivity (mhos)
$S_{a/b}$	spreading coefficient between liquids a and b (dynes/cm)
T	temperature ($^{\circ}\text{C}$)
t	time (s)
T_i	foam temperature ($^{\circ}\text{C}$)
T_s	fuel temperature ($^{\circ}\text{C}$)
V	volume (cm^3 or l^3)
v_s	spreading velocity of foam (cm/s)

Subscripts

add	addition of foam
drain	drainage of foam
drop	drop-out of foam
rad	radiation
vap	vaporization

Superscripts

\cdot	rate of change, as in \dot{m}
"	per unit area

CHAPTER 5

Foam System Calculations

Joseph L. Scheffey and Harry E. Hickey

Introduction

Foam agent fire protection is especially suited for the control and extinguishment of flammable and combustible liquid-type fire protection problems.

An impressive array of fire protection problems can be properly addressed using foam classification agents. The NFPA *Fire Codes*[®] discuss foam fire protection systems as suitable for the protection of numerous fire protection problems.¹ It is important to note that other classifications of fire extinguishing systems, including dry chemicals, wet chemicals, carbon dioxide, halon, and some special agents, may be suitable for similar hazards.

Table 4-5.1 identifies special hazards that may be suitable for adequate fire protection by different types of foam systems. Each special hazard is cross-referenced to one or more classifications of foam fire protection systems that are identified in NFPA standards as being suitable for the stated hazard. This table is useful for examining the scope and limitations of different types of foam application systems for special hazard fire protection. The referenced standards should be consulted concerning specification and design considerations for each specific problem condition.

Foam agent fire protection systems are suitable for Class A fires in ordinary combustible materials in addition to Class B fires (flammable and combustible liquids). Historically, portable foam fire extinguishers provided important fire protection for both Class A and Class B problems. The dual consideration of evaluating foam fire protection systems for both Class A and Class B fire protection problems is important. This consideration is especially important for mixed occupancy storage, which may be suitably protected by foam spray systems, foam water

sprinkler or spray systems, or closed head sprinkler systems using aqueous film forming foam (AFFF) type foam agents.

Objective Classification of Fire Problems for Foam Agent Fire Protection

The following objectives identify five performance areas for evaluating foam agent fire protection. Performance objectives may be combined for specific problem situations. These objectives form important considerations for the hydraulic design of foam agent systems.

Objective 1: Secure the surface of a flammable or combustible liquid that is not burning.

Flammable and combustible liquids emit vapors that may create a hazard condition. Flammable vapors may be suppressed by providing an adequate foam blanket over the surface area. Flammable liquid spills present a fire hazard. This hazard may be mitigated and/or controlled by the use of appropriate foam agent application.

Objective 2: Control and extinguish fires in flammable and combustible liquid hazardous locations in local areas within buildings.

Flammable and combustible liquids are often stored inside buildings in 55-gal (208-l) drums and other types of containers. These liquids are also used in association with manufacturing processes, industrial machinery, heating equipment, experimental activities, and so forth. The use of flammable and combustible liquids inside buildings may result in liquid spill and fuel ignition. Foam agents are appropriate for protecting localized flammable and combustible liquid problems inside buildings.

Objective 3: Extinguish fires in atmospheric storage tanks.

For nearly 100 years, foam agent fire protection has successfully extinguished fires in outdoor vertical atmospheric storage tanks. This type of protection still represents

Joseph L. Scheffey, P.E., is director of RDT&E at Hughes Associates, Inc., Baltimore, Maryland.

Dr. Harry E. Hickey is retired from the University of Maryland where he served as associate professor, Department of Fire Protection Engineering.

^aConsider in conjunction with automatic sprinklers

one of the most successful uses of foam agents; in fact, foam agent fire protection is the primary means for the proper protection of atmospheric storage tanks. Foam agents have been successfully used to extinguish flammable and combustible liquid fires in atmospheric storage tanks with diameters up to 200 ft (61 m).

Objective 4: Extinguish fires in outdoor and indoor processing areas.

A large variety of industrial processes utilize flammable and combustible liquids. In most processing plants, these liquids pass through pipelines and are captured in holding tanks. Foam agents, properly selected for the specific hazard, are suitable for controlling and extinguishing fires in process equipment. However, foam agents are not suitable for coping with vertical running fires or fires where the flammable material is flowing from an orifice under pressure.

Objective 5: Protect, prevent, control, and extinguish fire problems in selected special hazards.

In addition to the other specified objectives, foam fire extinguishing agents provide appropriate fire protection for numerous special hazard problems. Some important special hazard conditions that are suitable for foam fire protection are included in the following list: (See also Table 4-5.1.)

- Dike areas
- Engine test cells
- Transformers
- Engine rooms
- Laboratories using chemicals
- Aircraft hangars
- Nuclear research reactors
- High density storage of combustibles
- Rubber tires
- Rack container storage of aerosols
- Loading racks
- Automotive service station filling areas
- Ovens and furnaces

Basic Types of Foam System Protection

Foam fire protection systems are divided into four basic classifications by the National Fire Protection Association. Each of these classifications is briefly identified below. Conditions exist where it may be proper to use more than one classification of protection on a given fire problem. Examples of fixed foam systems are covered under supplemental topics later in this chapter on the hydraulic design of low expansion and high expansion foam systems.

Fixed Foam Systems

These systems are complete installations piped from a central foam station, discharging through fixed delivery outlets to the hazard to be protected. Any required pumping equipment is permanently installed. For example, a fixed system for a vertical atmospheric cone roof storage tank would include the following permanently installed

equipment: water supply lines, foam proportioning equipment, a foam liquid storage tank, foam solution lines to the storage tank, all necessary control valves, a tank solution riser pipe, and one or more topside foam chambers. Other equipment may be added based on the complexity of the problem and associated hydraulic conditions.

Semifixed Foam Systems

Two separate classifications of semifixed foam systems are identified below. The first classification is more predominantly used in the United States, although one major oil company does use applications of the second classification. Common to both classifications is the concept that part of the total system is permanently installed and part of the system is provided by portable elements.

The first classification of semifixed systems indicates a type in which the fire hazard is equipped with fixed discharge outlets connected to piping that terminates at a safe distance. The fixed piping installation may or may not include a foam maker. Necessary foam producing materials are transported to the scene after the fire starts and are connected to the piping.

The second classification of semifixed systems indicates a type in which foam solutions are piped through the area from a central foam station, the solution being delivered through hose lines to portable foam makers such as monitors, foam towers, hose lines, and so forth.

Mobile Systems

Mobile systems basically consist of a unit on wheels that transports all of the required equipment and foam liquid necessary for making finished foam. This concept includes any foam producing unit which is mounted on wheels, and which may be self-propelled or towed by a vehicle. These units may be connected to an available water supply or may use a premixed foam solution. The original concept of a mobile foam system was called a "foam house on wheels," a mobile piece of fire apparatus with a UL-rated fire pump, an integral part of the pumping network, a foam liquid tank, and fire hose. Essentially this unit can double as a structural fire suppression unit. NFPA 11C, *Standard for Mobile Foam Apparatus*, covers the specifications and performance criteria for mobile systems.¹

Portable Systems

Portable systems represent a rather economical approach to providing basic foam fire protection for small hazards. This classification considers that the foam producing equipment and materials, including the foam liquid, the proportion device(s), the discharge nozzle, the hose, and other required appliances, are transported by hand from a storage location to the incident scene. While portable systems are simple to operate, they are limited by their foam discharge rate capability; they may also be labor intensive to maintain a continuous foam supply over the required duration of discharge. Foam equipment manufacturers can provide technical information on a range of portable equipment.

Protection of Incipient Spills and Related Hazards

Portable fire extinguishers provide one method of protection for small flammable liquid storage hazards, fuel transfer hazards, and incipient spill fires.

Underwriters Laboratories (UL) has classified and listed chemical foam extinguishers. These extinguishers are now generally considered obsolete since their manufacture in the United States was discontinued in 1969. The National Fire Protection Association recommends that these units be replaced with currently available models.

Aqueous film forming foam agent portable fire extinguishers are used to replace the chemical-type foam extinguisher and provide protection for hazard conditions where this type of extinguishing agent is recommended. Extinguishers of this type are usually available in hand portable models of 2½-gal (9 l) capacity and in wheeled models having a liquid capacity of 33 gal (125 l). These extinguishers have ratings of 3A:20B and 20A:160B, respectively. The AFFF portable model closely resembles the stored pressure water extinguisher except for the special type of nozzle. NFPA 10, *Standard for Portable Fire Extinguishers*, should be consulted concerning the selection and placement of portable extinguishers.¹

Protection for Fixed Roof Atmospheric Storage Tanks

Fixed or cone roof atmospheric storage tanks for the storage of flammable liquids can be protected by fire fighting foam. Several techniques are available for correctly applying foam to a cone roof tank fire. Each technique should be carefully considered with reference to the size of the storage tank, the flammable or combustible liquid being stored in a given tank, and the foam agent classification that is suitable for the hazard. Some fundamental concepts associated with the proper protection for fixed roof atmospheric storage tanks are discussed below. Each individual topic is further developed through design problems on cone roof atmospheric storage tanks.

Foam Monitors

One or more foam monitors may be positioned around the periphery of a cone roof tank to project foam over the tank shell and onto the surface of a burning liquid. This technique has been successfully used on numerous fires. However, NFPA 11, *Standard for Low-Expansion Foam*, clearly indicates that foam monitors may be considered the primary means of protection for fixed roof tanks when the tank is less than 60 feet in diameter. This indication represents a severe limitation on the recommended use of foam monitors for the protection of cone roof tanks.

Foam Handlines

Similar to the concept of providing foam protection with foam monitors, foam handlines may be positioned around the periphery of a cone roof tank to project foam over the tank shell and onto the surface of a burning liquid.

Foam handlines have a flow range from 50 gpm (190 lpm) to less than 300 gpm (1136 lpm) and are only suitable for possible protection of fixed roof tanks with a diameter of less than 30 ft (9 m) and a height not greater than 20 ft (6 m). The selection of foam handline nozzles must be carefully considered to provide the correct total discharge for the flammable liquid problem to be protected.

Foam handlines are very important for supplemental fire protection requirements. Handlines delivering a minimum of 50 gpm (190 lpm) are very useful for extinguishing small spill fires and dike fires in the vicinity of a storage tank. The number of such supplemental foam hose streams is dependent on the diameter of the largest storage tank in the compound to be protected. (NFPA 11 should be consulted.)

Surface Application of Foam

One common and acceptable method of applying foam to the flammable liquid surface of a single roof storage tank is through fixed discharge outlets installed on the tank shell. Two distinct types of foam discharge outlets are available based on the hazard problem and the foam agent. Each type of device may be distinguished as follows:

Type I outlets: These approved discharge outlets will conduct and deliver foam gently onto the liquid surface without submergence of the foam below the flammable liquid surface and agitation of the surface. This type of device was originally intended to apply special alcohol resistant foams to polar solvent fuels. Today, Type I discharge outlets may be used with hydrocarbon fuels. (NFPA 11 should be consulted.)

Two classifications of Type I outlets are commercially available where this device is suitable. A porous tube is a Type I foam discharge outlet. The tube is coarsely woven and rolled up into a foam chamber so that there is an attached end at the foam maker and a free end. When foam is admitted to the tube at the foam chamber, the tube unrolls, dropping into the tank. The buoyancy of the foam causes the tube to rise to the surface, and foam flows out through the pores of the fabric directly onto the liquid surface.

A foam trough represents a second variety of a Type I discharge outlet. The trough consists of sections of steel sheet formed into a chute which is securely attached to the inside of the tank wall so that it forms a descending spiral from the top of the tank to within 4 ft (2 m) of the bottom.

Based upon advances in foam fire protection, porous tubes and foam chutes are rarely installed on new installations for the proper protection of cone roof atmospheric storage tanks.

Type II outlets: These approved discharge outlets do not deliver foam gently onto the liquid surface without submergence of the foam or agitation of the surface. An air foam chamber with a Type II outlet may be attached to the tank shell at the weak seam line. The Type II discharge outlet is positioned on the inside of the tank to permit discharge of the foam down the inside of the tank wall surface onto the flammable liquid surface. The number and discharge capacity of Type II foam chambers for a given

size (diameter) cone roof storage tank are presented in NFPA 11.

Portable foam towers: These devices represent specialized portable equipment that may be fitted with either a Type I or a Type II foam discharge outlet. A tower is a device that is brought to the scene of the fire, erected, and placed in operation for delivering foam to the burning surface of a tank after the fire starts. The Type II discharge outlets are shaped to apply foam inward toward the tank shell. The erection of foam towers adjacent to a burning tank and the operation of the foam towers may present a safety hazard to the personnel working with this equipment. The number of persons required to place foam towers in service is also a problem associated with these devices.

Subsurface Application of Foam

An alternative method of applying foam to a cone roof atmospheric storage tank is through subsurface injection, usually near the base of the tank but above the water bottom in the tank. This application technique involves injecting expanded foam into the flammable liquid near the bottom of the liquid level under controlled velocity conditions. The buoyancy of the foam allows the foam to slowly rise to the flammable liquid surface and spread across the surface to effect fire control and then total extinguishment.

There are three important conditions to consider in subsurface application of foam in fixed and semifixed systems.

1. Subsurface foam application is not considered suitable for the protection of Class IA hydrocarbon liquids.
2. Subsurface foam application is not currently suitable for polar solvent.
3. Subsurface and semisubsurface injection systems are not recommended for *open top* or *covered floating roof* tanks.

Semisubsurface Injection Method

A modified form of subsurface foam injection for cone roof tanks is used in a number of European countries. The modified technique is designated the semisubsurface injection method, based on the equipment used to insert the expanded foam into the tank shell. The semisubsurface injection method has not found any particular application in the United States.

Protection of Floating Roof Storage Tanks

In contrast to single roof tanks, floating roof tanks have a cover or roof over the flammable liquid that floats on the surface of the liquid and moves vertically with the liquid level in the tank. The floating roof may be open to the atmosphere. This physical arrangement of the tank is classified as an "open top floating roof tank." A permanently installed cover may be placed over the entire tank; this second designation is classified as a "covered floating roof tank."

The floating roof has a perimeter seal between the roof cover perimeter and the tank shell. The seal is necessary to prevent flammable vapors from escaping into the atmosphere and collecting over the floating roof. Three types of seal devices may be found on floating roof-type storage tanks: (1) a mechanical shoe seal or a pantograph-type seal, (2) a metal weather shield, and (3) a metal secondary seal.

NFPA 11 should be consulted for a description of each seal device and the physical arrangement of these devices. Some devices also require the use of a foam dam when protected by fixed foam fire protection systems. The requirements for foam dams are also given in the referenced standard.

The fire experience with floating roof tanks appears to be very good. Consequently, fixed foam outlets are not generally required on either open top floating roof tanks or covered floating roof tanks. When an oil company elects to protect these types of tanks or the local fire protection authority requests protection for these types of tanks, three different application techniques may be used for proper protection of open top floating roof tanks. A brief description of each technique follows.

Portable Nozzle Method

The basic fire problem associated with floating roof tanks is a fire burning in the seal area between the cover and the tank shell. Typically, the surface area of this fire is quite small. One technique to extinguish this type of fire is to advance a portable hose line to the top of the tank, supply foam to this hose line, and manually apply foam to the seal area. Personnel operating this hose line should be highly trained in this type of operation and follow established safety practices.

Catenary System Method

The catenary system consists of a series of foam makers at evenly spaced points in the roof near the seal. These foam makers are connected to a common section of piping which in turn is attached to a flexible hose that rides up and down with the access stairway to the roof cover. The stairway is fixed to the top of the tank shell, and the bottom portion of the stairway rides on a set of tracks attached to the floating cover. This arrangement allows the stairway to move both horizontally and vertically as the cover moves with the flammable liquid level.

At the time of a fire, foam solution is pumped under pressure through a vertical pipe and flexible hose to the foam makers. This system can be designed to discharge foam under the seal directly onto the flammable liquid, or foam can be discharged above the seal. Foam equipment manufacturers producing this type of equipment should be consulted for engineering data on design requirements, installation techniques, and hydraulic calculations.

Fixed Foam Maker Method

The fixed foam maker method consists of installing piping around the outside wall of the tank and connecting to it a series of foam makers installed on special mounting shields above the storage tank rim. The circumference of

the tank will determine the number of points needed for foam application. This method requires a foam dam to retain the foam over the seal or weather shield. This dam is normally 12 to 24 in. (305 to 610 mm) in height. Complete construction details of the foam dam may be found in the appendix of NFPA 11.

Covered floating roof tanks generally do not require fixed foam fire protection systems. There may be some cases of substandard installations or locations where local codes require proper protection for this classification of storage tank. The standards for fixed roof tanks should apply where it is required to protect covered floating roof-type tanks.

Protection of Storage or High-Volume Hazards with High-Expansion Foam

High-expansion foam is an agent for the control and extinguishment of both Class A and Class B fires. The classification of foam makes it particularly suitable as a flooding agent for use in confined spaces.

The development and application of high expansion foams for fire fighting purposes started with the work of the Safety in Mines Research Establishment in England concerning the difficult problem of fires in coal mines. It was found that by expanding an aqueous surface active agent solution to a semistable foam of about 1000 times the volume of the original solution, it was possible to force the foam down relatively long corridors, thus providing a means for transporting water to a fire inaccessible to ordinary hose streams. This work was expanded upon by the United States Bureau of Mines immediately after World War II.

Developmental work in the United States on high expansion foam has led to the refinement of specialized high expansion foam generating equipment for fighting fire in confined spaces, for specific applications to fire control problems in both municipal and industrial fire fighting, and for the protection of special hazard occupancies. Medium-expansion foam was developed to cover the need for a more wind-resistant foam than high-expansion foam for outdoor applications.

Concepts and Suitability for Medium- and High-Expansion Foams

Medium- and high-expansion foams are aggregations of bubbles that are mechanically generated by the passage of air or other bases through a net, screen, or other porous medium which is wetted by an aqueous solution of surface active foaming agents. Under proper conditions, fire fighting foams of expansions from 20:1 to 1000:1 can be generated. Such foams provide a unique agent for transporting water to inaccessible places, for total flooding of confined spaces such as basements, and for volumetric displacement of vapor, heat, and smoke. Extensive tests have demonstrated that under certain circumstances high expansion foam, when used in conjunction with water sprinklers, will produce more positive fire control and extinguishment than either extinguishment system by itself; this appears to be especially true with high rack storage of

mixed commodities (e.g., high piled storage of paper stock and mixed storage of Class A and Class B materials). Optimum efficiency of high-expansion foam in any one type of hazard is dependent to some extent on the rate of application and also the foam expansion and stability.

Personal Safety

Persons should not enter a space filled with high-expansion foam without wearing full protective gear, self-contained breathing apparatus, an attached lifeline, and operating in a "buddy" system. A person who is immersed in high-expansion foam can experience disorientation and other psychological and personal discomforts. Foam entering any of the body cavities may cause severe irritation and membrane swelling.

Special Considerations

The proper design and application of high-expansion foam systems are directly related to a number of special system considerations. Special design factors include maximum submergence time and location of foam generating equipment.

A maximum time needs to be specified for filling the enclosed space to the proper depth with expanded foam. The time, expressed in minutes, is a function of the type of combustible material and the arrangement of the combustible material. An important consideration in maximum submergence time is whether stock material should be considered at a constant storage level in the space to be protected. Also of importance is whether the stock is protected by automatic sprinklers in addition to the high expansion foam. The basic objective is to control a developing fire before the fire has an opportunity to spread vertically over the face of a storage pile.

Fixed installations using high-expansion foam fire protection will probably involve the use of customized foam generating equipment to produce the cubic feet per minute requirement of foam discharge. The following points should be observed in the selection and placement of high-expansion foam generating equipment:

1. Two generators positioned remotely from each other are more effective and efficient than a single generator.
2. Generating equipment should be top mounted to avoid back pressures on the foam making equipment. Generators are normally mounted on external towers or special roof supports.
3. Generating equipment should be so positioned as to avoid product-of-combustion air intake. Induced smoke into the generating equipment can significantly reduce the quality and quantity of the foam produced.
4. To effectively dampen convection currents from a developing fire in an area to be protected, the capacity of each required foam generator should be the same.

All of the above information on types and classifications of foam systems serves as the background for actually designing a specific foam fire protection system. Some important limitations concerning both low- and high-expansion foam systems are presented in the following section before some problem examples.

Limitations of Foam Fire Protection Systems

This section discusses both low- and high-expansion foam systems. The limitations of foam fire protection must be addressed relative to each of these two system classifications. The following points should be reviewed during the proper selection and design of foam-type fire protection.

Limiting Factors for Low-Expansion Foam Systems

1. Low-expansion foam application is limited to the extinguishment of horizontal or two-dimensional fire problems. This type of foam application is not suitable for three-dimensional fires.
2. Low-expansion foam systems are limited by foam agent suitability for the defined flammable or combustible liquid. Basically, foam agents are suitable for either hydrocarbon fuels or polar solvents. Alcohol resistant-type foams may be approved for both hydrocarbons and polar solvents.
3. Different types and brands of foam concentrates may be incompatible and should not be mixed in storage.
4. Foam solution consists of 90 percent or more water. Foam system limitations should be evaluated with respect to the proper use of aqueous based agents on flammable materials and the electrical conductivity of the application method.
5. Foam systems are limited by the equipment appliances and devices used to proportion the foam and to deliver the finished foam onto a given hazard or fire problem. Equipment limitations pertaining to flow rate, operating pressure ranges, and proportioning ranges should be carefully considered in the selection and application of foam systems.

Limiting Factors for High-Expansion Foam Systems

1. Medium- and high-expansion foams are finding applications for a broad range of fire protection problems. However, unlike low-expansion foam systems, medium- and high-expansion foam fire protection systems should be specifically evaluated for each type of hazard condition. The fact that each system requires a feasibility study and individual design may be considered a form of limitation when contrasted to the design concepts for low-expansion foam systems.
2. NFPA 11A, *Standard for Medium- and High-Expansion Foam Systems*,¹ states that "under certain circumstances it may be possible to utilize medium and high expansion foam systems for control of fires involving flammable liquids or gases under pressure, but no general recommendations can be made in this standard due to the infinite variety of particular situations which can be encountered in actual practice." This statement is considered to be a design limitation.
3. Medium- and high-expansion foam systems should not be used on fires in the following hazards unless competent evaluation, including tests, indicates acceptability:

- (a) Chemicals, such as cellulose nitrate, which release sufficient oxygen or other oxidizing agents to sustain combustion
- (b) Energized unenclosed electrical equipment
- (c) Water reactive metals, such as sodium and potassium (Na, K)
- (d) Hazardous water reactive materials, such as triethylaluminum and phosphorous pentoxide
- (e) Liquefied flammable gas

Hydraulic Calculation for Atmospheric Storage Tanks Protected by Low-Expansion Foam Systems

This section of the chapter is concerned with the proper design and associated hydraulic calculations for foam fire protection systems protecting atmospheric storage tanks with low-expansion foam systems. The material presented is limited to fixed protection systems using either top mounted foam chambers or subsurface injection, as discussed in the first section of this chapter. A single flammable liquid storage tank problem is presented for developing the appropriate methods and techniques for computing the foam agent requirements, system hardware requirements, and the necessary hydraulic calculations to properly deliver the required rate of foam to the subject hazard. The single example will be calculated using topside application of foam and subsurface injection of foam. This approach permits comparison and contrast of the system design and hydraulic requirements between the two foam application methods.

EXAMPLE 1:

Problem statement. The single outside storage tank depicted in Figure 4-5.1 is to be protected by a completely fixed foam system. The topside foam chamber arrangement is used in this problem. Note that the foam system is connected to a domestic water supply. The water supply curve is illustrated in Figure 4-5.2. For this problem, consider that the water available for the foam system is limited to the street main flow characteristics. A foam system job work sheet and a complete set of hydraulic calculations are to be prepared for this problem.

SOLUTION:

Procedure statements. A systematic outline follows for the proper design and hydraulic assessment associated with the stated problem; reference is made to criteria established in NFPA 11. This standard should serve as a companion guide to the systematic evaluation of each problem scenario. Individual item information is transferred to the referenced problem job sheet (Figure 4-5.3) and the associated hydraulic calculation sheet (Figure 4-5.4).

Problem assessment. In addition to the physical layout of the design problem, information is required on the hazard to be protected. The nature of the hazard drives the problem design. The following steps identify the hazard and standard requirements associated with the hazard:

Figure 4-5.1. Single storage tank with fixed foam system protection. The numbers 1 through 6 in the top portion of the drawing represent the reference points for hydraulic calculations for Example 1.

Step 1: Installation identification.

Refer to Figure 4-5.1. One vertical atmospheric storage tank is positioned in a dike area. The tank is protected by a fixed foam fire protection system and connected to the domestic water supply.

Step 2: Hazard classification.

Flammable liquid atmospheric storage tank

Step 3: Type of protection.

Fixed protection systems

Step 4: Hazard description.

120-ft diameter outdoor cone roof flammable liquid storage tank

Step 5: Flammable or combustible liquid area to be protected.

Calculate the flammable liquid surface area: $\text{Area} = 0.7854d^2$:

$$A = 0.7854(120)^2 = 11,310 \text{ ft}^2$$

Step 6: Flammable liquid or combustible liquid identification.

Gasoline—Sg. 0.72

Step 7: Foam application method.

Top mounted fixed foam chambers—Type II

Step 8: Description, number, and placement of foam application devices.

Several factors need to be simultaneously considered in responding to this step. The description should reference a given manufacturer's foam chamber because the flow and pressure characteristics of the foam chamber *may be* a factor or present options for the system design. Manufacturer's literature and the UL listing of foam equipment should be consulted on this matter.

For proprietary reasons, the selected foam chamber for this problem will be identified as an FMA chamber with an operating pressure range of 40 to 80 psi and a flow range from 300 to 700 gpm of foam solution.

The foam standard (NFPA 11) requires a minimum of two foam chambers for a 120-ft diameter tank. More foam makers may be used based on hydraulic considerations, or economies of scale based on equipment costs. Individual manufacturers of foam equipment must be consulted on these options.

Placement of foam makers should consider equal spacing around the upper tank perimeter and placement of the foam solution feed lines. If possible, maintain constant flow and pressure requirements of each device.

Step 9: Foam agent selected.

A 3 percent fluoroprotein foam is selected for the defined hazard. Note that the type of foam agent selected for a particular design problem may affect other variables or consideration in the foam system design. This caution is reflected in Step 10.

Step 10: Foam solution application rate.

Foam solution application rates for storage tanks containing liquid hydrocarbons should be at least 0.1 gpm/ft² of liquid surface area of the tank to be protected. It should be noted that other types of foam protection (e.g., portable nozzles) may require different application rates. Also, flammable and combustible liquids not classified as hydrocarbons may require different foam solution application rates. Reference should be made to NFPA 11 concerning design application rates.

The foam solution application rate for the stated problem is calculated as follows:

$$\text{rate (gpm)} = 0.1 \text{ gpm/ft}^2 \times 11,310 \text{ ft}^2 = 1131 \text{ gpm}$$

Figure 4-5.2. Water supply curve for fixed foam system for Examples 1 and 2.

However, the total rate is divided equally between two foam makers so it is appropriate to specify a rate of 1132 gpm, or 566 gpm per foam maker.

Step 11: Foam concentrate rate.

The foam concentrate rate is based on the foam agent proportioning rate. A 3 percent fluoroprotein foam is selected for this problem (see Step 9). In other words, 3 percent of the calculated solution rate is the foam concentrate rate. This rate may be determined as follows:

$$\begin{aligned} \text{foam concentrate rate} &= 0.03(\%) \times 1132 \text{ gpm} \\ &= 34 \text{ gpm} \end{aligned}$$

Note that a continuous supply of foam agent (concentrate) must be available at a rate of 34 gpm for the required duration of discharge (see Step 13).

Step 12: Water application rate.

Quite simply, the water application rate is the foam solution rate minus the foam concentrate rate. The water application rate proceeds as follows:

$$\begin{aligned} \text{water application rate} &= 1132 \text{ gpm} - 34 \text{ gpm} \\ &= 1098 \text{ gpm} \end{aligned}$$

The water application rate can also be determined as 97 percent of the "solution" rate when using a 3 percent foam concentrate.

Step 13: Duration of discharge.

A minimum foam solution discharge time is specified in NFPA 11 to control and extinguish a fire in a cone roof atmospheric storage tank. Duration of discharge is dependent on the classification of flammable or combustible liquid and the *type* of discharge outlet. Information for the given problem is contained in NFPA 11. The requirement for protecting gasoline with Type II foam chambers is 55 min. of continuous foam solution discharge.

Step 14: Gallons of foam required.

The required foam supply for any given problem should properly consider a primary supply and a reserve supply. The primary supply is computed by multiplying the determined rate of foam agent required by the duration of discharge as follows:

$$\text{foam agent required} = 34 \text{ gpm} \times 55 \text{ min} = 1870 \text{ gal}$$

The authority having jurisdiction may require that equal quantity of foam be placed in reserve for a second fire.

FOAM SYSTEM JOB WORK SHEET	
Designer: <u>Staff</u>	Sheet: <u>1</u> of: <u>1</u>
Installation identification: <u>Ourville Oil Company</u>	Date: <u>1986</u>
Hazard classification: <u>Flammable liquid atmospheric storage tank</u>

Hazard description: <u>120 ft diameter outdoor cone roof flammable liquid storage tank</u>	
Flammable or combustible liquid area to be protected: <u>11,310 ft²</u>	
Flammable or combustible liquid identification: <u>Gasoline</u> <u>Sq. 0.72</u>	
Foam application method: <u>Type II-fixed chambers</u>	
Description, number, and placement of foam application devices: <u>2-Chambers equally spaced</u>	
Foam agent selected: <u>Fluoroprotein-3%</u>	
Foam solution application rate: <u>0.1 gpm per sq ft or 1131 gpm</u>	
Foam concentration rate: <u>34 gpm</u>	
Water application rate: <u>1098 gpm</u>	
Duration of discharge: <u>55 min</u>	
Gallons of foam required: <u>1870 gallons</u>	
Gallons of water required: <u>60,390 gallons</u>	
Water supply information: <u>See Figure 4-5.2</u>	
Special foam design considerations: _____	

Figure 4-5.3. Foam system job work sheet.

Step 15: Gallons of water required.

The basic procedure follows the concept presented in Step 14. The water requirement is the product of the water rate times the time.

$$\text{water required} = 1098 \text{ gpm} \times 55 \text{ min} = 60,390 \text{ gal}$$

While the above calculation is straightforward, the answer may come as a surprise. Fixed foam protection systems for atmospheric storage tanks require a large quantity of water. The total quantity of water must be available at the site to assure foam delivery over the required time.

Step 16: Special foam system design considerations.

The first 15 steps in this problem analysis focus on fundamental considerations required to determine foam agent and water supply requirements. It is now appropriate to examine a series of special considerations that directly relate to the hydraulic design factors associated

with this problem. Other design factors may be appropriate for different problems. However, the basic considerations outlined below should serve to guide similar calculations for other design problems.

1. Pipe size selection.

Water supply pipe and foam solution pipe may be sized to minimize head loss between identified supply and demand points; pipe may also be designed on the basis of a mean velocity flow in a given section of pipe. A flow velocity of 10 ft per second may be used in the absence of other specific criteria for the determination of both water supply pipe and foam solution pipe. Pipe will be sized in this manner for the stated problem.

2. Valves in the pipe system.

- (a) The laterals of each foam chamber or fixed roof tank should be separately valved outside of the dike installation.

pressure profile, the pump horsepower requirement, and the pump intake-discharge positions with respect to the total installation of pipe.

Hydraulic analysis for Example 1: The supporting documentation above provides a foundation for conducting a hydraulic design for the problem depicted in Figure 4-5.1. The design parameters and associated calculations are presented in sequential steps below. All reference points conform to Figure 4-5.1. Computations are also charted on a hydraulic calculation sheet as shown in Figure 4-5.4.

Step 1: Starting point.

The design objective is to provide each of the two foam chambers with the required pressure to discharge the calculated quantity of foam solution. The stated problem requires a foam maker discharge of 566 gpm at 50 psi. An orifice plate is supplied by the foam equipment manufacturer to provide the correct discharge at the design pressure (50 psi). The design pressure is a function of the range of pressures that can be used with a specific manufacturer's foam chamber.

Step 2: Design tank riser.

The vertical pipe supplying the foam chamber (reference points 1-2) is sized on the basis of a maximum flow velocity of 10 feet per second. The pipe size is determined as follows:

Formula:

$$\text{Velocity} = \frac{0.40852 \times \text{gpm}}{d^2}$$

- Solve for d
- $10 \text{ fps} = \frac{0.4085 \times 566 \text{ gpm}}{d^2}$
- $d^2 = 23.12 \text{ in.}$
- $d = 4.8 \text{ in.}$
- 5-in. pipe is selected. (Note: The authority having jurisdiction may require a 6-in. pipe.)

Step 3: Enter hydraulic calculation from reference points 1-2.

- Friction loss, FL, is determined by the Hazen-Williams formula

$$\text{FL} = \frac{4.52 \times Q^{1.85}}{C^{1.85} \times d^{4.87}}$$

where

$Q = 566 \text{ gpm}$

$C = 100$

$d = 5.047$ (internal diameter of pipe)

$\text{FL} = 0.0420 \text{ psi/ft}$

- Note: All friction losses and head losses are summed in the required pressure column.
- The head loss, H_L , for 48 ft of elevation difference between reference points is computed as follows:

$$H_L = 0.433 \text{ psi/ft} \times 48 \text{ ft} = 20.8 \text{ psi}$$

- The pipe section includes one standard elbow at reference point 2. For hydraulic calculations, fittings are treated as equivalent feet of pipe in accordance with NFPA 13, *Standard for the Installation of Sprinkler Systems*.¹

Step 4: Enter hydraulic calculations from reference point 2 (bottom of tank) to reference point 3.

- The flow is constant (566 gpm) so the pipe size remains the same at 5 in.
- Pipe fittings include a globe valve outside the dike area and a standard tee at reference point 3.

Step 5: Enter hydraulic calculations from reference point 3 to the foam house (reference point 4).

- The total foam solution flow (1132 gpm) is supplied by line 2-3.
- Determine the pipe size based on a maximum flow velocity of 10 ft/s.

$$3. \text{ velocity} = \frac{0.4085 \times \text{gpm}}{d^2}$$

$$10 \text{ fps} = \frac{0.4085 \times 1132 \text{ gpm}}{d^2}$$

$$d = 6.8 \text{ in.}$$

- An 8-in. pipe is recommended between the foam house and reference point 3.
- The friction loss in the stated line includes the linear distance plus the gate valve.
- It should be observed that the required pressure at the discharge side of the foam house is 90.0 psi.

Step 6: Enter the hydraulic calculations in the foam house.

- To the left of the top view, bottom half, Figure 4-5.1, is an illustration of the foam proportioning ratio controller inserted into the water line. The proportioning device selected for this problem has a friction loss of 4 psi at a solution flow rate of 1132 gpm. Foam equipment manufacturers should be consulted on head loss characteristics for specific devices. The ratio controller takes up a lineal distance of 2 ft leaving 18 ft of straight run pipe in the foam house.
- The calculations provided do not include provisions for a water pump.

Step 7: Enter the hydraulic calculations from the foam house to the street main.

- The flow rate in line 5-6 is 1098 gpm. Note the change in friction loss.
- An 8-in. main is used to connect the street main to the foam house.

Step 8: Summary.

- The water demand requirement at reference point 6 is 1098 gpm at 97.0 psi.
- The hydraulic demand has been calculated to provide a foam solution flow of 566 gpm at 50 psi for each designated foam chamber.
- The water supply curve referenced as Figure 4-5.2 shows 1098 gpm available at 53 psi. Therefore, a water

pump is required in the pump house to boost the pressure from 50 psi (loss of pressure from reference points 6 to 5 is approximately 3 psi) to 97 psi or approximately 50 psi. A pump can be engineered for this specific application.

EXAMPLE 2:

Overview statement. The flammable liquid storage tank presented as Example 1 is also presented as Example 2; only the method of fire protection changes. Example 2 considers the depicted 120-ft diameter storage tank to be protected with subsurface application of foam to the described hazard. The subsurface application technique requires new design considerations with respect to foam equipment and hydraulic calculations. The following principles should be observed in the design of subsurface application foam systems:

1. Foam solution is expanded outside of the dike area by a "high back pressure" foam maker. A typical foam expansion of 4:1 is achieved at the foam maker.
2. The expanded foam flows through a carefully designed pipeline from the foam maker to an opening in the tank shell just above the water bottom in the tank. In accordance with NFPA 11, *Standard for Low-Expansion Foam*, the foam velocity at the point of discharge into the tank contents shall not exceed 10 ft/s for Class IB liquids and 20 ft/s for other type liquids. An excessive input velocity to the tank can cause the foam to be saturated with fuel pickup.
3. Foam entering the product rises to the fuel surface by natural buoyancy.

Problem statement. A single outside storage tank illustrated in Figure 4-5.5 is to be protected by a completely fixed foam system. The subsurface foam application method is used for this problem. The Figure 4-5.2 water supply curve is to be applied with this problem. Consider that the water available for the foam system is limited to the street main flow characteristics. A foam system job work sheet and a complete set of hydraulic calculations are to be prepared for this problem.

Procedure statements. A systematic outline follows for the proper design and assessment associated with Example 2. Reference is made to criteria established in NFPA 11 by paragraph reference. NFPA 11 should serve as a companion guide to the systematic evaluation of each problem scenario. Individual item information is transferred to the referenced problem sheet (Figure 4-5.6) and the associated hydraulic calculation sheet (Figure 4-5.7).

Problem assessment. In addition to the physical layout of the design problem, information is required on the hazard to be protected. The nature of the hazard is identical to Example 1; only the method of protection changes. Some of the following steps are repeated for maintaining a sequence to the problem solution. New material will be explained in detail. Calculations for similar material are referenced to Example 1.

Step 1: Installation identification.

Refer to Figure 4-5.5. One vertical atmospheric storage tank is positioned in the dike area. The tank is pro-

Figure 4-5.5. Subsurface application foam system with reference points used in Example 2.

ected by a fixed subsurface injection foam fire protection system and connected to the domestic water supply.

Step 2: Hazard classification.

Flammable liquid atmospheric storage tank

Step 3: Type of protection.

Subsurface application to fixed roof storage tanks (Re: NFPA 11, Section 3-2.4)

Step 4: Hazard description.

120-ft-diameter outdoor cone roof flammable liquid storage tank

Step 5: Flammable or combustible liquid area to the protected.

11,310 ft² (See Step 5—Example 1)

Step 6: Flammable liquid or combustible liquid identification.

Gasoline—Sq. 0.72

FOAM SYSTEM JOB WORK SHEET

Special foam design considerations: <u>Foam injection piping to be sized for a maximum fluid velocity of 10 fps</u>	

Figure 4-5.6. Foam system job work sheet.

Step 7: Foam application method.

Subsurface application to a liquid hydrocarbon (Re: NFPA 11, Section 3-2.4)

Step 8: Description, number, and placement of foam application devices.

Several equipment design variables must be considered simultaneously in this step. Again, reference must be made to a specific foam manufacturer's equipment offerings or the conduct of a comparative analysis between two or more manufacturers of suitable equipment. The manufacturer's literature and the UL listing of foam equipment should be consulted on this matter.

The following substeps outline the key features of the design to be evaluated and computed at this overall step in the design development. Each substep may impact

on other substeps and therefore all substeps must be evaluated before selecting a set of equipment and associated calculations.

Step 8(a): Velocity of approach into the storage tank.

Gasoline is a Class IB liquid, and therefore the injection velocity of the expanded foam into the product tank should not exceed 10 ft/s. This does not mean that the velocity of foam between the foam maker and the injection point has to be controlled to a maximum of 10 ft/s. Rather, the foam velocity at the physical point of entry to the product is the key consideration.

Remember that the foam is expanded at the entry point to the product. Special flow curves must be examined to determine velocity characteristics with expanded foam. These curves are not available in the current edition

diameter of the pipe to establish uniform velocity. Therefore, a straight run of 10-in. pipe at least 17 ft in length is necessary.

The foam outlet is not required to be at the tank shell. Note that the 10-in. pipe is actually inserted into the tank. This design approach permits economizing the pipe sizes between the tank and the high back pressure foam maker. The high back pressure foam maker is to be positioned outside of the dike area. A gate valve and a check valve are installed adjacent to the tank shell.

Step 9: Foam agent selected.

A 3 percent fluoroprotein foam is selected for the defined hazard. The foams should be listed for subsurface injection.

Step 10: Foam solution application rate.

For tanks containing liquid hydrocarbons, the foam solution rate must be at least 0.10 gpm/sq ft of liquid surface area of the tank to be protected. The maximum rate must be 0.20 gpm/sq ft. (Re: NFPA 11, Table 3-2.4.3.)

The foam solution application rate for Example 2 is the same foam solution rate calculated for Example 1; the application rate is 1132 gpm.

Step 11: Foam concentrate rate.

The foam concentrate rate is determined in the same manner as set forth for Example 1. Using a 3 percent fluoroprotein foam, the requirement is 34 gpm for a total solution rate of 1132 gpm. This requirement impacts on Step 14 of this example.

Step 12: Water application rate.

The water application rate is also determined in the same manner as set forth in Example 1. The water application rate is the foam solution rate minus the foam concentrate rate: the water rate is 1098 gpm.

Step 13: Duration of discharge.

The minimum discharge time for subsurface application of foam is identical to the requirement for Type II application. (Re: NFPA 11, Section 3-2.4.3.) Gasoline product requires a total discharge time of 55 minutes.

Step 14: Gallons of foam required.

The gallons of foam required is computed in the same manner as set forth in Example 1. The primary foam supply is computed by multiplying the determined rate of foam agent by the duration of flow, which indicates a requirement of 1870 gal.

Step 15: Gallons of water required.

The water requirement is the product of the water rate times the discharge time, or 60,390 gal.

Step 16: Special foam system design considerations

One special design consideration is presented in Step 8(a) and involves the pipe requirements for injecting foam

into the base of a storage tank under controlled velocity conditions. Other special conditions that apply specifically to subsurface injection of foam to storage tanks are given below.

1. *High-back-pressure foam maker.* A high-back-pressure foam maker is designed for capability to make foam and discharge the foam against considerable back pressure. The high-back-pressure foam maker selected for the example problem is designed to operate satisfactorily at inlet pressures of 100 to 300 psi and produce foam of 2:4 expansion against back pressures not exceeding 40 percent of the inlet pressure. With an inlet pressure of 150 psi, for example, 60 psi is available at the discharge for forcing the foam through a hose and/or piping into the storage tank and to overcome the fuel head in the tank. Manufacturers of high-back-pressure foam equipment should be consulted for obtaining flow and pressure characteristics and back pressure limitations. Two high-back-pressure foam makers are used with Example 2. The two foam makers are located in the foam house and are arranged for parallel operations. (See Figure 4-5.5.)
2. *Pipe size selection.* Expanded foam flowing in conduit (pipe) does not follow the head loss characteristics expressed in the Hazen-Williams formula. A set of flow curves have been developed for determining friction loss for expanded foam discharge by a high-back-pressure foam maker.² A set of these curves is provided in the Appendix to this chapter with the permission of National Foam System, Inc. (See Figures 4-5A.1 and 4-5A.2.)
A flow velocity of 10 ft/s is used for the determination of pipe sizes flowing foam solution and water. If necessary, water supply pipe and foam solution pipe may be sized to minimize head loss between identified supply and demand points.
3. *Valves in the pipe system.* (Re: NFPA 11, Section 3-2.6.3.) For subsurface application, each foam delivery line must be provided with a valve and check valve, unless the latter is an integral part of the high-back-pressure foam maker or pressure generator to be connected at the time of use. When product lines are used for foam, product valving must be arranged to ensure foam enters only the tank to be protected.
4. *Foam proportioner selections.* The practices and procedures outlined in Example 1 apply to Example 2. However, to accommodate the pressure requirements associated with a high-back-pressure foam maker, a balanced proportioner would appear to provide the best level of constant proportioning over designated pressures.
5. *Water pumps.* The required pressure at the intake to the high-back-pressure device is approximately 150 psi. The static pressure on the water system is only 75 psi. Therefore, a water pump is required to boost the water-solution pressure in the foam hose. The most efficient approach to designing a required water pump installation is to select or design a pump-driver combination that will boost the available residual pressure to the required residual pressure at the demand flow. In

other words, with the right capacity pump, the driver horsepower is calculated to raise the pressure over the differential range. Other criteria must be used if a standard fire pump is required by the authority having jurisdiction.

Hydraulic analysis for Example 2: The information above provides a foundation for conducting a hydraulic design for the problem depicted in Figure 4-5.5. The design parameters and associated calculations are presented in sequential steps below. All reference points conform to Figure 4-5.2. Computations are also charted on a hydraulic calculation sheet, designated as Figure 4-5.7.

Step 1: Precalculation for high-back-pressure foam maker. The hydraulic characteristics of the high-back-pressure foam maker must be considered before the computations start. A high-back-pressure foam maker delivering 550 gpm at 150 psi is selected for each finished foam line to the tank.

- a. Determine a K value for the specified unit:

$$Q = K\sqrt{150}$$

$$K = 44.9$$

- b. Required discharge per foam maker is 566 gpm.
- c. Determine the required input pressure for a flow of 566 gpm:

$$566 \text{ gpm} = 44.9\sqrt{P}$$

$$P = 159 \text{ psi}$$

- d. The available back pressure becomes 40 percent of 159, or 64.0 psi.

Remember: Head loss converted to psi between the foam maker discharge and the foam discharge outlet to the tank, plus the product head, must not exceed 64 psi.

Step 2: Size foam injection pipe to tank.

Step 8(a) under problem assessment for Example 2 establishes that a 10-in. pipe is required to maintain a flow velocity under 10 ft/s.

Step 3: Determine head loss from production storage.

Finished foam rising through the product must overcome the product head. Gasoline is the product for this series of problems with a $Sq. = 0.72$.

$$\text{psi loss} = 48 \text{ ft} \times 0.433 \text{ psi/ft} \times 0.72 \text{ Sq.}$$

$$\text{psi loss} = 15$$

Step 4: Size the foam supply line from the tank shell to the foam house.

The stated pipe is selected on the basis of the allowable friction loss of 64 psi minus the product head loss which equals 15 psi. Therefore, 49 psi (64 psi – 15 psi) can be dissipated from the tank to the foam maker through 500 ft of pipe and be used as an initial estimator; the flow rate is 2264 gpm. Figure 4-5.8 indicates a 6-in. pipe is required. A 6-in. check valve and a 6-in. gate valve will be installed on the foam supply line adjacent to the tank in

Figure 4-5.8. Typical four-bay warehouse complex.

the dike area. The required friction loss calculations are presented in Figure 4-5.7.

Calculation note: Subsurface foam system hydraulics actually divide into two separate calculation sets, as follows: (1) the hydraulics between the high-back-pressure foam maker and the storage tank and (2) the hydraulics between the street main supply and the high-back-pressure foam maker.

Step 5: Street main to fire pump calculation.

The lateral supply line will be designated at a velocity of 10 ft/s. Recall that only water is moving through this line.

$$\text{Velocity} = \frac{0.4085 \times \text{gpm}}{d^2}$$

a. Solve for d

b. $10 \text{ ft/s} = \frac{0.4085 \times 1098 \text{ gpm}}{d^2}$

c. $d^2 = 44.85 \text{ in.}$

d. $d = 6.69 \text{ in.}$

e. Use an 8-in. pipe

Step 6: Piping in foam hose.

8-in.-diameter pipe will be used in the foam house to connect between the water pump, the foam proportioner, and the high-back-pressure foam maker.

High-Expansion Foam Systems

Many of the fundamental hydraulic concepts presented with low-expansion foam system design problems also apply to high-expansion foam systems. Some similarities and differences between the hydraulic design for high-expansion foam systems and low-expansion foam systems are presented in Table 4-5.2. In this analysis, a low-expansion foam system using top-mounted foam

chambers is compared to an elevated high-expansion foam generator installation.

Example 3 considers the use of a high-expansion foam system in conjunction with automatic sprinkler protection for fire control and suppression in a specified government warehouse. Be careful to note the generator flow rates, foam concentrate rates, and water supply rates. One of the advantages for considering high-expansion foam for the protection of confined space hazards is the low rate of foam application and associative water rate when compared to other aqueous types of systems.

EXAMPLE 3:

Problem statement. An owner has elected to protect a number of warehouse complexes with a combination of automatic sprinklers and high-expansion foam. A typical four-bay warehouse complex is illustrated in Figure 4-5.8. The storage item is crude rubber piled 12 ft 6 in. high in 2000 ft² pile areas. The installed sprinkler design is 0.2 gpm/ft². The location of the high-expansion foam generators is illustrated on the 12-in. wide brick fire walls. Each foam generator is equipped with a set of remote-controlled baffels that permits directional flow of foam into adjacent fire areas. Custom generators are used that have a foam solution rate requirement of 1.83 gpm per 1000 ft³ of foam production. Three percent foam proportion with a UL-listed high-expansion foam is used for this system.

Procedure statements. The key consideration in high-expansion foam system design is the proper sizing of the foam-generating equipment to be used for a specific application. A special job work sheet is provided to systematically calculate the foam generation requirements. (See Figure 4-5.9.) Individual item information is transferred from the referenced job sheet to the associated hydraulic calculation sheet. (See Figure 4-5.10.) Reference is made to criteria established in NFPA 11A, *Standard for Medium- and High-Expansion Foam Systems*. This standard should serve as a companion guide to the systematic evaluation of the warehouse protection problem.

Problem assessment. The fundamental considerations of the hazard to be protected establish the elements of the

Table 4-5.2 Comparison of Design Criteria for Low-Expansion and High-Expansion Foam Systems

Design/Hydraulic Step Function	Low-Expansion Foam System—Top Chamber	High-Expansion Foam System—Top Generator
Starting point	Foam chamber(s)	Foam generator(s)
Second determination	Foam solution requirement per chamber (gpm)	Expanded foam requirement per chamber (cfm)
Third determination	Foam solution delivery rate between foam maker and foam house	Same determination
Fourth determination	Size pipe from foam maker(s) to foam house	Size pipe from foam generator(s) to foam house
Fifth determination	Determine type and size of foam proportioner	Same determination
Sixth determination	Determine hydraulic requirements in foam house	Same determination
Seventh determination	Evaluate water supply/demand requirement at foam house	Same determination
Eighth determination	Assess requirement for water pump in foam house; recalculate hydraulic requirements in foam house	Same requirement

Figure 4-5.9. High-expansion foam system job work sheet.

problem design. In the case of high-expansion foam, some subjective criteria needs to be established due to the lack of specific information in NFPA 11A. Subjective criteria will be fully noted in the problem development. The following steps identify the hazard and the standard calculations associated with the hazard.

Step 1: Installation identification.

Refer to Figure 4-5.8, a defense materials warehouse.

Step 2: Hazard classification.

High density combustibles. Note: The actual storage material is crude rubber provided in irregular flat sheets.

This commodity is not specifically specified in Table 2-3.4 of NFPA 11A. Therefore, some judgment must be made when selecting foam submergence time as required for the calculations below.

Step 3: Type of protection.

The warehouse is protected by a drypipe automatic sprinkler system with a maximum discharge capability of 0.2 gpm/ft² over 2000 ft². This discharge density is not considered adequate protection for crude rubber in 2000 ft² piles. The automatic sprinkler protection is supplemented by a fixed high-expansion foam system. The foam generators are mounted on the coping section

merge the hazard in a defined period of time. This determination can be accomplished by applying a rate formula developed by the NFPA Foam Committee. The formula is given in Figure 4-5.9, under sub-item 6. The formula can be applied by first calculating and then assigning values to the formula variables.

1. *Submergence volume* (Re: NFPA 11A, Section 2-3.3).

$$\text{Floor area: } 200 \text{ ft} \times 200 \text{ ft} = 40,000 \text{ ft}^2$$

Foam Depth:

$$(a) 1.1 \times \text{height} = 1.1 \times 12.5 = 13.75 \text{ ft}$$

$$(b) \text{Height} + 2 \text{ ft} - 12.5 \text{ ft} + 2 \text{ ft} = 14.5 \text{ ft}$$

Use the larger of the two values or 14.5 ft for calculations.

Volume = area \times depth

$$\text{Volume} = 40,000 \text{ ft}^2 \times 14.5 \text{ ft} = 580,000 \text{ ft}^3$$

(See Step 4—no deduction is made for stock)

2. *Submergence time* (Re: NFPA 11A, Section 2-3.4).

5 minutes for high density materials with sprinkler protection

3. *Rate of foam breakdown for sprinklers* (Re: NFPA 11A, Section 2-3.5.2).

(a) Discharge from sprinklers:

$$Q = 0.2 \text{ gpm/ft}^2 \times 2000 \text{ ft}^2 = 400 \text{ gpm}$$

(b) Apply formula:

$$R_s = 10 \text{ cfm} \times 400 \text{ gpm} = 4000 \text{ cfm}$$

4. *Compensation for shrinkage*. Set at 1.15 as a constant (Re: NFPA 11A, Section 2-3.5.2).
5. *Compensation for leakage*. Use 1.1 to allow for some leakage around doors (Re: NFPA 11A, Section 2-3.5.2).
6. Apply formula:

$$\text{cfm} = (v/T + R_s) \times C_N \times C_L$$

$$\text{cfm} = (580,000 \text{ ft}^3/5 \text{ min} + 4000 \text{ cfm}) \times 1.15 \times 1.1$$

$$= 151,800 \text{ cfm}$$

Note: The foam breakdown from sprinklers is a relatively small value compared to the total cfm rate.

- Step 6:** Description, number, and placement of generators.

Custom-built foam generators will be required for this problem. Each generator will have a capacity of 80,000 cfm with a foam solution rate of 146 gpm. (See given information with problem statement.) Five generators will be required to protect the entire warehouse. Generators mounted on interior fire walls will be equipped with baffles arranged to discharge foam into either adjacent compartment; electrical controls will be operated from the foam house. Generators are actually mounted 22 ft above the finished floor.

- Step 7:** Foam solution rate.

The foam solution rate per generator is given in Step 6. The solution rate requirement is 1.83 gpm per 1000 ft³ of foam production.

$$\text{Solution rate} = 80,000 \text{ ft}^3/1000 \text{ ft}^3 \times 1.83 \text{ gpm} = 146 \text{ gpm}$$

Two generators require 292 gpm.

- Step 8:** Foam concentrate rate.

The foam selected for this problem proportions at 3 percent. Therefore, the concentrate rate is 3 percent \times 292 gpm = 9 gpm.

- Step 9:** Duration of discharge.

Duration of discharge for the foam systems should be checked with the authority having jurisdiction. A basic minimum discharge time is 15 minutes of continuous operation.

- Step 10:** Gallons of foam required.

It is assumed that enough foam will be placed in storage to meet both a main and a reserve requirement: 9 gpm \times 15 min \times 2 = 270 gal.

- Step 11:** Gallons of water required.

The primary water supply must provide a rate of 283 gpm for 15 minutes or 4245 gal. A like amount must be supplied for the secondary demand.

- Step 12:** The problem considers that the water supply to the foam house is adequate to meet the calculated demand for the system.

- Step 13:** The foam system is arranged to be activated by the automatic sprinkler system when the drypipe valve trips due to a sprinkler head operating. The system can also be activated manually.

Hydraulic analysis for Example 3

- Step 1:** The inlet pressure requirement for the foam generator is 50 psi.

- Step 2:** The foam solution line supplying each foam generator and the riser pipe to the top of the fire wall are sized on the basis of a maximum flow velocity of 10 ft/s.

$$\text{Velocity} = \frac{0.4085 \times \text{gpm}}{d^2}$$

- 10 fps = $\frac{0.4085 \times 146 \text{ gpm}}{d^2}$

- $10d^2 = 59.64$

- $d^2 = 5.96$

- $d = 2.44$

- Use a 3-in. pipe

Since the same size pipe is used from the foam generator to ground level, the hydraulic analysis can go from reference point 1 to reference point 3. The elevation head to be considered is 22 ft.

- Step 3:** The flow and pressure demand at the base of each riser supplying a foam generator is the same, since the generator sizes are equal. It is necessary to calculate a flow constant at this location so the pressure points upstream can be correctly adjusted for higher pressure values developed by friction loss between supply points. The demand constant is calculated as follows:

$$\text{(reference point 3)}$$

$$Q = K\sqrt{P}$$

$$146 \text{ gpm} = K \sqrt{68.6}$$

Step 4: The ground-level cross-main connecting the foam generator risers is sized on the basis of a maximum flow velocity of 10 ft/s. The flow from two generators is used for the flow computations.

$$\text{Velocity} = \frac{0.4085 \times \text{gpm}}{d^2}$$

- a. $V = \frac{0.4085 \times 292 \text{ gpm}}{d^2}$
- b. $10d^2 = 119.282$
- c. $d^2 = 11.928$
- d. $d = 3.45$
- e. Use a 4-in. pipe

Step 5: Determine the actual flow characteristics for the high-expansion foam generator at reference point 4.

Use the K value (constant) determined in Step 3 to calculate the actual supply to the second foam generator at reference point 4. The new pressure at the riser base is (reference point 6) 70.7 psi from the hydraulic calculation sheet. The higher pressure is used with the K value to determine the actual flow for the second high-expansion foam unit.

$$Q = K\sqrt{P}$$

$$Q = 17.6\sqrt{70.7}$$

$$Q = 148$$

The actual flow increases by 2 gpm for the second generator.

Step 6: Determine the flow and pressure requirements at the foam house. Determine the friction loss for the total flow back to the foam hose and add in 4 psi for the foam proportioner.

Step 7: System demand.

The final system demand is 294 gpm at 90.0 psi at the foam proportioner inlet to supply the two high-expansion foam generators. The water supply to the foam house must meet this demand.

The Advent of Class A Foams

Class A foams have been used extensively in wild-land fire suppression. The success of Class A foam for the confinement, control, and extinguishment of natural cover fuel fires suggests that this type of foam may be effective for structural fire protection as foam solution in fire streams. Initial research has been conducted to quantify the fire fighting efficiency of Class A foams to improve the operating efficiency of these foams when compared to plain water fire streams. The National Fire Protection Research Foundation has published research findings on Class A foam effectiveness: one in December 1993³ and one in November 1994.⁴ A synopsis of the findings are presented below.

The National Fire Protection Research Foundation (NFPRF) sponsored a research program with Underwriters Laboratories, Inc. (UL), to investigate the effectiveness of Class A foams by means of three discharge devices: (1) a standard spray nozzle, (2) an air-aspirated spray nozzle, and (3) by injecting compressed air into the Class A foam solution. This research investigation has two objectives: (1) to develop test data related to the fire fighting effectiveness of Class A foam solutions as compared to water only and (2) to conduct laboratory analysis of the Class A foam concentrate used in the performance tests.

Briefly, the initial fire test plan included a Class 20A wood crib fire with foam solution concentrates selected at 0.1, 0.3, and 0.5 percent. Adjunct variables included nominal expansion ratios of 5 for a standard nozzle at 15 gpm, 7.5 for an air-aspirated nozzle at 15 gpm, and 7.5 for injecting compressed air into the Class A foam solution.

The wood crib fire tests were conducted at UL's test facility located in Northbrook, Illinois, and are reported in the December 1993 publication.

In summary, the initial set of fire tests provide support of the following conclusions by the Technical Advisory Committee (TAC):

- Handheld hoselines supplied with Class A foam solutions provide enhanced fire fighting performance when compared to handheld hose lines supplied with water only.
- The best foam quality, as measured by retention and exposure protection tests, was achieved with compressed air foam.
- Results of the wood crib fire tests indicated superior characteristics in terms of fire control time for Class A foams when compared to water application only.
- Fire tests conducted with the air-aspirated test nozzle had the longest reignition times, while tests conducted with the Compressed Air Foam had the lowest crib weight losses.
- Exposure protection test results demonstrated the ability of the Class A foam to lengthen the ignition time of a combustible surface when compared to cribs protected by the same rate and duration of water.
- Retention-of-weight tests demonstrated that wood cribs exposed to Class A foam retain more weight than cribs treated with water.

The testing program outline above was very controlled in a laboratory setting. Foam applications were not subjected to many real world variables that could include wind, weather conditions, fuel geometry, pre-burn times, and human factors in the foam application. Despite such conditions, the reported testing program clearly supports a number of advantages for using Class A foam on structural type fires.

The Phase II research project report of 1994 reviews the conduct of structural fire suppression tests. These tests were also conducted at UL's test facilities in Northbrook, Illinois. A test cell measuring 30 by 36 by 30 ft was used for the Class A foam comparative analysis tests. Two fuel package scenarios were used as follows:

- The Series I UL 1626 residential fuel package consisted of a wood crib and simulated furniture positioned in one corner of the enclosure.
- The Series II fuel package consisted of a corner upholstered sofa scenario.

Fire test monitoring of the enclosure included measurements of the Class A foam solution or water flow rate; room temperature gradients at distances of 2, 9, 18, 24, 33, 48, and 72 in. below the ceiling; rate of heat release; oxygen content; smoke density; and heat flux. In each test series, observations were made of fire knockdown and damage to the walls of the enclosure and the fuel package.

Upon ignition, the fuel package was allowed to burn until flashover was achieved in the enclosure. Five seconds after flashover, a water application or a Class A foam solution was applied to suppress the fire using either a direct or indirect application method. The direct application method consisted of discharging the agent directly onto the walls of the enclosure and the fuel package. In contrast, the indirect application method consisted of discharging the agent first onto the ceiling and walls and then onto the fuel package.

The 1994 Class A Foam Study Report divides the summary information according to the Series I and II testing programs. The Series I abbreviated findings are summarized as follows:

- Class A foam using a direct application method took less time and quantity of agent to lower heat release to 500 KW than plain water.
- Class A Compressed Air Foam (CAF) using the indirect application method was more effective in reducing heat release values down to 500 KW.

The Series II abbreviated findings are limited to the following selective observations:

- The test results using Class A foam solutions generally provided for a reduced amount of total heat release from the fire and less damage to the sofa.
- Class A Compressed Air Foam applied at 7 gpm using the direct application method demonstrated the shortest time period and the lowest quantity of agent required to reduce the rate of heat released to 500 KW.
- The direct application method provides for a reduced amount of total heat release and less damage to the sofa when compared to the same tests conducted using the indirect application method.

Both reports recommend additional research on the application of Class A Foams with special attention given to hardware devices that include handheld fixed nozzles, proportioning equipment, and foam-generating equipment.

Additional research has been conducted by the National Institute of Standards and Technology.⁵ The effectiveness of Class A foams on Class A and Class B fire threats were characterized. Four representative Class A foams were chosen for evaluation. A series of Class B fire

suppression tests were conducted in conformance with UL 162 *Standard for Foam Equipment and Liquid Concentrates*. These tests utilized a 4.6-m² (50-ft²) heptane pool fire and consisted of the suppression of the fire and then testing for reignition and burnback resistance. Agent was applied at 2.44 and 4.88 lpm/m² (0.06 and 0.12 gpm/ft²), which is one and one-half and three times the rate required by the standard for AFFF application. The higher flow rates were used because the agents could not extinguish the fire at the standard AFFF application rate. The four agents had fire knockdown (control) times similar to AFFF, but two of the agents did not completely extinguish the fire in all the tests. AFFF had a higher resistance to burnback and longer time to re-ignition than the other four agents.

Full-scale fire experiments were conducted with 92.9-m² (1000-ft²) gasoline pool fires. Agent application was made with a 454 lpm (120 gpm) hose stream (i.e., 4.88 lpm/m² [0.12 gpm/ft²]). Two application techniques were used with each of the four agents in the large-scale tests. One application was made with a self-aspirating tube nozzle, and one application was made with a non-aspirating adjustable fog nozzle. AFFF and water were used as benchmark agents for these tests. Plain water could not extinguish this fire. AFFF exhibited better fire control and extinguishment characteristics, and substantially better burnback resistance, than those of the Class A foams.

In tests conducted for the U.S. Air Force, the Naval Research Laboratory assessed a compressed air foam system for possible use for aircraft hangar scenarios involving JP-8 fuel.⁶ The breadboard unit used AFFF as the fire extinguishing agent. It was found that a commercial off-the-shelf non-air-aspirating nozzle was as effective as the air-aspirating nozzle provided with the unit. Air injection for aeration of the AFFF stream before discharge from the nozzle was found to be unnecessary.

Nomenclature

C	Hazen-Williams coefficient (constant)
C_L	foam leakage correction factor
C_N	normal foam shrinkage factor
d	internal pipe diameter (in.)
FL	friction loss (psi/ft)
K	nozzle discharge coefficient (gpm/psi ^{1/2})
Q	flow (gpm)
R	total foam generator capacity (cfm)
R_s	total rate of foam breakdown [$S \times Q$] (cfm/gpm)
S	rate of foam breakdown by sprinklers per gpm of sprinkler discharge (cfm/gpm)
T	submergence time (min)
V	velocity (ft/s)
v	submergence volume (ft ³)

CHAPTER 6

Halon Design Calculations

Casey C. Grant

Introduction

Halogenated agent extinguishing systems are a relatively recent innovation in fire protection, but, despite this, they already face extinction. As of January 1, 1994, the global production of fire protection halons in many countries ceased.

The obvious question is, "Why maintain this chapter on halon design calculations?" Although global production of fire protection halons essentially ceased on January 1, 1994, it is expected that this technology will continue for an extended period of time to address the modification and maintenance of existing systems, and new essential systems that will use recycled surplus stock.

The stratospheric ozone layer depletion issue is a problem confronting the global community unlike any other. Late in 1987, the United States and 24 other countries (including the European Economic Community) signed the Montreal Protocol to protect stratospheric ozone.¹ Originally, the protocol restricted the consumption of ozone-depleting chlorofluorocarbons (CFCs) to 50 percent of the 1986 use levels by 1998, and halon production was to be frozen in 1993 at 1986 production levels. But the November, 1992, Copenhagen revision to the Montreal Protocol accelerated this, such that all production of the chemicals ceased worldwide as of January 1, 1994.

The Montreal Protocol is based on unprecedented trade restrictions and is the first time nations of the world have joined forces to address an environmental threat in advance of fully established effects. The trade restrictions concern nations not participating in the agreement (the nonsignatories). Within one year of the agreement taking effect, each party shall ban the import of the bulk chemicals from the nonsignatory nations. About four years after

the effective date of the agreement, imports of products containing the identified chemicals from nonsignatory nations would be banned. Within five years, products made with the chemicals (but not containing them) would be banned or restricted. This is truly significant since many products, including many electronic components, are currently manufactured using CFCs.

Today, high technology demands new and different fire protection techniques for which halon systems have proved ideal.

Characteristics of Halon

Background, Definition, and Classifications of Halon Compounds

Although there are a variety of methods available for applying halogenated agents, the most common is the total flooding system. The most popular halogenated agent is Halon 1301, with its superior fire extinguishing characteristics and low toxicity. Halogenated agent extinguishing systems are a promising tool for the fire protection engineer and have great potential for solving many of our fire protection problems now and in the future.

Halogenated extinguishing agents are hydrocarbons in which one or more hydrogen atoms have been replaced by atoms from the halogen series: fluorine, chlorine, bromine, or iodine. This substitution confers flame extinguishing properties to many of the resulting compounds that make them ideal for certain fire protection applications.

The halogenated extinguishing agents are currently known simply as halons, and are described by a nomenclature that indicates the chemical composition of the materials without the use of chemical names. This simplified system was proposed by James Malcolm at the U.S. Army Corps of Engineers Laboratory in 1950 and avoids the use of possibly confusing names.² The United Kingdom and parts of Europe still use the initial capital "alphabet" system, that is, bromotrifluoromethane (Halon 1301) is BTM

Casey C. Grant, P.E., is Secretary, NFPA Standards Council. He is a former member of the NFPA Technical Committee on Halogenated Fire Extinguishing Agent Systems and was previously supervisor of systems design engineering at Fenwal Incorporated.

and bromochlorodifluoromethane (Halon 1211) is BCF. The number definition for the chemical composition of Halon 1301, perhaps the most widely recognized halogenated extinguishing agent, is 1 (carbon), 3 (fluorine), 0 (chlorine), 1 (bromine), and 0 (iodine).

By definition, the first digit of the number represents the number of carbon atoms in the compound molecule; the second digit, the number of fluorine atoms; the third digit, the number of chlorine atoms; the fourth digit, the number of bromine atoms; and the fifth digit, if any, the number of iodine atoms. Trailing zeros in this system are not expressed. Figure 4-6.1 graphically demonstrates this concept by illustrating Halon 1301 in comparison to methane.

There are three halogen elements commonly found in halon extinguishing agents used for fire protection: fluorine (F), chlorine (Cl), and bromine (Br). Compounds containing combinations of fluorine, chlorine, and bromine can possess varying degrees of extinguishing effectiveness, chemical and thermal stability, toxicity, and volatility. In general, the relevant properties of these three halogen elements are characterized as shown in Table 4-6.1.

Due to the many chemical combinations available, the characteristics of halogenated fire extinguishing agents differ widely. It is generally agreed that the agents most widely used for fire protection applications are Halon 1301, Halon 1211, Halon 1011, and Halon 2402. Also somewhat common is Halon 122, which has been used as a test gas because of its economic advantages. However, because of its widespread use as a test agent, many individuals have wrongly assumed that Halon 122 is an effective fire extinguishing agent. Table 4-6.2 illus-

Table 4-6.2 Halons Commonly Used for Fire Protection

Chemical Name	Formula	Halon Number
Methyl bromide	CH ₃ Br	1001
Methyl iodide	CH ₃ I	10001
Bromochloromethane	CH ₂ BrCl	1011
Dibromodifluoromethane	CF ₂ Br ₂	1202
Bromochlorodifluoromethane	CF ₂ BrCl	1211
Dichlorodifluoromethane ^a	CF ₂ Cl ₂	122
Bromotrifluoromethane	CF ₃ Br	1301
Carbon tetrachloride	CCl ₄	104
Dibromotetrafluoroethane	C ₂ F ₄ Br ₂	2402

trates the halogenated hydrocarbons most likely to be used today.

History

The earliest halogenated fire extinguishing agent known to be used for industrialized fire protection was carbon tetrachloride (Halon 104).³ First becoming available as early as 1907, it was most widely used in hand-pump portable extinguishers and was popular due to its low electrical conductivity and lack of residue following application. Also referred to as "pyrene" extinguisher fluid, Halon 104 caused a number of accidental deaths and serious injuries due to its toxicity, and eventually its use was halted during the 1950s.

Methyl bromide (Halon 1001) gained popularity after it was discovered in the late 1920s to be a more effective extinguishing agent than carbon tetrachloride. Due to its high toxicity, it was never used in portable extinguishers even though it was used extensively in British and German aircraft and ships during World War II. Interestingly, methyl bromide possesses a narrow "flammability" range between 13.5 and 14.5 percent in air, though above and below this range it is an efficient fire extinguishant. Germany developed bromochloromethane (Halon 1011) in the late 1930s to replace methyl bromide, but it failed to enjoy widespread use until after World War II.⁴

Thus, prior to World War II, three halogenated fire extinguishing agents were available: Halon 104, Halon 1001, and Halon 1011. Yet because of their inherently high toxic nature, these agents slowly disappeared from typical system applications. By the mid-1960s Halon 104 and Halon 1001 were no longer being used, and Halon 1011 was only in limited use for specialized explosion suppression applications. Figure 4-6.2 represents a chronology chart that indicates the usage of these early halons as well as the halons more commonly used today.

Joint research was undertaken in 1947 by the U.S. Army Chemical Center and the Purdue Research Foundation to evaluate the fire suppression effectiveness and toxicity of the large number of available agents.² After testing more than 60 new agents, 4 were selected for further study: dibromodifluoromethane (Halon 1202), bromochlorodifluoromethane (Halon 1211), bromotrifluoromethane (Halon 1301), and dibromotetrafluoroethane

Figure 4-6.1. Molecular composition of methane and Halon 1301.

Thermal stability	Enhances	Reduces	Reduces
Fire extinguishing effectiveness	—	Enhances	Enhances

Figure 4-6.2. Time span usage of selected halons.

(Halon 2402). Further testing revealed that Halon 1202 was the most effective yet also most toxic, while Halon 1301 was the second most effective and least toxic. As a result of this testing, the use of halon to provide fire protection for modern technology took on new dimensions. Halon 1202 was used by the U.S. Air Force for military aircraft engine protection while the Federal Aviation Administration (FAA) selected Halon 1301 for a similar application in commercial aircraft engine nacelles.⁵ Portable extinguishers using Halon 1301 were implemented by the U.S. Army. The use of total flooding systems originated in 1963, and in the following five years several total flooding systems were installed based on carbon dioxide system technology.

In 1966, attention began to focus on the use of Halon 1301 for the protection of electronic data processing equipment. That year, the NFPA organized a Technical Committee (NFPA 12A) to standardize the design, installation, maintenance, and use of halon systems. Their resulting work was officially adopted by the NFPA membership as a standard in 1968.⁶ Subsequent recognition that there were differences among the halon agents made it apparent that separate standards would be necessary. The initial halon standard, NFPA 12A, *Standard for Halon 1301 Fire Extinguishing Systems* (hereinafter referred to as NFPA 12A), focused on the use of Halon 1301 due to its high desirability and growing popularity.⁷ Work on an additional standard, NFPA 12B, *Standard on Halon 1211 Fire Extinguishing Systems*, concerning the use of Halon 1211, was started in 1969 and was officially adopted by the NFPA as a standard in 1972.⁸ A tentative standard on the use of Halon 2402 (NFPA 12CT) was established, but has not been officially adopted.⁹

Another NFPA committee directly concerned with the use of halon is the NFPA Committee on Electronic Computer/Data Processing Equipment (NFPA 75, *Standard for the Protection of Electronic Computer/Data Processing Equipment*).¹⁰ Even though this standard was adopted in 1961, the use of halon was not considered until after 1972, when extensive testing by several major companies demonstrated that the use of Halon 1301 was suitable for protecting electronic computer and data processing equipment.¹¹ Halon 1301 eventually became the most widely used extinguishing agent for this purpose in the United States and throughout much of the world. However, certain areas of Europe have preferred Halon 1211 and 2402.

In anticipation of the worldwide production phase-out of fire protection halons, which eventually settled at January 1, 1994, for developed countries, a new committee was established during 1992 within the NFPA standards-making system designated as the Technical Committee on Alternative Protection Options to Halon. The committee's first document is NFPA 2001, *Standard on Clean Agent Fire Extinguishing Systems*, which addresses the design, installation, maintenance, and operation of total-flooding fire extinguishing systems that use halon replacement agents.¹²

Halon 1301

Attributes and limitations: Of all the halogenated extinguishing agents used in fire protection today, Halon 1301 is by a wide margin the most commonly used. The primary use of this agent is for the protection of electrical and electronic equipment, flammable liquids and gases, and surface-burning flammable solids such as thermoplastics. Areas normally or frequently occupied, air and ground vehicle engines, and other areas where rapid extinguishment is important or where damage to equipment or materials or cleanup after use must be minimized are also ideally protected by this agent. However, Halon 1301 is not a panacea, and it is appropriate to recognize its limitations as well as its attributes. The benefits of Halon 1301 are: fast chemical suppression, penetrating vapor, clean (no residue), noncorrosive, compact storage volumes, nonconductive, and colorless (no obscuration). There are also limitations to using Halon 1301: it has minimal extinguishing effectiveness on reactive metals and rapid oxidizers, it may have unfavorable side effects on deep-seated Class A fires, the agent is expensive, and it is potentially harmful to the environment. Obviously, the most significant limitation is the detrimental effect that the halons have on the earth's stratospheric ozone layer.

Because Halon 1301 inhibits the chain reaction of the combustion process, it chemically suppresses the fire very quickly, unlike other extinguishing agents that work by removing the fire's heat or oxygen. Stored as a liquid under pressure and released at normal room temperature as a vapor, Halon 1301 gets into blocked and baffled spaces readily and leaves no corrosive or abrasive residue after use. A high liquid density permits compact storage containers, which on a comparative weight basis, makes Halon 1301

approximately 2.5 times more effective as an extinguishing agent than carbon dioxide. Since it is virtually free of electrical conductivity, Halon 1301 is highly suitable for electrical fires. Halon 1301 is a colorless vapor when discharged into a hazard volume, though it sometimes temporarily clouds the volume due to the chilling of any moisture in the air. But of all its attributes, the most promising is that of people compatibility, for unlike other extinguishing agents, Halon 1301 is essentially nontoxic in the concentrations usually required for fire suppression.

There are several types of flammable materials on which Halon 1301 is ineffective and not recommended. Reactive metals such as potassium, NaK eutectic alloy, magnesium, sodium, titanium, and zirconium burn so intensely that they overpower the agent's extinguishing abilities.⁵ Included with these are the metal hydrides such as lithium hydride, and petroleum solvents such as butyllithium. Autothermal decomposers and fuels that contain their own oxidizing agent will also burn freely in the presence of halon agents. These latter substances, such as gunpowder, rocket propellants, and cellulose nitrate, have an oxidizer physically too close to the fuel, and the agent cannot penetrate the fire zone fast enough. Halon is also not effective in preventing the combustion or reaction of chemicals capable of autothermal decomposition such as hydrazine or organic peroxides. Even though Halon 1301 is effective with certain surface-burning flammable solids such as thermoplastics, deep-seated Class A fires typically require relatively high agent concentrations for long soaking periods. When exposed to deep-seated fires for long periods of time, Halon 1301 may decompose into toxic and corrosive products of decomposition. Therefore, it is important that the agent be dispersed while the fire is small. The expense necessary to purchase, install, and maintain a properly functioning Halon 1301 system for more specific Class A hazards is often not economically justified. Halon 1301 fire suppression systems are usually not associated with everyday commodities, but instead are found in applications pertaining to highly valued risks.

Properties

Physical properties: On the average, Halon 1301 requires 10 percent less agent on a gas-volume basis than does Halon 1211 to extinguish any given fuel.² However, both agents are approximately 2.5 times more effective on a weight-of-agent basis than carbon dioxide. Halon 1301 is a gas at 70°F (21°C) with a vapor pressure of 199 psig. Although this pressure would adequately expel the material, it decreases rapidly to 56 psig (4 bar) at 0°F (-18°C) and to 17.2 psig (1.2 bar) at -40°F (-40°C). Therefore, it is necessary to increase the container pressure with dry nitrogen either to 360 or 600 psig (25 or 41 bar) at 70°F (21°C), ensuring adequate performance at all temperatures. Figure 4-6.3 demonstrates the temperature-pressure profile for Halon 1301 and Halon 1301 superpressurized with dry nitrogen.

Halon 1301 is normally stored in a pressure vessel as a liquid before it is released to occupy the hazard volume as a vapor. With a boiling point of -72°F (-58°C), it is ap-

Figure 4-6.3. Temperature-pressure relationship for pure Halon.

proximately 1.5 times more dense than water in its liquid phase and approximately 5 times heavier than air in its vapor phase. Thus, Halon 1301 vapor will typically escape through openings in the low portions of a totally flooded volume. Other physical properties are shown in Table 4-6.3.

Traditionally, there were three distinct elements assumed for combustion: heat, fuel, and oxygen. Known as the fire triangle, this theory had to be modified as halons became more widely used and better understood. Typical fire extinguishment involves either removing the fuel from the fire, limiting oxygen to the fire (smothering), or removing the heat (quenching). The halons do not extinguish fire in any of these ways, but instead break up the uninhibited chain reaction of the combustion process. The tetrahedron of the fire, as it is now called, is shown in Figure 4-6.4.

Table 4-6.3 Selected Physical Properties of Halon 1301

Boiling point	-72.0°F
Freezing point	-270.4°F
Specific gravity of liquid (@70°F)	1.57
Specific gravity of vapor (@70°F)	5.14
Liquid density @70°F	98.0 lb/ft ³
Vapor density @70°F	7.49 lb/ft ³ (standard)
Critical temperature	152.6°F
Critical pressure	575 PSIA

Figure 4-6.4. *The tetrahedron of fire.*

The extinguishing mechanism of the halogenated agents is not completely understood, yet there is definitely a chemical reaction that interferes with the combustion process. The halogen atoms act by removing the active chemical species involved in the flame chain reaction. While all the halogens are active in this way, bromine is much more effective than chlorine or fluorine. With Halon 1301 (54 percent by weight bromine), it is the bromine radical that acts as the inhibitor in extinguishing the fire. Yet the fluorine in the molecule also serves a specific task since it is the fluorine that gives the agent thermal stability and keeps Halon 1301 from decomposing until approximately 900°F (480°C).¹³

Extinguishing effectiveness: As shown in Figure 4-6.5, the four types of fire are ordinary combustibles (Class A), flammable liquids and gases (Class B), electrical (Class C), and reactive metals (Class D).⁵

It was previously mentioned that Halon 1301 is ineffective on Class D fires and is not as desirable as other agents in extinguishing deep-seated Class A fires. The effectiveness of Halon 1301 on Class A fires is not as predictable as with other classes of fire. It depends to a large extent upon the burning material, its configuration, and how early in the combustion cycle the agent is applied. Most plastics behave as flammable liquids and can be extinguished rapidly and completely with 4 to 6 percent concentrations of Halon 1301.⁷

Other materials, particularly cellulosic products, can in certain forms develop deep-seated fires in addition to flaming combustion. The flaming portion of such fires can be extinguished with low 4 to 6 percent Halon 1301 concentrations, but the glowing deep-seated portion of the fire may continue under some circumstances. Even so, the

deep-seated fire can be controlled since its rate of burning and consequent heat release will be reduced. Considerably higher concentrations (18 to 30 percent) of Halon 1301 are required to achieve complete extinguishment, but these levels are seldom economical to apply and their application may result in unwanted products of decomposition. However, the concept of controlling deep-seated fires with halogenated agents has been accepted in the respective NFPA standards.⁷

It is Class B and Class C fires for which halon is particularly well suited. The most common applications involve Class C electrical hazards, with the increase in popularity of Halon 1301 keeping well in stride with the development of high technology. Typically, electrical and electronic equipment are protected with a concentration of 5 percent Halon 1301 by volume, though a significantly lower concentration will suitably extinguish a potential fire.¹⁴ The concentrations necessary to extinguish Class B fires have been the subject of much testing with results that vary widely. The effectiveness of halogenated agents on flammable liquid and vapor fires is quite dramatic, especially in total flooding systems. Rapid and complete extinguishment is obtainable with low concentrations of the agent.⁷ To be effective, the fire must be contained (such as inside a building) so that the agent can react with it; Halon 1301 applied to large exterior running pool fires dissipates into the atmosphere without penetrating the flame zone.

Corrosive effects of undecomposed halons: Unlike Halon 1301 and Halon 1211, the early nonfluorinated halogenated agents had significant corrosive problems. Laboratory tests by DuPont in a 44-month exposure period with aluminum, magnesium, steel, stainless steel, titanium, and brass exposed to undecomposed Halon 1301 support the fact that this agent will not corrode these metals, which may all commonly be used in fixed fire extinguishing systems.¹³ This is not surprising from a chemical standpoint because the presence of the fluorine atom in a molecule generally reduces its chemical reactivity and corrosive properties and increases its stability.

The presence of free water in systems containing Halon 1301 should be avoided. Free water is defined as the presence of a separate water phase in the liquid halon. When present in a small quantity, free water can provide a site for concentrating acid impurities into a corrosive liquid.¹⁵ Free water should not be confused with dissolved water, which is not a problem in a Halon 1301 system.

Halon 1301 is inert toward most elastomers and plastics. In general, rigid plastics that are normally unaffected include polytetrafluoroethylene, nylon, and acetal copolymers. Most of the commonly used plastics undergo little, if any, swelling in the presence of Halon 1301, with the exception of ethyl cellulose and possibly cellulose acetate/butyrate. Elastomers are particularly suitable when exposed to Halon 1301 for extended periods of time with the notable exception of silicone rubber.¹³ Halons decomposed at high temperatures during suppression produce halogen acids and free halons that can be corrosive.

Figure 4-6.5. *The four classes of fire.*

Toxicity

General toxic properties: The relative safety of Halon 1301 has been established through more than 30 years of medical research involving both humans and test animals. No significant adverse health effects have been reported from the proper use of Halon 1301 as a fire extinguishant since its original introduction into the marketplace.⁷

Early studies by the U.S. Army Chemical Center on Halon 1301 determined the approximate lethal concentration for a 15-minute exposure to be 83 percent by volume.² Animals exposed to concentrations below lethal levels exhibit two distinct types of toxic effects. Concentrations greater than 10 percent by volume produce cardiovascular effects such as decreased heart rate, hypotension, and occasional cardiac arrhythmias.¹⁶ Concentrations of Halon 1301 greater than 30 percent by volume result in central nervous system changes including convulsions, tremors, lethargy, and unconsciousness. Effects are considered transitory and disappear after exposure.¹⁷

Human exposure to concentrations of Halon 1301 greater than 10 percent by volume have shown indications of pronounced dizziness and a reduction in physical and mental dexterity.¹⁸ With concentrations between 7 and 10 percent by volume, subjects experienced tingling of the extremities and dizziness, indicating mild anesthesia. Exposure to Halon 1301 concentrations less than 7 percent by volume have little effect, with the exception of a deepening in the tone of voice caused by a higher density in the medium between the vocal chords. The effects at all levels of concentration disappear quickly after removal from the exposure. Testing of Halon 1301 for potential teratogenic (i.e., altering the normal process of fetal development) and mutagenic (a carcinogen in humans) effects have indicated that no serious problems exist.⁵

Most fire protection applications today have a design concentration of 5 percent by volume, thus the question of toxicity is not usually a serious concern. Exposure limitations for Halon 1301 (indicated by NFPA 12A) are summarized in Table 4-6.4.⁷

In addition to possible toxic effects, liquid Halon 1301 (including the spray in the immediate proximity of a discharge) may freeze the skin on contact and cause frostbite. However, direct contact is necessary for this to occur and is unlikely, since with engineered Halon 1301 fire extin-

guishing systems the discharge nozzles are typically distant from all occupants.

Products of decomposition: Consideration of the life safety of Halon 1301 must also include the effects of breakdown products which have a relatively higher toxicity than the agent itself. Upon exposure to flames or hot surfaces above approximately 900°F (480°C), Halon 1301 decomposes to form primarily hydrogen bromide (HBr) and hydrogen fluoride (HF).¹⁹ Trace quantities of bromine (Br₂), carbonyl fluoride (COF₂), and carbonyl bromide (COBr₂) have been observed, but the quantities are generally too small to be of concern. Although small amounts of carbonyl halides (COF₂ and COBr₂) were reported in early tests, more recent studies have failed to confirm the presence of these compounds. Table 4-6.5 summarizes the predominant products of decomposition for Halon 1301.²⁰

The primary toxic effect of the decomposition products is irritation. Even in concentrations of only a few parts per million, the decomposition products have characteristically sharp, acrid odors. This characteristic provides a built-in warning system since the irritation becomes severe well in advance of truly hazardous levels. In addition, the odor also serves as a warning that carbon monoxide and other potentially toxic products of combustion may be present. Prompt detection and rapid extinguishment of a fire will produce the safest post-extinguishment atmosphere.

Other Halons

Physical properties: The predominant halogenated agent in existence today for total flooding fire extinguishing systems is Halon 1301, though some areas of Europe have utilized Halon 1211 for this purpose. One reason for this use of Halon 1301 (besides toxicity) is the ability of the agent to vaporize and penetrate all portions of the hazard volume. Table 4-6.6 shows that Halon 1301 has the lowest boiling point and Halon 1211 has the second lowest.

With the discharge of a halon system at ambient temperature, Halon 1301 flashes to a vapor almost instantaneously, while Halon 1211 tends to pool momentarily. Agents with boiling points exceeding the temperature of the hazard volume will stay liquid until heated by the fire itself. These high boiling point halogenated agents have two distinct attributes: they can be projected in a liquid stream and they have a quenching effect in addition to

Table 4-6.4 Permitted Exposure Time for Halon 1301

Concentration (percent by volume)	Permitted Time of Exposure
Normally occupied areas	
0-7%	15 min
7-10%	1 min
Above 10%	Not permitted
Normally unoccupied areas	
0-7%	15 min
7-10%	1 min
10-15%	30 s
Above 15%	Prevent exposure

Table 4-6.5 Predominant Halon 1301 Decomposition Products

Compound	Formula	ALC ^a for 15-min Exposure ppm by Volume in Air
Hydrogen fluoride	HF	2500
Hydrogen bromide	HBr	4750
Bromine	Br ₂	550
Carbonyl fluoride	COF ₂	1500
Carbonyl bromine	COBr ₂	—

^aApproximate lethal concentration

Table 4-6.6 Selected Physical Properties of Typical Halogenated Fire Extinguishing Agents

Halon Number	Type of Agent	Approximate Boiling Point (°F)	Approximate Freezing Point (°F)	Specific Gravity of Liquid (@70°F)
104	Liquid	170	-8	1.59
1001	Liquid	40	-135	1.73
1011	Liquid	151	-124	1.93
1202	Liquid	76	-223	2.28
1211	Liquefied gas	25	-257	1.83
1301	Liquefied gas	-72	-270	1.57
2402	Liquid	117	-167	2.17

breaking the uninhibited chain reaction. Thus, portable extinguishers generally use Halon 1301 as a propellant for other halon agents.

Toxicity

One of the primary reasons that Halon 1301 is the most preferred of the halogenated agents is its relatively low toxicity, as discussed earlier. Table 4-6.7 compares the approximate lethal concentration of both the natural and decomposed vapors for a variety of fire extinguishing agents. Included with this list of halon agents is carbon dioxide for sake of comparison. As a natural vapor, Halon 1301 is the least toxic halogenated agent. Carbon dioxide may appear to compare favorably with Halon 1301, yet high concentrations of carbon dioxide are necessary for fire extinguishment, which also makes the hazard volume lethal to human occupants.

Halon in the Fire Protection Spectrum

Halogenated agent extinguishing systems are only one segment of the total fire protection spectrum. Good engineering judgment is necessary when trying to determine the applicability of halon and whether it should be used instead of, or in addition to, other fire protection measures. It must be clearly understood that halogenated agent extinguishing systems are not the panacea for all fire hazards, yet they do offer a safe method to extinguish

Table 4-6.7 Approximate Lethal Concentrations (ppm) for 15-min Exposure to Vapors of Various Fire Extinguishing Agents

Formula	Halon Number	Natural Vapor	Decomposed Vapor
CCl ₄	104	28,000	300
CH ₃ Br	1001	5,900	9,600
CH ₂ ClBr	1011	65,000	4,000
CF ₂ Br ₂	1202	54,000	1,850
CF ₂ ClBr	1211	324,000	7,650
CF ₃ Br	1301	832,000	14,000
C ₂ F ₄ Br ₂	2402	126,000	1,600
CO ₂	—	658,000	658,000

Table 4-6.8 Necessary Control Measures for Computer Room Fire Stage Sequence

Fire Stage	Control	Serious Danger Concern
1. Pre-ignition	Good housekeeping practices, control combustible furnishings and interior finish	
2. Initial pyrolysis	Smoke detection system	Occupants and business interruption
3. Incipient	Portable fire extinguishers, Halon 1301 automatic suppression system	Occupants and contents
4. Pre-flashover	Automatic sprinklers	Occupants and structure
5. Post-flashover	Fire walls, compartmentalization	Surrounding structures

certain fires in their very early stages. Thus, these systems are commonly applied to situations where even the smallest fire is absolutely unthinkable.

As an example, total computer room fire protection might involve several different control measures addressing different possible fire conditions. Table 4-6.8 illustrates this concept, based on the different stages of a growing fire. The table is not a rigid description of the fire protection requirements of every computer room, but instead an example of how total fire protection is the overall objective when approaching a design situation.

An important factor of developing halogenated agent extinguishing systems is the interaction of all concerned individuals. To design, install, maintain, and operate a halon system requires a cooperative effort from a number of different groups. As shown in Figure 4-6.6, these individuals include the end users, consultants, manufacturers, installers, insurance representatives, and other selected authorities. Representatives from all these groups work together to develop and enhance model codes, which provide guidance and understanding for proper halon system usage.

System Configurations

Detection

The three primary parts of every halogenated agent extinguishing system are detection, control panel, and agent delivery. Since there is no single type of detector that offers the ultimate for every application, consideration must be given to the types of combustibles and combustion that are likely to occur in the protected area.

Photoelectric and ionization smoke detectors have different response characteristics to fires and can be susceptible to false or unwanted alarms. Thermal detectors, although more reliable, react more slowly to fire conditions. In certain applications, speed is critical and optical detectors would be required.

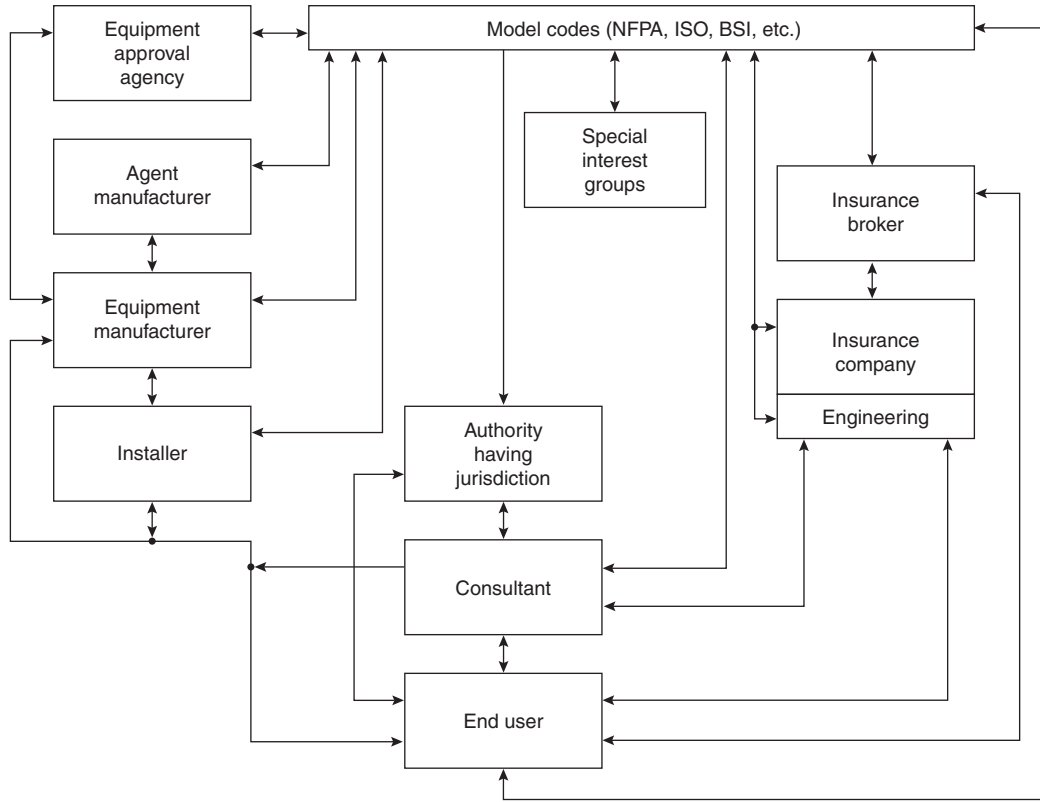

Figure 4-6.6. Typical inter-relationship of halon fire protection interests.

To optimize the speed and reliability of detection systems, it is important to use two different types of detectors on two separate detection loops within the hazard area. This method is referred to as cross-zone detection. Each detection loop functions independently to provide both added reliability with a comforting degree of redundancy.²¹

Control Panels

Features: As its name implies, the control panel is the device that controls system operation and allows the system to function as designed. When a control panel protects more than one area, each individual area is referred to as a zone of protection. Each zone of every halon control panel has three different types of circuits: initiating, signaling, and release. A fire alarm zone and halon zone are compared in Table 4-6.9 to illustrate the differences between these circuit types. It is unusual for a single halon control panel to protect more than five zones at once due to the high number of circuits required. Fire alarm control panels, on the other hand, may have dozens of individual zones.

Initiating circuits provide the input into the panel and support automatic detectors, manual pull stations, and other initiating devices. Automatic detectors are normally cross-zoned, which implies two separate detection circuits. One circuit is required for prealarm and both circuits are necessary for halon release. The signaling circuits, sometimes referred to as bell or auxiliary circuits, are used for audible/visual alarms and other auxiliary

functions. The release circuits allow the halon to release from the containers and are sometimes referred to as firing, solenoid, initiator, dump, or halon circuits.

Modes of operation: At any time, a halon control panel and the halon system could be in one of four modes of operation; as shown in Table 4-6.10 these include unpowered, normal, alarm, and trouble condition. The alarm condition is further definable with prealarm, prerelease, release, and postrelease condition. Typical systems utilizing cross-zoning detection activate, when required, into prealarm and/or release condition, but this often becomes more complicated with time delays, abort switches, and other auxiliary functions. Unless otherwise specified, manual pull stations activate all alarm conditions, override abort switches, if present, and immediately release the halon. These different alarm conditions provide a convenient mechanism for sequential operation

Table 4-6.9 Typical Control Unit Features

	Halon Zone	Fire Alarm Zone
Initiating circuit	Two cross zone detection circuits	One circuit for detection
Signaling circuit	Multiple signaling sequence	Multiple signaling sequence
Release circuit	One circuit	None

Table 4-6.10 Modes of Control Panel Operation

Unpowered condition	Off
Normal condition	On
Alarm condition:	
Prealarm	One detector activates.
Prerelease	Two cross-zoned detectors activate. Time delay starts.
Release	Time delay ends or manual pull station activates. Halon is released.
Postrelease	Halon has been released.
Trouble condition	Failure or disruption of field wiring. Insufficient power input.

of audible/visual signaling, equipment shutdown, fire service notification, and other auxiliary functions.

Control panel economics: As halogenated agent extinguishing systems become more numerous, the frequency of large-scale projects with multiple halon zones in a single facility is increasing. Today, entire data processing centers and telecommunications buildings are protected with Halon 1301 systems. To protect a large building with many halon zones, it may appear that the most effective way of configuring the system is by using a single large control panel with the capacity for all required halon zones. This is not true, since there is a limitation to the number of halon zones that any one halon panel can effectively manage. Figure 4-6.7 illustrates an alternative method, where the individual halon zones of a large building each have their own halon panel wired to give an alarm or trouble signal to a central fire alarm panel.

A typical halon zone requires an average of 12 wires to support all the necessary system functions. Thus, the cost of running multiple wires and large conduit instead of only two wires (for interpanel communication) often

offsets the cost of smaller, more numerous panels located near the halon zones. This configuration offers flexibility for future consolidations or additions, which are common for high technology facilities. Aesthetics are enhanced at the master control location, and system operation is simplified. Installation checkout and servicing is easier when the halon control panel is within the hazard area. Finally, the overall system is more reliable due to less wiring, lack of design complexity, simplified maintenance, and multi-source dependence.

Agent Delivery

In addition to the control panel and detection, the other primary part of every halogenated agent extinguishing system is agent delivery. The agent delivery includes the discharge nozzles, agent storage container(s), release mechanism, and associated piping. As shown in Table 4-6.11, three methods of agent delivery exist: (1) central storage, (2) modular, and (3) shared supply. Central storage has the container(s) centrally located, with the agent piped accordingly. This method is popular due to its similarity with carbon dioxide system technology (which helped develop early systems), along with usually having the lowest initial cost. Modular systems use smaller containers strategically located throughout the hazard area, with minimal piping. The high reliability of modular systems is based on lack of dependancy on piping integrity, negligible piping calculations, total system supervision, multisource dependence, and the inherent ability to be heat actuated regardless of catastrophic system failure. Modular systems are simple to design, are relatively easy to install, and have a high degree of future flexibility. Systems utilizing shared supply are essentially central storage systems with container(s) shared by more than one hazard volume. Even though fewer containers are used, directional valves and extensive piping do not often allow shared supply systems to be cost effective.

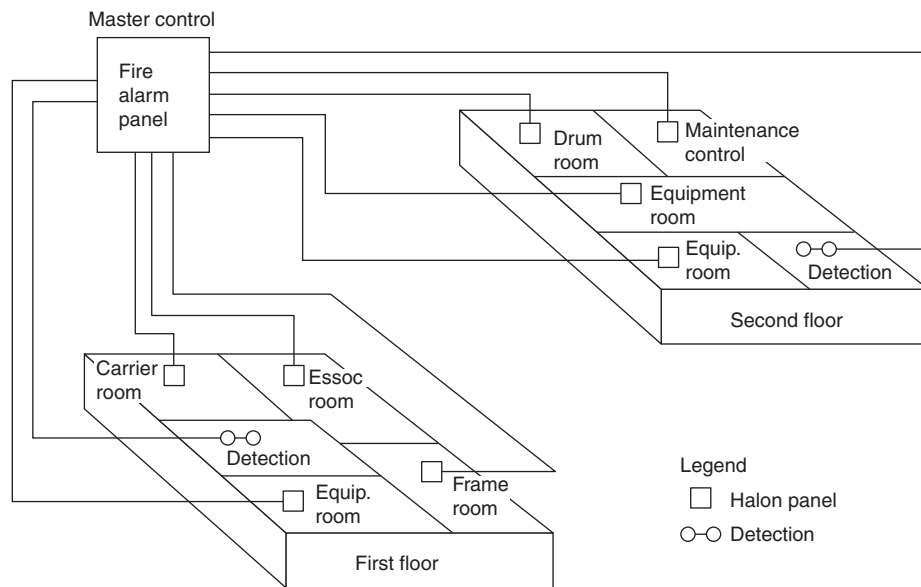

Figure 4-6.7. The network concept of control panel interface for a typical halon application.

Table 4-6.11 Comparison of Different Methods of Agent Delivery

	Central Storage	Modular	Shared Supply
Hardware cost	Moderate	High	Moderate
Installation cost	Moderate	Low	Moderate
Design simplicity	Difficult	Simple	Difficult
Installation simplicity	Difficult	Medium	Difficult
Operation and maintenance simplicity	Medium	Medium	Medium
Reliability	Moderate	High	Low
Future flexibility	Low	High	Low

Adding to its unpopularity are its design and installation complexity, low reliability, and impaired future flexibility. When a shared supply halon system activates for one hazard, the remaining hazards become unprotected until the system is completely recharged.

Design Concepts and Methodology

Definitions and Terminology

Halogenated agent extinguishing systems are typically classified as either total flooding or local application systems. A total flooding system is designed to develop and maintain a concentration of halon that will extinguish fires in combustible materials located in an enclosed space. Local application systems are designed to apply the agent directly to a fire that may occur in an area or space that is not immediately enclosed. In addition to these, there are specialized applications, which may include combination total flooding/local application or partial flooding. The vast majority of installed halon systems today are the total flooding type using Halon 1301.

The definitions of halon system and halon zone are often confusing. This is especially true to individuals closely associated with the fire alarm industry, since fire alarm terminology is similar. Figure 4-6.8 defines the basic features of a halon system and halon zone and offers a comparison with each respective fire alarm counterpart.

A halon zone usually equates to an area of halon coverage functioning on a single release circuit, while the zones in a fire alarm system typically are each detection circuit. As an example, one halon zone could be a single computer room, whereas a fire alarm zone could be the entire floor of a building. A halon system also has much fewer (though more comprehensive) zones than a fire alarm system.

Halon Design Guidelines

The design process necessary for total flooding systems is easily quantified. The procedure can be separated into five definable steps: (1) hazard identification, (2) determination of agent quantity, (3) specification of operating requirements, (4) determination of hardware requirements, and (5) generation of postdesign information.

The initial step is to provide a definition of the hazard. This includes determining the fuels involved, the di-

Figure 4-6.8. Halon/fire alarm differences.

mensions and configuration of the enclosure, the maximum and minimum net volumes, the status of occupancy, the expected hazard area temperature range, and possible unclosable openings. Based on this information, the minimum design concentration can be established. Next, the agent quantity is determined based upon the design concentration, the volume, minimum expected temperature, leakage due to ventilation or unclosable openings, and altitude above sea level. Usually, the gross volume is used to calculate the agent quantity to allow for extra agent to replace that lost through normal building leakage. However, agent concentrations must conform with the applicable toxicity criteria with respect to the minimum net volume and maximum temperature. The operating specifications are then required if they have not already been established. These will indicate how the system is to operate, the modes of operation, the type of agent delivery, and so forth. When these are known, the necessary hardware requirements must be obtained and the design of the system completed. The final step is to generate the postdesign information necessary for others to install, test, operate, and maintain the system. Postdesign information should contain all design calculations (including hydraulic calculations), complete blueprint drawings, and detailed information describing the testing, operation, and maintenance of the system.

Local Application and Special Systems

Local application systems are often installed to extinguish fires involving flammable liquids, gases, and surface burning solids. Such systems are designed to apply the agent directly to a fire that may occur in an area or space not immediately enclosed. They must be designed to deliver halon agent to the hazard being protected in such a manner that the agent will cover all burning surfaces during discharge of the system. Because of its lower volatility, Halon 1211 may be better suited than other forms of halon for local application systems. The lower volatility, plus a high liquid density, permits the agent to be sprayed as a liquid and thus propelled into the fire zone to a greater extent than is possible with other vaporized agents. Examples of areas protected by local application are spray booths, dip and quench tanks, oil-filled electric transformers, printing presses, heavy construction equipment, and vapor vents. An example of a local application system is shown in Figure 4-6.9.

Figure 4-6.9. Local application system.

Currently, NFPA standards do not set a minimum limit on the discharge time for a local application design. The rate of discharge and the amount of agent required for a given application must be determined by experimentation and evaluation. The most critical components of these systems are the discharge nozzles; the discharge velocity and rate must be sufficient to penetrate the flames and produce extinguishment but not be so great as to cause splashing or spreading of fuel and thus increase the fire hazard. The minimum design discharge quantity should not be less than 1.5 times the minimum quantity required for extinguishment at any selected design rate.²⁰ Also of critical importance are type and location of detectors.

As with other types of gaseous suppression systems, local application systems can be designed according to the rate-by-volume method or the rate-by-area method. The rate-by-area method determines nozzle discharge rates based on the exposed surface area of the hazard being protected. This method is less popular than the rate-by-volume method, which requires discharge rates sufficient to fill (within the discharge time) a volume whose imaginary boundaries extend a limited distance from the protected hazard. This method is favored since it performs similarly to total flooding systems. Important factors to be considered in the design of a local application system are the rate of agent flow, the distance and area limitations of the nozzles, the quantity of agent required, the agent distribution system, and the placement of detectors.

Unlike total flooding systems, only the liquid portion of the discharge is effective for local application systems. The computed quantity of agent needed for local application must be increased to compensate for the residual vapor in the storage container at the end of liquid flow. An additional 25 percent storage capacity is required in the absence of an enclosure that would prevent gas dissipation. Systems should also compensate for any agent vaporized in the pipe lines due to heat absorption from the piping. The heat transfer is important when the piping is at a higher temperature than the agent. The following equation determines the amount of agent increase necessary to compensate for this effect:⁷

$$W_x = \frac{2\pi kL(T_p - T_a)(t)}{3600h(\ln r_o/r_i)} \quad (1)$$

where

W_x = amount of agent increase, kg (lb)

k = thermal conductivity of the piping, W/m·K (Btu·t/hr·ft²·°F)

L = linear length of the piping, m (ft)

T_p = pipe temperature, °C (°F)

T_a = agent temperature, °C (°F)

t = system discharge time

h = heat of vaporization of the agent at T_a , kJ/kg (Btu/lb)

r_o = outside pipe radius, mm (in.)

r_i = inside pipe radius, mm (in.)

Specialized systems using a variety of agents are in wide use throughout the world to protect hazards such as aircraft engine nacelles, military vehicles, emergency generator motors, earth moving equipment, and racing cars. The characteristic common to all these systems is that they can only be applied to the specific hazard for which they were designed and tested. One unusual concept used to protect aircraft flight simulator areas is known as partial flooding, where only the volume containing the simulator equipment receives the total flooding concentration, and not the expansive open areas above it. A design concentration of 7 percent is recommended to achieve a 5 percent concentration in the hazard area and should provide for a minimum agent height level relative to the agent concentration of approximately 1.5 m (5 ft) above the highest part of the hazard. The placement of the nozzle is critical and should be designed to direct agent discharge approximately 30 degrees below the horizontal plane. As shown in Figure 4-6.10, the savings associated

Figure 4-6.10. Agent reduction associated with partial flooding systems.

with partial flooding systems can be substantial, especially in areas with very high ceilings.¹⁹

Agent Requirements: Total Flooding

Design Concentrations: Solid Fuels

Flammable solids may be classified as those that do not develop deep-seated fires and those that do. Class A combustible solids that develop deep-seated fires do so after exposure to flaming combustion for a certain length of time, which varies with the material. Some materials may begin as deep seated through internal heating such as spontaneous ignition. With respect to Halon 1301 total flooding systems, a fire is considered deep seated if a 5 percent concentration will not extinguish the fire within 10 min after agent discharge.⁷ Materials that do not become deep seated undergo surface combustion only and may be treated much the same as those in a flammable liquid fire.

The presence of Halon 1301 in the vicinity of a deep-seated fire will extinguish the flame and reduce the rate of burning, yet the quantity of agent required for complete extinguishment of all embers is difficult to assess. Often it is impractical to maintain an adequate concentration of Halon 1301 for a sufficient time to ensure the complete extinguishment of a deep-seated fire. Factors affecting this concentration include

1. Nature of fuel
2. Time during which it has been burning
3. Availability of oxygen within the enclosure

4. Ratio of burning surface area to the volume of the enclosure
5. Geometric characteristics of the fuel
6. Fuel distribution within the enclosure

Table 4-6.12 illustrates the extinguishing concentrations of selected flammable solid fires as indicated by six different halon industry groups.²²

Even where the fire has inadvertently become deep seated, application of a low Halon 1301 concentration has two benefits. First, all flaming combustion is halted, preventing rapid spread of the fire to adjacent fuels. Second, the rate of combustion is drastically reduced. These two characteristics justify the ability of Halon 1301 to control, if not extinguish, deep-seated fires. However, Halon 1301 systems that are specifically designed to extinguish deep-seated fires are seldom economical to apply and may not be as effective in these fires as other types of extinguishing systems.

Design Concentrations: Liquid and Gas Fires

There are two general types of flammable liquid or gas fires. First, a flammable or explosive mixture of vapors exists that must be prevented from burning, and second, fuel is burning that must be extinguished. Associated with each of these conditions is a minimum level of Halon 1301 extinguishing concentration, respectively known as inerting and flame extinguishment. When determining the halon design concentration, proper consideration must be given to the quantity and type of fuel

Table 4-6.12 Extinguishing Concentrations of Selected Flammable Solid Fires

involved, the conditions under which it normally exists in the hazard, and any special conditions of the hazard itself. If certain hazards have explosion potential either before or following a fire due to the presence of volatile, gaseous, or atomized fuel, then special consideration should be given to vapor detection and explosion suppression measures.

As its name implies, the flame extinguishment concentration assumes that the given fuel is burning and that Halon 1301 injected into the air surrounding the fuel at the stated concentration will extinguish the fire.⁷ Design concentrations for flame extinguishment are given in Table 4-6.13. These concentrations are not considered effective with premixed flames or explosive mixtures of fuel vapor in air, but instead apply to diffusion flames, where the flames emanate from pure fuel vapor, and oxygen suffuses into the flame zone from the outside. If the possibility of a subsequent reflash or explosion exists, then the flame extinguishing concentration is not sufficient. NFPA 12A⁷ defines these conditions as "when both:

1. The quantity of fuel permitted in the enclosure is sufficient to develop a concentration equal to or greater than one-half of the lower flammable limit throughout the enclosure, and
2. The volatility of the fuel before the fire is sufficient to reach the lower flammable limit in air (maximum ambient temperature or fuel temperature exceeds the closed cup flash point temperature) or the system response is not rapid enough to detect and extinguish the fire before the volatility of the fuel is increased to a dangerous level as a result of the fire."

Most fuels exhibit about a 30 to 40 percent higher concentration for inerting than for flame extinguishment. The minimum inerting concentration suppresses the propagation of the flame front at the "flammability peak" or stoichiometric fuel/air composition and inerts the enclosure so that any fuel/air mixture will not burn. The higher inerting concentration is often considered safer to use even if the flame extinguishment concentration is feasible, yet the sacrifices include higher system cost and higher concentrations to which personnel may be exposed. (See Table 4-6.14.)

Table 4-6.13 Design Concentration for Flame Extinguishment

Fuel	Minimum Design Concentration (percent by volume)
Acetone	5.0
Benzene	5.0
Ethanol	5.0
Ethylene	8.2
Methane	5.0
<i>n</i> -Heptane	5.0
Propane	5.2

Fuel	Minimum Concentration (percent by volume)
Acetone	7.6
Benzene	5.0
Ethanol	11.1
Ethylene	13.2
Hydrogen	31.4
Methane	7.7
<i>n</i> -Heptane	6.9
Propane	6.7

Includes a safety factor of 10 percent added to experimental values

It is possible to calculate whether the flame extinguishing concentration is acceptable by determining if the fuel present in the hazard will permit attainment of the one-half lower flammable limit of the fuel. The equation to determine the maximum allowable fuel loading (*MFL*) for flame extinguishment concentrations is

$$MFL = \frac{(K_c)(LFL)(MW)}{T} \quad (2)$$

where

MFL = maximum allowable fuel loading, kg/m³ (lb/ft³)

K_c = conversion factor, 0.06093 (0.00685)

LFL = lower flammable limit of fuel in air, percent volume

MW = molecular weight of fuel

T = temperature, K (R)

This can be compared with the actual fuel loading (*FL*), which is calculated by

$$FL = \frac{(VF)(W_{H_2O})(SG)}{V} \quad (3)$$

where

FL = fuel loading, kg/m³ (lb/ft³)

VF = volumetric quantity of fuel, m³ (ft³)

W_{H₂O} = specific weight of water, 997.9 kg/m³ (62.3 lb/ft³)

SG = specific gravity of fuel

V = volume of enclosure, m³ (ft³)

If the fuel loading, *FL*, exceeds the maximum allowable fuel loading, *MFL*, then the inerting concentration for the particular fuel should be used. Most applications involve a variety of fuels within a single enclosure. If the sum of the actual fuel loadings, *FL*, is greater than any single maximum allowable fuel loading, *MFL*, then the most stringent inerting concentration is recommended. If it is determined that a flame extinguishment concentration is sufficient, the value for the fuel requiring the greatest concentration is most applicable.

Calculation of Agent Quantity

The calculations necessary for determining the Halon 1301 total flooding quantity are dependent on temperature, volume of the enclosure, agent concentration, altitude with respect to sea level, and losses due to ventilation and leakage. Most applications are based on a static volume enclosure with all openings sealed and all ventilation systems shut down prior to discharge. This simplifies the calculation significantly. Often the ventilation system does not shut down but instead is damped to allow recirculating air (without makeup air) to continue cooling sensitive electronic equipment and promote the mixing of halon and air. Total flooding quantities are still based on a static volume for these applications. However, in this instance, it may be necessary to include the volume of the ventilation ductwork in addition to the volume of the enclosure. The equation to determine the Halon 1301 total flooding quantity is

$$W = \frac{(V)(C)(A_c)}{S(100 - C)} \quad (4)$$

where

W = 3 weight of Halon 1301 required, kg (lb)

C = Halon 1301 concentration, percent by volume

A_c = altitude correction factor—(Refer to Table 4-6.15)

S = specific vapor volume based on temperature, m^3/kg (ft^3/lb)

$S = 0.14781 + 0.000567T$; T = Temperature °C

$S = 2.2062 + 0.005046T$; T = Temperature °F

Application Rate

Discharge time and soaking period: When designing a Halon 1301 total flooding system, it is important to determine the system discharge time and soaking period.

As indicated in NFPA 12A, "the agent shall be completed in a nominal 10 seconds or as otherwise required by

the authority having jurisdiction."⁷ The reasons for a rapid discharge time include keeping unwanted products of decomposition to a minimum and achieving complete dispersal of agent throughout the enclosure. Sometimes a much faster application rate is required due to the possibility of a fast spreading fire; yet, discharge times longer than 10 s are sometimes necessary for areas such as museums requiring that turbulence be kept to a minimum, or areas with unavoidably difficult piping configurations.

The soaking time is another important requirement for a Halon 1301 total flooding system. This is especially true for deep-seated fire or fires that may reflash. The most common application today for total flooding systems is the protection of valuable electronic equipment. Fires in these applications are almost always extinguished within a few seconds by the Halon 1301 agent, yet a 10-min soaking period is usually required. This estimated time period allows responsible individuals to arrive at the scene to take follow-up action. It is important to remember that halogenated agent extinguishing systems in most cases have only a single chance to control an unwanted fire.

Effects of ventilation: When Halon 1301 is discharged into a total flooding enclosure that is ventilated, some agent will be lost with the ventilating air. Assuming that ventilation must continue during and after discharge, a greater amount of agent is required to develop a given concentration. Also, to maintain the concentration at a given level requires continuous agent discharge for the duration of the soaking period. If an enclosure initially contains pure air, the Halon 1301 discharge rate required to develop a given concentration for agent at any given time after the start of discharge is⁷

$$R = \frac{(C)(E)}{(S)(100 - C)[1 - e^{(-Et_1/V)}]} \quad (5)$$

where

R = Halon 1301 discharge rate, kg/s (lb/s)

E = ventilation rate, m^3/s (ft^3/s)

t_1 = discharge time, s

e = natural logarithm base, 2.71828

The Halon 1301 discharge rate necessary to maintain a given concentration of agent is⁷

$$R = \frac{(C)(E)}{(S)(100 - C)} \quad (6)$$

After the agent discharge is stopped, the decay of the agent concentration with respect to time is⁷

$$C = C_0 e^{(-Et_2/V)} \quad (7)$$

where

C_0 = agent concentration at end of discharge, percent volume

t_2 = time after stopping discharge, s

Table 4-6.15 Correction Factors for Altitudes

Altitude		Correction Factor

6000	1829	0.80
7000	2134	0.77
8000	2438	0.74
9000	2743	0.71
10000	3048	0.69
11000	3353	0.66
12000	3658	0.64
13000	3962	0.61
14000	4267	0.59
15000	4572	0.56

Compensation for leakage: Occasionally a Halon 1301 total flooding system is designed for an enclosure that has openings that cannot be closed. An example may be a conveyor belt penetrating an enclosure wall, yet even these openings can sometimes be closed using inflatable seals. Halon 1301 discharged into an enclosure for total flooding will result in an air/agent mixture that has a higher specific gravity than the air surrounding the enclosure. Therefore, any openings in the lower portions of the enclosure will allow the heavier air/agent mixture to flow out and the lighter outside air to flow in. Fresh air entering the enclosure will collect toward the top, forming an interface between the air/agent mixture and fresh air. As the leakage proceeds, the interface will descend toward the bottom of the enclosure. The space above the interface will be completely unprotected, whereas the lower space will essentially contain the original extinguishing concentration. There are two methods of compensating for unclosable openings: initial overdose and extended discharge.

The initial overdose method provides for an adequate overdose of Halon 1301 to ensure a preestablished minimum of agent at the end of the desired soaking period. Mechanical mixing is required within the enclosure to prevent stratification of agent concentration and a descending interface. Also caution must be used to prevent personnel exposure to the high initial concentrations. The necessary initial concentration depends upon the extended protection time required, the opening height, the opening width, and the volume of the enclosure. Referring to Figure 4-6.11, the equation used to determine the initial concentration for a final concentration of 5 percent is⁷

$$G = \frac{(K)(W_o)(2g_c H^3)^{1/2}}{3V} \quad (8)$$

where

G = geometric constant

K = orifice discharge coefficient, 0.66

W_o = opening width, m (ft)

g_c = acceleration due to gravity, 9.81 m/s² (32.2 ft/s²)

H = opening height, m (ft)

The other method used to compensate for unclosable openings is extended discharge. This involves at least two separate piping systems: one to achieve the initial agent concentration, and the other to provide a continuous addition of Halon 1301 at a rate which will compensate for leakage out of the enclosure during the soaking period. The agent must be discharged in such a way that uniform mixing of agent and air is obtained. This mixing is often difficult due to the extremely low flow rates being discharged over the entire soaking period, occasionally resulting in small nozzles freezing due to air moisture. Based on the design concentration and opening height, Figure 4-6.12 can be used to determine the Halon 1301 makeup rate per unit opening width.

Assuming the design concentration of Halon 1301 is established in the enclosure initially, the time required for

Figure 4-6.11. Initial amount of Halon 1301 to produce a 5 percent residual concentration in enclosures equipped for mechanical mixing.

the interface to reach half-way down the enclosure height can be calculated. Referring to Figure 4-6.13, the geometric constant previously calculated for initial overdose is used to find the soaking time based on the initial design concentration.

Flow Calculations

Piping Theory

The overall objective of designing a Halon 1301 piping system is to properly disperse the required concentration of Halon 1301 throughout the hazard volume within the specified time period. Systems must be engineered to operate quickly and effectively. The discharge time (usually a nominal 10 s as indicated by NFPA 12A) is a critical system constraint and is measured as the interval between the first appearance of liquid at the nozzle and the time when the discharge becomes predominantly gaseous.⁷ The hydraulic calculations are considered to be the most difficult part of the entire design process, and are almost always calculated with the aid of computer programs due to the tedious nature of manual calculations.

As illustrated in Figure 4-6.14, the primary components of a Halon 1301 piping system are the agent storage

Figure 4-6.12. Extended discharge rate of Halon 1301 to maintain constant concentrations in enclosures with openings.

container, the discharge nozzle, and the pipe. Often, more than one nozzle is required, complicating the calculations significantly. An attempt should always be made to keep the piping system simple and if possible, balanced. A balanced system has the actual and equivalent pipe lengths from container to each nozzle within ± 10 percent of each other and has equal design flow rates at each nozzle.⁷

As with sprinkler systems or other systems involving fluid flow, the methodology for solving Halon 1301 piping calculations involves seeking terminal characteristics based on property changes encountered due to the movement of the fluid. The system hydraulics are controlled by the selection of the orifice area at the discharge nozzle. This orifice area is calculated from the nozzle pressure, which is based on the starting pressure in the container and pressure losses in the pipe. Because the flow of Halon 1301 is nonsteady and has a change in phase from liquid to vapor, the calculations become highly complex. To simplify calculations, the average discharge conditions are determined so that they might reasonably represent the entire discharge time span. This time-independent model is based on the moment in time when half the liquid phase of the agent has left the nozzle. All the calculations for a 10 s discharge condition shown in Figure 4-6.15 would be solved at the mid-discharge condition (5 s). Hence, the critical characteristics that vary with dis-

charge, such as the storage container pressure and the pressure-density relationship in the pipeline, are replaced with average time-independent values.²³

By the time half of the liquid agent is out of the nozzle, the original pressure in the storage container has dropped considerably. To calculate the mid-discharge storage container pressure, the percent of agent still within the pipe must be determined. Also, the initial drop in pressure immediately after the start of discharge is nonlinear. As seen in Figure 4-6.16, the pressure recovery is due to the nitrogen vigorously boiling out of the halon/nitrogen mixture within the storage container.

Unlike water-based fluid flow, the pressure drop occurring when Halon 1301 flows through a pipe is nonlinear and is dependent on the pipeline agent density, not the distance traveled. The pipeline flow is two phase, with a mixture of liquid and vapor agent. As the agent travels in the pipe, the pressure and density decrease, which increases the velocity and the amount of halon vapor. Interestingly, the evolution of the nitrogen from the halon/nitrogen mixture in the storage container causes the halon to drop in temperature and become more dense. This phenomenon fortunately is not a factor in the calculations since a time-independent model is being used. The increase in density at any one location over the entire time span should not be confused with the decrease in density that occurs when the agent flows from one location to another.

Figure 4-6.13. Time required for interface between effluxing Halon 1301/air mixtures and influxing air to descend to center of enclosures not equipped for mixing.

Figure 4-6.14. Primary components of a Halon 1301 piping system.

Guidelines and Limitations

Unrealistic distribution networks often fail to perform to specifications and are difficult if not impossible to predict from a calculation standpoint. As the piping system becomes more unrealistic, the calculations become more unreliable. To aid in the development of accurate calculations, certain fundamental limitations are necessary to ensure proper system design. These limitations are especially important with respect to computer programs since these programs have a tendency to be operated abusively

Figure 4-6.15. Summary of Halon 1301 discharge conditions based on a 10-s discharge.

with high expectations. Summarized below are the design constraints for Halon 1301 hydraulic calculations.²⁴

1. Good design practice
2. Discharge time ≤ 10 s
3. Favorable system temperature

Figure 4-6.16. Pressure profile during system discharge.

4. Initial container pressure = 2482.2 kPa (360 psig) or 4137.0 kPa (600 psig)
5. Initial container fill density $\leq 1121.4 \text{ kg/m}^3$ (70 lb/ft³)
6. Percent in pipe \leq maximum value
7. Turbulent flow \geq minimum value
8. Nozzle pressure \geq minimum value
9. Actual nozzle area \leq percentage of feed pipe area
10. Actual nozzle area = calculated nozzle ± 5 percent

Good design practice includes such items as favoring balanced systems, keeping the degree of flow/split imbalance below a maximum value, avoiding vertically installed tees, and avoiding nozzles on different floor levels which may separate the halon gas/vapor mixture. The values for some of the constraints are determined by the individuals developing computer programs that are verified by approval agencies through testing.

Calculation Procedure

The piping calculations comprise four steps:

1. Determining the necessary input data
2. Calculating the average storage container pressure
3. Calculating the nozzle pressure at each nozzle, and
4. Calculating the nozzle orifice areas

Pipeline calculations are performed for each segment of pipe having both a constant flow rate and a uniform pipe diameter; thus the piping network is divided into sections called junctions. Each discharge nozzle is also

identified. The forms necessary for the input data, pressure calculations, and nozzle calculations are contained in Figures 4-6.17 and 4-6.18. Assuming the appropriate input data are known, the average storage container pressure is determined from Figure 4-6.19 based on the percent agent in pipe, which itself is determined by⁷

$$\% \text{ in pipe} = \frac{K_1}{(W_i/V_p) + K_2} \quad (9)$$

where

W_i = initial charge weight of Halon 1301, lb

V_p = internal pipe volume, ft³ (See Table 4-6.16)

K_1 and K_2 = constants (See Table 4-6.17)

Once the average storage container pressure is known, Figures 4-6.18 and 4-6.20 and Equations 10 through 22 can be used to determine the nozzle orifice areas for a 360 psig system. Usually the calculations are based on a 10-s discharge time, though this is sometimes changed slightly to produce flow rates in accordance with Table 4-6.18. Turbulent pipeline flow can also be achieved by using smaller pipe sizes. Pipe diameters that are too small result in unacceptably high pressure losses; therefore, care must be used in pipe size selection. It is important to recognize that approximations have been made for Y and Z factors and nozzle coefficients. The calculation procedure presented here is only intended to demonstrate the current methodology and not to provide a rigorous solution. The necessary equations are^{7,25}

Postdesign Considerations

Postdesign considerations are divided into two categories: system documentation and inspection/acceptance practices. Good halon system design is not complete until full documentation is provided for installation, acceptance, and eventual end user operation. Proper documentation is especially important to prevent the inadvertent discharge of a halon system for other than a fire, since replacement of the halon agent could be very difficult with future availability being dependent on recycled stock.

System Documentation

System documentation should include the items listed below. This material is necessary for others to install, test, operate, and maintain the system. Information can be recorded entirely on system drawings or in both a written manual and system drawings.

System manual

1. Design Data
 - (a) Functional and operational description
 - (b) Halon 1301 weight calculations
 - (c) Hydraulic piping calculations
 - (d) Special considerations
2. Installation, Maintenance, and Inspection Instructions

As-built system drawings

1. Floor Plan Layout
 - (a) Suitable dimensions
 - (b) Equipment locations
 - (c) Special installation details
2. Electrical Schematic
3. Equipment Identification
4. Special Notes

Inspection and Acceptance

After installation, each system should be inspected and tested by technicians trained by the equipment manufacturer covering the items listed below:

1. Test system wiring for proper connection, continuity, and resistance to ground
2. Check system control unit in accordance with factory recommended procedures
3. Calibrate and test each detector in accordance with factory recommended procedures
4. Test each releasing circuit for proper resistance by means of a current-limiting meter
5. Test the operation of all ancillary devices such as alarms, dampers, magnetic closers, and so on.
6. Obtain a certificate of inspection signed and dated by the installing contractor and the authority having jurisdiction

An installation checklist is often used, which expands on the above items in complete detail.²⁶ These checklists are available from agent and equipment manufacturers, installers, insurance groups, and consultants.

When accepting a newly installed halon system, it is important to determine compliance with design specifications. In previous years, a full discharge test was required to provide unquestionable evidence of performance, yet this could be a costly and sometimes unnecessary burden carried by the end user. End users with multiple systems would often prove system acceptance based on the performance characteristics of their other systems.

The primary reason for discharge test failure, when it was performed, was because the hazard enclosure would not hold the design concentration over the entire soaking period.²⁷ Checking the enclosure for possible halon leak-

age points has always been difficult and is the only questionable part of the acceptance/inspection procedure. A method referred to as the enclosure integrity test has proved to be very effective for this problem, and validates the integrity of the protected enclosure.⁷ This technique shows much promise and has potential for substantially enhancing the reliability of proper system operation.

The most immediate and effective use of fan pressurization techniques is for leakage path indication.²⁸ This involves pressurizing or depressurizing the enclosure with the fan pressurization apparatus and using an indicating device, such as a smoke pencil or acoustic sensor, to determine leakage paths. The installers' visual inspection of the enclosure now becomes very effective since even the smallest cracks can be located. Due to low cost and simplicity, a smoke source is usually the most desirable method for locating leaks, but an excellent alternative is the use of a directional acoustic sensor that can be selectively aimed at different sound sources.²⁹ Highly sensitive acoustic sensors are available that can detect air as it flows through an opening and are sensitive enough to clearly hear a human eye blink.³⁰ Openings can also be effectively detected by placing an acoustic source on the other side of the barrier and searching for acoustic transmission. Another method is to use an infrared scanning device if temperature differences across the boundary are sufficient.³¹ These techniques are not quantitative, but they are effective, inexpensive, and easily performed.

Environmental Considerations

Scientific evidence indicates that fire protection Halon 1301 is one of several man-made substances adversely affecting the earth's ozone layer.³² Ozone exists naturally as a thin layer of gas in the stratosphere that blocks the sun's harmful ultraviolet rays and thus is vital to life on earth. Several adverse environmental and direct health effects are linked to ozone layer depletion, and its preservation is of paramount concern to mankind. It's believed that Halon 1301 (and other chlorofluorocarbons) chemically destroy ozone when emitted into the atmosphere.

Earlier, the phase-out of full system discharge tests that were used to verify enclosure integrity received special attention since they accounted for a proportionately large percentage of fire protection halon emissions. Fortunately, the amount of fire protection Halon 1301 released for actual fires is relatively small. Testing a system by performing a full discharge test allows the release of Halon 1301, which on a cumulative basis may be potentially harmful to the environment and depletes relatively precious stocks of halon agent that should be dedicated to suppressing fires. The release of Halon 1301 should be minimized.

With regard to ozone layer depletion, halons used for fire protection are different than halons used for other industrial applications.³³ Fire protection halons are unique because of their essential mission to prevent the loss of life, minimize the loss of irreplaceable property, assure the continuity of vital operations, and reduce the amount of fire byproducts polluting the atmosphere. Efforts have

been made to minimize the release of fire protection halons for noncritical tasks like training, testing, and research. It is assumed that halon systems will remain in existence for many more years, despite the present worldwide restriction on their production.

Nomenclature

a	constant (see Table 4-6.19)
A	pipe size factor
A_c	altitude correction factor—(refer to Table 4-6.15)
b	constant (see Table 4-6.19)
B	pipe size factor
c	constant (see Table 4-6.19)
C	Halon 1301 concentration, percent by volume
C_0	agent concentration at end of discharge, percent by volume
d	constant (see Table 4-6.19)
D	actual pipe diameter, in.
e	natural logarithm base, 2.71828
E	ventilation rate, m^3/s (ft $^3/s$)
f	nozzle coefficient (approximation = 0.7)
F	nozzle orifice area, in. 2
FL	fuel loading, kg/m^3 (lb/ft 3)
g_c	acceleration due to gravity, 9.81 m/s^2 (32.2 ft/ s^2)
G	geometric constant
h	heat of vaporization of the agent at T_a , kJ/kg (Btu/lb)
H	opening height, m (ft)
k	thermal conductivity of the piping, $W/m \cdot K$ (Btu $\cdot t/hr \cdot ft^2 \cdot f$)
K	orifice discharge coefficient, 0.66
K_c	conversion factor, 0.06093 (0.00685)
L	linear length of piping, m (ft)
L_e	pipe elevation length, ft
LFL	lower flammable limit of fuel in air, percent volume
MFL	maximum allowable fuel loading, kg/m^3 (lb/ft 3)
MW	molecular weight of fuel
P	pressure, psig
P_0	junction starting pressure, psig
P_e	elevation pressure, psig
P_T	temporary pressure, psig
Q	flow rate, lb/s
r	agent density, lb/ft 3
R	Halon 1301 discharge rate, kg/s (lb/s)
r_i	inside pipe radius, mm (in.)
r_o	outside pipe radius, mm (in.)
S	specific vapor volume of Halon 1301 based on temperature, m^3/kg (ft $^3/lb$)
SG	specific gravity of fuel
t	system discharge time
T	temperature, K (R)
t_1	discharge time, s

t_2	time after stopping discharge, s
T_a	agent temperature, C (F)
T_p	pipe temperature, C (F)
V	enclosure volume, m^3 (ft 3)
VF	volumetric quantity of fuel, m^3 (ft 3)
V_p	internal pipe volume, ft 3 (See Table 4-6.16)
W_x	amount of agent increase, kg (lb)
W_{H_2O}	specific weight of water, 997.9 kg/m^3 (62.3 lb/ft 3)
W	weight of Halon 1301 required, kg (lb)
W_o	opening width, m (ft)
W_i	initial charge weight of Halon 1301, lb
Y_1	first Y factor
Y_2	second Y factor
Y_T	temporary Y factor
Z	Z factor

CHAPTER 7

Halon Replacement Clean Agent Total Flooding Systems

Philip J. DiNenno

Introduction

The regulation of Halon 1301 under the Montreal Protocol and its amendments culminated in the phaseout of production of halons in the developed countries on December 31, 1993. This regulation engendered tremendous research and development efforts across the world in a search for replacements and alternatives. Over the past several years, several total flooding, clean agent alternatives to Halon 1301 have been commercialized, and development continues on others. In addition to clean total flooding gaseous alternatives, new technologies, such as water mist and fine solid particulate, are being introduced. This chapter focuses on total flooding clean agent halon replacements.

Table 4-7.1 is a summary of the most important halocarbon and inert gas extinguishing agents developed to date. The table gives the chemical name; trade name; American Society of Heating, Refrigerating, and Air-Conditioning Engineers, Inc. (ASHRAE) designation (for halocarbons); and chemical formula.

Characteristics of Halon Replacements

Clean fire suppression agents are defined as fire extinguishants that vaporize readily and leave no residue.¹ Clean agent halon replacements fall into two broad categories: (1) halocarbon compounds and (2) inert gases and mixtures. Halocarbon replacements include compounds containing carbon, hydrogen, bromine, chlorine, fluorine, and iodine. They are grouped into five categories: (1) hydrobromofluorocarbons (HBFC), (2) hydrofluorocarbons (HFC), (3) hydrochlorofluorocarbons (HCFC), (4) perfluorocarbons (FC or PFC), and (5) fluoriodocarbons (FIC).

Philip J. DiNenno, P.E. is president of Hughes Associates Inc., a fire protection engineering research and development firm. He has been actively involved in the testing and development of halon replacement chemicals and alternative fire suppression technologies.

Table 4-7.1 Commercialized Halon Replacement Nomenclature

Chemical Name	Trade Name	ASHRAE Designation	Chemical Formula
Perfluorobutane	CEA-410	FC-3-1-10	C ₄ F ₁₀
Heptafluoropropane	FM-200	HFC-227ea	CF ₃ CH ₂ CF ₃
Trifluoromethane	FE-13	HFC-23	CHF ₃
Chlorotetrafluoroethane	FE-24	HCFC-124	CHClFCF ₃
Pentafluoroethane	FE-25	HFC-125	CHF ₂ CF ₃
Dichlorotrifluoroethane (4.75%)	NAF-SIII	HCFC	CHCl ₂ CF ₃
Chlorodifluoromethane (82%)		Blend A	
Chlorotetrafluoroethane (9.5%)			CHClFCF ₃
Isopropenyl-1-methylcyclohexene (3.75%)			
N ₂ /Ar/CO ₂	Inergen	IG-541	N ₂ (52%) Ar (40%) CO ₂ (8%)
N ₂ /Ar	Argonite	IG-55	N ₂ (50%) Ar (50%)
Argon	Argon	IG-01	Ar (100%)

While the characteristics of halocarbon clean agents vary widely, they share several common attributes:

1. All are *electrically nonconductive*.
2. All are *clean agents*; that is, they vaporize readily and leave no residue.
3. All are *liquefied gases* or display analogous behavior (e.g., compressible liquid).
4. All can be stored and discharged from typical Halon 1301 hardware (with the possible exception of HFC-23, which more closely resembles 600 psig [40 bar] superpressurized halon systems).
5. All (except HFC-23) use nitrogen superpressurization in most applications for discharge purposes.

6. All are less efficient fire extinguishants than Halon 1301 in terms of storage volume and agent weight. The use of most of these agents requires increased storage capacity.
7. All are total flooding gases after discharge. Many require additional care relative to nozzle design and mixing.
8. All produce more decomposition products (primary HF) than Halon 1301, given similar fire type, fire size, and discharge time.
9. All are more expensive at present than Halon 1301 on a weight (mass) basis.

Inert gas alternatives include nitrogen and argon, and blends of these. One inert gas replacement has a small fraction of carbon dioxide. Carbon dioxide is not an inert gas, because it is physiologically active and toxic at low concentrations (approximately 9 percent). Inert gas clean agents are stored as pressurized gases. They are electrically nonconductive, form stable mixtures in air, and leave no residue.

Extinguishing Mechanisms

Halocarbon clean agents extinguish fires by a combination of chemical and physical mechanisms, depending upon the compound. Chemical suppression mechanisms of HBFC and HFIC compounds are similar to Halon 1301; that is, the Br and I species scavenge flame radicals, thereby interrupting the chemical chain reaction. Other replacement compounds suppress fires primarily by extracting heat from the flame reaction zone, thereby reducing the flame temperature below that which is necessary to maintain sufficiently high reaction rates by a combination of heat of vaporization, heat capacity, and the energy absorbed by the decomposition of the agent.

Oxygen depletion also plays an important role in reducing flame temperature. The energy absorbed in decomposing the agent by breaking fluorine and chlorine bonds is quite important, particularly with respect to decomposition product formation. There is undoubtedly some degree of "chemical" suppression action in flame radical combustion with halogens, but it is considered to be of minor importance since it is not catalytic (e.g., one F radical combines with one H flame radical).

The lack of significant chemical reaction inhibition in the flame zone by HCFC, HFC, and FC compounds results in higher extinguishing concentrations relative to Halon 1301. The relative importance of the energy sink represented by breaking halogen species bonds results in higher levels of agent decomposition relative to Halon 1301.

Inert gas acts by reducing the flame temperature below thresholds necessary to maintain combustion reactions. This condition is created by reducing the oxygen concentration and by raising the heat capacity of the atmosphere supporting the flame. The addition of a sufficient quantity of inert gas to reduce the oxygen concentration below 12 percent (in air) will extinguish flaming fires. The agent concentration required is also a function of the heat capacity of the inert gas added. Hence, there are differences in minimum extinguishing concentration between inert gases.

Flame Suppression Effectiveness

Flame suppression effectiveness of total flooding halon replacement agents has been evaluated in a number of ways. The predominant small-scale test method for establishing flame extinguishing concentrations for liquid and gaseous fuels is the ICI cup burner or variations thereof.

Figure 4-7.1 is a schematic of the ICI cup burner. A small laminar flame is established above a "cup" of fuel surrounded by a cylindrical chimney. An air/agent mixture flows up the chimney surrounding the flame. The minimum concentration of agent (in air) at which the flame is extinguished is the minimum extinguishing concentration (MEC). There are many variations of the basic device as used by different laboratories. These variations include cup and chimney diameter, different mixing and measuring methods, chimney height, and agent/air mixture velocity past the flame.² Table 4-7.2 gives some indication of the variation in cup burner extinguishing concentration for a range of extinguishment concentrations for a range of agents with *n*-heptane as the fuel.

Figure 4-7.1. Schematic of ICI cup burner apparatus.²

^bNational Institute of Standards and Technology

Given the wide variation in test methods, the minimum extinguishing concentrations measured from these different devices are reasonably close.

The cup burner can also be used to establish the MEC for inert gases; Ansul obtained a value of 2.91 percent for IG-541. This result is in contrast to concentrations of 32, 41, and 23 percent by volume measured by the National Institute of Standards and Technology (NIST) for nitrogen, argon, and carbon dioxide, the components of Inergen.

NIST has conducted investigations on a wide range of halon replacement chemicals for aviation use. In order to give a wider perspective on the type and range of chemicals being evaluated for fire suppression use, Table 4-7.3 is included. The table gives cup burner *n*-heptane flame extinction data for a wide range of potential halon replacements.

Table 4-7.4 presents cup burner MEC for a range of fuels and agents taken from various sources. Where multiple values of the MEC were found, they are given. The nitrogen data are presented as representative inert gas values. Argon/N₂ blend MEC values would be higher. These data should not be used for design purposes without ensuring that the concentrations are consistent with system manufacturer requirements and third-party approvals.

Table 4-7.5 presents cup burner and full-scale data from VdS. Table 4-7.6 is a compilation of "best values" of cup burner data from a range of sources compiled by Tapscott.

In addition to the cup burner apparatus, researchers at NIST have utilized an opposed-flow diffusion flame (OFDF) apparatus to rank halon replacements for fire extinguishing effectiveness. The OFDF burner is commonly used for combustion research. It has many advantages as a research tool for fundamental combustion studies. Its primary advantage is in its ability to relate the results to fundamental predictions of flame structure and conditions at flame extinction. The oxidizer (and suppressant) stream is forced down onto the fuel surface, exhaust gases are drawn down through an annulus or jacket around the fuel cup, and a flat flame is established. Water cooling is provided for the fuel cup and exhaust gas.

The OFDF burner can vary the turbulence intensity or strain rate of the flame. For most applications of clean

agent fire suppression, the strain rate is not a major concern, but in specialized applications, such as engine nacelles with high fuel and oxidizer flow rates or in high-pressure spray or jet fires, the strain rate will substantially impact the minimum condition for extinguishment. Figure 4-7.2 is a sample plot showing the variation of the mole fraction of extinguishing agent versus the strain rate at extinction for *n*-heptane fuels for a range of suppressants. For typical natural fires, the strain rate is approximately 25 s⁻¹. At high strain rates, the flame is extinguished at lower agent concentrations.

Figure 4-7.3 shows the relationship between MEC for the cup burner and OFDF apparatus. As expected, the cup burner concentration is quite similar to the OFDF concentration at a low strain rate (25 s⁻¹), typical of natural fires. In all cases, the MEC of agent is much lower for high strain rate flames. This further reinforces the value of

^aCalculated on the basis volume of discharged extinguishant

the cup burner and OFDF apparatus for evaluation of minimum extinguishing concentration.

Extinguishing concentrations for Class A fuels were traditionally developed using wood cribs as part of the equipment listing/approval process. Further, the minimum Class A extinguishing concentration used for de-

sign purposes was required to be greater than or equal to the minimum extinguishing concentration for heptane. Recently, additional tests utilizing plastic sheet arrays of polymethylmethacrylate (PMMA), acrylonitrile-butadiene-styrene (ABS), and polypropylene (PP) have been required.^{9,10} Typical results are shown in Figure 4-7.4

Figure 4-7.4. Typical Class A extinguishment results for HFC-227ea.

for two different room sizes. The results of these tests indicate that for extinguishment times exceeding 3 min, the extinguishing concentrations for these materials are below the heptane cup burner value and in general well above the 10-min extinguishment time value for wood cribs.

Clean agent systems are widely used in electronic equipment areas where fires involving electrically energized cables and equipment are often encountered. Extinguishment tests involving PMMA heated externally with Nichrome wire indicated that agent concentrations substantially higher than those typical for plastic fuels were required. For example, extinguishing concentrations of 9.5, 9, and 20 percent were required for FC-3-1-10, HFC-227ea, and HFC-23, respectively.

Extinguishment tests on actual wire and cable materials were reported by McKenna et al.¹² Three types of tests were conducted: ohmic heating, conductive heating, and printed wiring board arcing. The ohmic heating tests involved deliberate electrical overheating of the conductor. These results are summarized in Table 4-7.7 for HFC-227ea. Note that even under severe overcurrent conditions, all cable assemblies were extinguished at 5.8 percent, a typical Class A extinguishing concentration. The one exception was the 18 AWG polyethylene (PE) coaxial cable, which is generally not used in power applications. The striking difference between these results and those discussed earlier for PMMA probably lies in the fire-retardant nature of real electrical wire and cable assemblies.

Results for cable assemblies heated at the ends by conduction, a situation simulating an overheated connection, showed results similar to the ohmic heating tests for Hypalon and PVC cables.

Tables 4-7.8 and 4-7.9 summarize the fire suppression capability of halon replacement agents relative to Halon 1301 for halocarbon and inert gas agents, respectively. Agent mass and storage volume ratio equivalents for Halon 1301 are given as 1. All comparisons are based on 120 percent of the agent manufacturer's recommended

MEC, based on the cup burner. The design values used are as provided by the manufacturer. Design values for HCFC Blend A and Argon are problematic, because these values are below the MEC as measured by the cup burner.

Note that all clean agent alternatives require at least 60 percent more agent by weight and storage volume. This requirement is a consequence of the elimination of bromine in the compounds and subsequent level of catalytic recombination of flame radicals. These data should be taken as representative values, as there are variations between hardware manufacturers.

The storage volume equivalents are based on the maximum fill density permitted in a storage cylinder with a pressure rating as recommended by the manufacturer. The approximate 10 : 1 storage volume requirement for inert gases is a consequence of the inability to liquefy these gases at ambient temperature.

The storage volume equivalent does not translate directly to a required area or volume for storage cylinders. The relative "footprint" of these storage volume equivalents will vary with the volume of the space protected and the maximum storage cylinder size offered by a manufacturer for a particular gas. In general, the floor area required for storage of inert gases exceeds 10 : 1 for large protected volumes.

Explosion Inerting

One of the most important application areas of total flooding fire suppressants is explosion inerting. The inerting concentration of an agent is the concentration required to prevent unacceptable pressure increases in a premixed fuel/air/agent mixture subjected to an ignition source. Inertion concentrations are typically measured in small laboratory-scale spheres, with an electric spark initiator.

The measured inerting concentration of an agent is dependent on the details of the test apparatus used, particularly the ignition source strength and "allowable" pressure rise. The allowable pressure rise is a surrogate

DNE: did not extinguish

measurement of the distance the flame front travels inside the constant volume sphere prior to suppression. Inerting concentration is not appropriate for use in deflagration or detonation (explosion) suppression.

Small-scale sphere data are used to develop flammability diagrams for various fuel/oxidizer/agent concentrations. Section 2, Chapter 7, which addresses flammability limits, gives an excellent introduction to the subject. There is a wealth of data in the combustion literature on flamma-

bility limits for inert gases, such as nitrogen and argon, for a variety of fuels available.

Table 4-7.10 provides inerting concentration data for several agents and fuels, taken from small-scale inertion spheres.¹³⁻¹⁵ There are some substantial differences in results. Heinonen¹⁶ has identified both ignition source type and strength as important variables with differences of ± 40 percent for Halon 1301 inerting concentrations reported. Figure 4-7.5 shows flammability

diagrams derived from small-scale inertion data such as that presented in Table 4-7.10, along with points taken from a large-scale (22.5 m³) explosion vessel. While the small- to large-scale agreement is reasonable, there are scale effects.

Explosion Suppression

Explosion suppression systems employ rapid delivery of agent following very early detection of an ignition. Such systems employ significantly higher agent quantities (than flame suppression or inertion), delivered at higher rates. The total agent delivery time is on the order of 100 milliseconds.

Explosion suppression systems must be specifically designed for a particular application. There are no generic design requirements or standards currently available for such systems.

Senecal¹⁷ and Senecal et al.¹⁸ report on explosion suppression testing in occupied armored fighting vehicles and aerosol filling rooms. Results were obtained on premixed fuel droplet sprays. In contrast to flame suppression or inerting, suppression or deflagration requires significantly more agent. The aerosol filling room tests employed 20 kg of HFC-227ea, FC-3-1-10, and HFC-236fa, and 10 kg of water in a 80-m³ test room to suppress a 90-g propane release in a simulated aerosol filling station. Suppression of the propane-air deflagration was achieved, and the maximum

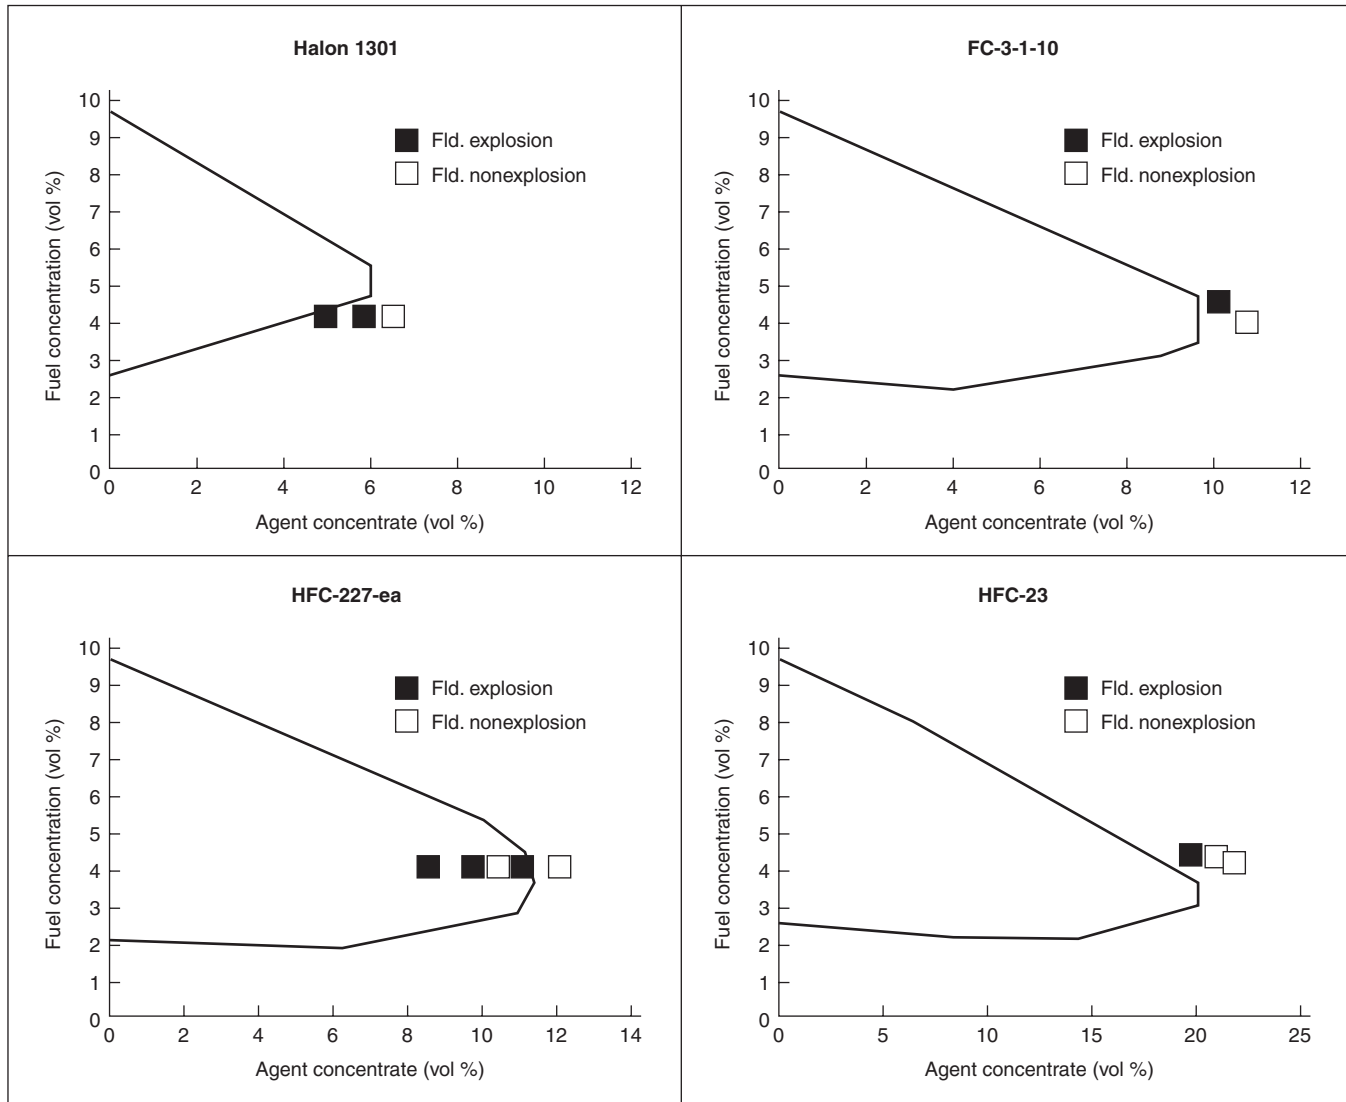

Figure 4-7.5. Small-scale flammability diagrams for propane and several replacement agents. Squares denote explosion/nonexplosion points in large-scale 22.5 m³ chamber.¹⁹

flame front extension was approximately 4 ft. Suppression tests of heated diesel fuel droplet cloud deflagrations were conducted in simulated armored fighting vehicle crew compartments.

Table 4-7.11 summarizes typical data for flame suppression, inertion, and deflagration suppression concentrations. Note these values are for comparison purposes only. They should not be used in any way for design purposes.

Suppression of detonations requires substantially higher agent concentrations. An excellent discussion is given in Reference 3.

Toxicity

A major factor in the use of a clean agent fire suppressant in a normally occupied area is toxicity. While all

halocarbon agents are tested for long-term health hazards, the primary end point is acute or short-term exposure. The primary acute toxicity effects of the halocarbon agents described in this chapter are anesthesia and cardiac sensitization. For inert gases, the primary physiological concern is reduced oxygen concentration.

Halocarbon agents: Cardiac sensitization is the primary short-term toxicity problem for fire suppression applications. Cardiac sensitization is a term describing the sudden onset of cardiac arrhythmia in the presence of a concentration of an agent, caused by sensitization of the heart to epinephrine. The presence of epinephrine is critical to the onset of arrhythmia. This knowledge is important in fire protection applications because production of epinephrine is increased by the body under stress.

HFC-23	12	20.2	—
IG-541	29	49.0	—

The two toxicity end points used to describe cardiotoxicity and allowable exposure levels are (1) no observed adverse effect level (NOAEL) and (2) the lowest observed adverse effect level (LOAEL). The NOAEL is the highest concentration of an agent at which no “marked” or adverse effect occurred. The LOAEL is the lowest concentration at which an adverse effect was measured.

The procedures used to evaluate cardiac sensitization vary somewhat. The procedure involves intravenous dosing of male beagle hounds with epinephrine for 5 min. Continuous inhalation exposure to the agent follows for 5 min. Following this inhalation exposure, the hound is dosed again with epinephrine and monitored for 5 min to determine the effect of the agent and epinephrine. The protocol is performed at higher doses until an effect occurs.

Effects are monitored by electrocardiograph (EKG) measurements. An adverse effect is generally considered to be the appearance of five or more arrhythmias or ventricular fibrillation. The data from these tests are evaluated by medical experts, and the appropriate NOAEL and LOAEL values are reported by the Environmental Protection Agency (EPA) under the Significant New Alternatives Policy (SNAP) program.

There is no direct correlation between the experimental results from hounds to humans. It is generally accepted, due to the combination of the high doses of epinephrine in the tests and the similarity in cardiovascular function between hounds and humans, that the results can be applied to humans.

In addition to the short-term chronic exposure limits of interest in fire suppression system design, the EPA evaluates longer term inhalation data for these compounds. Table 4-7.12 summarizes NOAEL, LOAEL, and LC₅₀ values. Note that the LC₅₀ (the concentration lethal to 50 percent of a population) values greatly exceed the NOAEL at typical fire extinguishing concentrations.

Recently, the exposure limits for halocarbon agents have been modified. Physiologically based pharmacokinetic modeling (PBPK) for evaluation of acute exposure to

^cMaximum concentration before oxygen depletion

halocarbon agents has been used to establish alternative exposure limits for halogenated agents.²⁰ PBPK modeling attempts to account for the time-dependent uptake rate of halocarbons in the body and establishes exposure limits based on the rate of uptake.²¹⁻²⁵ The limits are based on the concentration of agent and the time at which the concentration of agent in the blood equals that of the LOAEL. Typical PBPK results for safe exposure times for HFC-227ea and HFC-125 are given in Table 4-7.13. Note that exposure above the NOAEL limits and up to the LOAEL is permitted.

These limits were derived and supported by the EPA, which has the primary regulatory authority for health and toxicity associated with halon replacements. The use of the PBPK approach partially accounts for the differences between laboratory animal tests and humans. The laboratory results form the basis of the end points (LOAEL) and are still conservative due to the nature of epinephrine dosage used during the animal tests.²⁶

Where PBPK modeling data do not exist, the use of halocarbon agents in occupied areas is subject to the constraint that the design concentration must be less than the NOAEL. While it is recommended that all systems employ predischage alarms and that personnel evacuate prior to system actuation, it is understood that inadvertent discharges and short-term exposures will occur, hence the limitation. It is expected that emergency exposures for up to several minutes at or below the NOAEL are reasonably safe. In no case should systems be designed or installed where intentional exposure of any duration is anticipated.

It has been proposed by the EPA that agents be permitted for use at concentrations up to the LOAEL where evacuation will occur in less than 60 s. This proposal has not been integrated into design standards to date due to the uncertainty of accidental exposure conditions.

Table 4-7.13 Exposure Limits Derived from PBPK Modeling for HFC-227ea and HFC-125²⁰

HFC-227ea Concentration			HFC-125 Concentration		
% V/V	ppm	Human Exposure Time (min)	% V/V	ppm	Human Exposure Time (min)
9.0	90,000	5.00	7.5	75,000	5.00
9.5	95,000	5.00	8.0	80,000	5.00
10.0	100,000	5.00	8.5	85,000	5.00
10.5	105,000	5.00	9.0	90,000	5.00
11.0	110,000	1.13	9.5	95,000	5.00
11.5	115,000	0.60	10.0	100,000	5.00
12.0	120,000	0.49	10.5	105,000	5.00
			11.0	110,000	5.00
			11.5	115,000	5.00
			12.0	120,000	1.67
			12.5	125,000	0.59
			13.0	130,000	0.54
			13.5	135,000	0.49

Based on the limitation that the design concentration must be below the NOAEL, it can be seen from Table 4-7.12 that three agents are acceptable for use in normally occupied areas for flame extinguishant purposes: HFC-227ea, HFC-23, and FC-3-1-10.

Inert gas agents: Inert gas agents are, in effect, physiologically inert. The primary physiological problem with these agents is the reduced oxygen concentration caused by the high agent design concentrations. One inert gas blend employs a low concentration of CO₂ (which is not physiologically inert) in order to counter the effects of the reduced oxygen concentration. The mechanism of this effect is discussed in Reference 27.

Current limitations on exposure limits for inert gases are as follows: for gas concentrations up to 43 percent (a residual oxygen concentration of 12 percent), exposure time is limited to 5 min. For agent concentrations between 43 and 52 percent (12 and 10 percent residual oxygen concentration), the exposure time is limited to 3 min. For concentrations greater than 52 percent, exposure time is limited to 30 s.

There is strong indication that small concentrations of CO₂ added to inert gases (such as IG-541) substantially reduce hypoxic effects and improve human performance at low oxygen levels. Regulatory authorities have not yet differentiated between such agents and other inert gases or blends.²⁷

Environmental Factors

The evaluation of clean agent fire suppressants includes a consideration of environmental factors. International, national, and local government regulations control the use of any alternatives in this regard. The primary environmental consideration is ozone depletion potential (ODP). ODP is a measure of a chemical's ability to deplete stratospheric ozone, with CFC-12 as a basis with an ODP of 1. All chemicals with non-zero ODP are subject to phaseout under the Montreal Protocol and its amendments. Table 4-7.14 summarizes environmental impact data for halocarbon alternatives. Note that FC and HFC compounds have zero ozone depletion potential. The HCFC compounds have quite low ODP. Other HCFC compounds are widely used as CFC replacements for refrigerants.

Other environmental factors that are potentially important in a regulatory context are global warming potential (GWP) and atmospheric lifetime. GWP is a measure of the contribution of a gas to the so-called greenhouse effect. It is a function of atmospheric lifetime and the ability of the gas to absorb infrared radiation. The evaluation of GWP is an extremely complex issue, and, currently, none of these compounds are regulated on that basis in the United States. Long atmospheric lifetime, a measure of the persistence of a chemical in the atmosphere, is of concern not only as it relates to GWP, but also due to the uncertainty of the effects of chemicals for long time periods in the atmosphere. The EPA currently has use restrictions on FC-3-1-10 based primarily on its long atmospheric lifetime. These restrictions permit the use of this chemical

Table 4-7.14 Environmental Factors for Halocarbon Clean Agents

in applications where no other alternative is technically feasible.

Thermophysical Properties

Tables 4-7.15 and 4-7.16 give thermophysical properties of clean agent replacements from NFPA 2001,¹ in English and SI units, respectively. Table 4-7.17, extracted from Reference 28, gives independent data and estimates for

some thermophysical properties. Additional thermophysical and transport property data can be found in Reference 4 for FM-200, and Reference 28 for a range of halocarbon alternatives.

Isometric diagrams for halocarbon agents HFC-227ea, pressurized at 360 and 600 psig at 70°F with nitrogen, and HFC-23 are given in Figures 4-7.6, 4-7.7, and 4-7.8, respectively. Note that HFC-23 is not pressurized with nitrogen. Figure 4-7.9 gives the pressure/temperature relationship

Clean Agent System Design

Once the agent has been selected, the general discussion on clean agent system design presented by Grant in Section 4, Chapter 6 should be reviewed. The basic process is outlined below:

1. Determine the design concentration.
2. Determine the total agent quantity.
3. Establish the maximum discharge time.

4. Select piping material and thickness consistent with pressure rating requirements.
5. Design piping network and select nozzles to deliver required concentration at required discharge time to ensure mixing.
6. Evaluate compartment over/underpressurization and provide venting if required.
7. Establish minimum agent hold requirements and evaluate compartments for leakage.

These attributes apply only to the mechanical design of the system.

The detection and actuation systems are critical and integral parts of a clean agent system design. The detection system should be designed to actuate the system, with ap-

Figure 4-7.6. Isometric diagram of HFC-227ea, pressurized to 360 psig with N₂, at 70°F.⁴

Figure 4-7.7. Isometric diagram of HFC-227ea, pressurized to 600 psig with N₂, at 70°F.⁴

appropriate pre-discharge alarms, before unacceptable thermal or nonthermal damage occurs. This aspect is particularly important where the thermal decomposition products of halocarbon clean agents are a concern. Section 4, Chapter 1 provides engineering methods and calculation procedures for this purpose.

In addition to the detection, actuation, and alarm systems, the enclosure itself is critical in the design of any total flooding suppression system. The most important considerations are that the enclosure be of sufficient integrity to (1) prevent preferential agent loss during discharge and (2) prevent excessive agent/air mixture loss after discharge to ensure adequate hold time.

As a general rule, all openings, notably doors and ventilation fans and/or openings, must be secured prior to discharge in conjunction with the detection and alarm

Figure 4-7.8. Isometric diagram of HFC-23.¹

systems. Agent system installation in rooms with unclosable openings should not be attempted unless sufficient test data are available to ensure adequate concentrations. Some enclosures, such as very tightly sealed low EMF emission electronics spaces, require additional care to avoid compartment damage due to over/underpressurization during agent discharge.

Design Concentration

Flame extinguishment: Design concentrations for various agents and fuel combinations are generally determined by a combination of small-scale testing, large-scale testing, independent laboratory approval of hardware, and addition of design safety factors.

Historically, minimum design concentrations for Halon 1301 were set by the cup burner extinguishing concentration plus a 20 percent safety factor. A minimum Halon 1301 design concentration of 5 percent was also established for all applications. For heptane, the cup burner value was approximately 3 percent; with a 20 percent safety factor, a design concentration of 3.6 percent is obtained. At the minimum design concentration set by NFPA 12A, *Standard on Halon 1301 Fire Extinguishing Systems*, 1992 edition, of 5 percent, a 66 percent safety factor was achieved. For fuels with cup burner extinguishing concentrations greater than 4.2 percent, the safety factor remained at 20 percent.

Figure 4-7.9. Isometric diagram of inert gases and blends, treated as ideal gases, pressurized to 2175 psig, at 70°F.¹

The basic requirement for determining the design concentration of clean agents in NFPA 2001, *Standard on Clean Agent Fire Extinguishing Systems*, 1994 edition, is two-fold. First, the minimum extinguishing concentration as determined by the cup burner must be established. Second, after this minimum is established by the *system* manufacturer, full-scale third-party approval testing is conducted using the manufacturer's hardware on heptane, wood crib, and selected flammable liquids. These tests are performed at the cup burner minimum extinguishing concentration, not the design concentration. Further, they are conducted with flooding factors lower than utilized in design. Hence, the minimum set by the cup burner or equipment manufacturer, whichever is higher, is tested in full scale as part of the approval/listing process for the agent/system combination. Often, hardware manufacturers will establish a minimum concentration greater than the cup burner value to account for nozzle inefficiency.

There has been some full-scale test work that indicates that the 20 percent safety factor may be insufficient. Sheinson et al. noted significant improvement in extinguishing time performance with a safety factor of 40 percent.²⁹ Brockway noted similar results, with no performance improvement beyond a safety factor of 40 percent.³⁰

Analysis by Schlosser³¹ indicated that the probability of failure of a system was reduced from approximately 15

to 10 percent when the safety factor increased from 20 to 30 percent. In addition to these data, the variation in cup burner values used as a basis for design concentration was significant due in part to a lack of standardization in the method. Some full-scale test results³² also indicated a need for higher design concentrations.

Based on these factors, the first edition of ISO 14520-1 required a minimum safety factor of 30 percent.³³ The current edition of NFPA 2001²⁰ requires a 30 percent safety factor for Class B hazards and for any system actuated by manual means only.

In addition to increased safety factors, the concept of design factors was introduced into the 2000 edition of NFPA 2001. A design factor is used to increase the agent quantity for a specific installation or design that has attributes for which the minimum safety factor may not be sufficient. The only variable for which design factors have been quantified is for systems with multiple flow splits protecting more than four enclosures simultaneously. The motivation for a design factor in these rare cases is the uncertainty in the split of agent mass flow at unbalanced tee junctions and the compound of that uncertainty with more than four tees in series.

It has also been noted by several investigators that higher safety factors result in lower thermal decomposition products.^{29,30,34} None of the above referenced investigations utilized listed or approved hardware for the specific agents tested; as in most cases, the tests were performed before such hardware was available.

There is an exception in NFPA 2001, to the general rule that a minimum extinguishing concentration be established by the cup burner method. It was alleged that reliable cup burner data were not available for HCFC Blend A due to the fact that (1) the agent was a blend and (2) one of the blend components heats at a low vapor pressure. In the case of this agent, a minimum extinguishing concentration of 7.2 percent and, hence, a design concentration of 8.6 percent was established through limited full-scale testing. Since at the time insufficient data were available to evaluate the claim, the exception that requires full-scale testing at minimum extinguishing concentration consistent with UL 1058, *Halogenated Agent Extinguishing System Units*,³⁵ was invoked. Since that time, reliable cup burner data were obtained for the blend from several laboratories. The data are consistent with MEC values for the blend components, primarily HCFC 22. Furthermore, some full-scale testing has indicated that the design concentration of 8.6 percent may be inadequate.³⁶ This issue is, however, unresolved at the present time.

For Class A fires, NFPA 2001 requires full-scale testing and third-party approval for evaluating design concentration on solid polymeric materials. In many cases, the MEC for heptane is used as a practical minimum.

There has been no systematic evaluation of these agents under so-called "deep-seated" fire scenarios. Part of the problem is the circular definition of deep-seated fires in NFPA 12A. However, the Underwriters Laboratories Inc. (UL) and Factory Mutual Research Corporation (FMRC) listing procedures require testing on wood cribs subsequent to long preburn times (approximately 5 min). Under these tests, surface oxidation and char reactions do occur.

Design concentrations for fire scenarios involving long preburn times in thick arrays of cellulosic fuels will require additional testing. For most applications where incidental quantities of cellulosic materials may be involved and preburn times are relatively short (<5 min) time frames (i.e., automatic actuation), the flame extinguishing concentrations for Class A fuels will be less than, or equal to, that of n-heptane and can be used. Surface oxidation or charring reactions do not occur with most polymers; hence, so-called “deep-seated” fires are not a concern where Class A fuels are involved.

IG-541 is used at 37.5 percent minimum design concentration where Class A materials are involved. Other inert gases should have similar or higher minimum design concentrations.

As previously discussed, the minimum design concentration is a function of the fuel, the agent, and the delivery systems. Design concentrations for specific hazards must be determined in accordance with the system manufacturer’s approval or listing.

Agent Quantity

Once the design concentration is established, the quantity of agent necessary to achieve that concentration is determined. The quantity of halocarbon agent necessary is determined by the following equation:

$$w = \frac{V}{S} \left(\frac{C}{100 - C} \right) \tag{1}$$

where

V = net volume of protected space

C = design concentration (%)

w = specific weight of agent required

S = specific volume [ft³/lb (m³/kg)] and is determined by

$$S = k_1 + k_2(T) \tag{2}$$

where T is the minimum ambient temperature of the protected space, and k₁ and k₂ are constants. Values for k₁ and k₂ used in Equation 2 are given in Table 4-7.18.

The flooding factor in Equation 1 [C/(100 - C)] implies that the agent/air mixture “lost” during discharge is well mixed and has an agent concentration of C. This formula makes no assumption regarding leakage of the enclosure. During UL/FMRC approval testing, the agent is evaluated with a flooding factor of (C/100), essentially assuming that losses during discharge are 100 percent air.

For inert gases, the following formula is used:

$$X = 2.303 \frac{V}{S} \log \left(\frac{100}{100 - C} \right) V_s \tag{3}$$

where

X = volume of inert gas required at 70°F

V_s = specific volume at 70°F

V = net protected hazard volume

S = specific volume at ambient temperature in protected volume (from Equation 2) = k₁ + k₂ (T)

Table 4-7.18 Specific Volume Constants

Agents	°F		°C	
	k ₁	k ₂	k ₁	k ₂
FC-3-1-10	1.409	0.0031	0.0941	0.0003
HCFC Blend A	3.612	0.0079	0.2413	0.00088
HCFC-124	2.352	0.0057	0.1578	0.0006
HFC-125	2.724	0.0063	0.1701	0.0007
HFC-227ea	1.885	0.0046	0.1269	0.0005
HFC-23	4.731	0.0107	0.2954	0.0012
IG-541	9.7261	0.0211	0.649	0.00237
IG-01	8.514	0.0185	0.5685	0.00208
IG-55	10.0116	0.0217	—	—

The flooding factor used here, log [100/(100 - C)], is derived assuming that leakage from the compartment during discharge occurs with a varying concentration of agent from zero to C from beginning to the end of discharge. It is identical to the expression used in CO₂ system design. It assumes that the displaced atmosphere is freely vented from the enclosure.

Discharge Time

The maximum discharge time permitted for halocarbon clean agent systems is 10 s. This discharge time is taken to be the moment where all liquid agent has cleared the nozzle. The total discharge time will be longer as agent vapor and nitrogen are expelled from the system.

The 10-s discharge time limitation for halocarbon agents is designed to aid four objectives:

1. Provide high flow rates through nozzles to ensure adequate mixing of agent with air inside the enclosure.
2. Provide sufficient velocity through pipes to ensure homogeneous flow of liquid and vapor.
3. Limit the formation of agent thermal decomposition products.
4. Minimize direct and indirect fire damage, particularly in fast-developing fire scenarios.

The most important of these objectives relative to discharge time is the minimization of agent thermal decomposition product formulation. Items 1 and 2 alone are determined by the piping system design.

The discharge time requirement for inert gases is currently 60 s.¹ Longer discharge times are typically used for these systems in Europe. The two primary reasons to constrain the discharge time of inert gas agents that form no thermal decomposition products are (1) to limit the direct and indirect fire damage and (2) to minimize the length of time that the fire burns in a depleted oxygen atmosphere. As more information is developed on the effect of discharge time on inert gas agent performance, this 60-s limit may be increased for certain applications.

In some applications, such as flammable liquid hazards and explosion inerting, it is necessary to discharge the agent quickly to minimize direct fire damage or to ensure that the agent concentration is achieved prior to the lower explosive limit (LEL) being reached.

Thermal Decomposition Products

All of the halocarbon replacement agents form higher levels of thermal decomposition products than Halon 1301 under similar conditions. For a given fuel, the two primary variables determining the level of decomposition products are (1) the size of the fire at the time of discharge and (2) the time required to reach an extinguishing concentration in the compartment.

The dependence of thermal decomposition product formulation on discharge time and fire size has been extensively evaluated.^{29-34,36-39} Figure 4-7.10 from Reference 36 is a plot of peak HF concentration as a function of fire size to room volume ratio. Similar data for 10-min average HF concentrations are given in Figure 4-7.11. Data are given for Halon 1301, HFC-23, HFC-227ea, FC-3-1-10, and HCFC Blend A from three series of fire tests done at different room scales. The data are for a total discharge time of 15 s, which is analogous to a 10-s discharge time based on nozzle liquid runoff. The data are for heptane pool or heptane pool and spray fires.

The first observation is that the quantity of HF formed is approximately five to ten times higher for all halocarbon replacements relative to Halon 1301. There may be differences between the various HFC/HCFC compounds tested, but it is not clear from these data whether such differences (1) occur, (2) are attributable to agent mixing and distribution, or (3) are attributable to locally high velocities or concentrations of agent from the nozzle. In all of the data reported, the fire source, that is, heptane pans of varying sizes, was baffled to prevent direct interaction with the agent jet.

These data were taken with an FTIR spectrometer at a location approximately 1 m from the floor, or about mid-flame height, near the wall. The method used was correlated to grab sample and ion-specific electrode (ISE) methods.³⁷ In all cases, the agreement was good, except for the HCFC blend. In this case, the HF concentration inferred from the treated grab sample was significantly

Figure 4-7.10. Maximum HF concentration resulting from extinguishment of heptane fires with nominal 10-15 s total discharge times.³⁶

Figure 4-7.11. Average HF concentration resulting from extinguishment of heptane pool or heptane pool and spray fires with nominal 15-s total discharge time.³⁷

(>50 percent) higher than that measured using the FTIR. Since the HCFC blend contains an HF “scrubber,” it is postulated that treatment of the grab sample with a basic solution, as required for the ISE measurements, caused formation of additional HF by reentry with F loosely bound up by reaction with the scrubber. Hence, the FTIR data presented for HCFC Blend A represent a significantly lower quantity of HF than would actually be expected if the product was hydrolyzed. This condition is also consistent with the fact that the agent was tested at the manufacturer’s recommended design concentration, which is approximately 40 percent lower than the basis for all other agents.

The effect of long discharge times or delayed extinguishing times is shown in Figure 4-7.12.³⁷ The variation between the HFC/HCFC alternatives and Halon 1301, relative to HF production, is approximately the same as that shown in Figure 4-7.11 for different fire sizes.

Figure 4-7.12. Maximum HF concentration resulting from extinguishment of 4.0-kW heptane fires.³⁷

Although other thermal decomposition products have been identified in some cases, it appears that HF is the primary thermal decomposition product of interest relative to human safety and equipment damage.

HF, like HCl, is an irritant gas, detectable at very low concentrations. For HF there are very large differences between the approximate lethal concentration (ALC) and human detection and severe sensory irritant thresholds (approximately two and three orders of magnitude, respectively).

Fire size necessary to generate short-term lethal concentrations of HF in an enclosure (on the order of >1000 ppm) can, in some cases, pose a greater hazard to personnel in the protected space during a discharge in a fire incident, due to the fire and its effects, than the secondary impact of agent thermal decomposition products. This, however, should be verified for a particular application under a range of fire scenarios, using engineering methods discussed by Hanauska⁴⁰ and Hanauska et al.⁴¹

The production of HF and other agent decomposition products forms a potential hazard for occupants. Table 4-7.19²⁰ summarizes potential health effects in healthy individuals. Note that exposure above 200 ppm may begin to impair escape particularly at exposure times exceeding 5 min.

Emergency Response Planning Guidelines (ERPG) values, developed by the American Industrial Hygiene

Association, for 10-min exposures, are as follows: ERPG-2, a level at which mitigating steps such as evacuation should be taken is 50 ppm, and ERPG-3, the maximum non-lethal exposure concentration for 10 min is 170 ppm. The ERPG values are in contrast to an analysis by Melchrum,⁴² which indicates that a dose of 12,000 ppm/min has 1 percent lethality in exposed animals. Additional health-effect and risk-assessment data are given in References 43 to 46.

The impact of thermal decomposition products on electronics equipment is another area of concern. There are not sufficient data at present to predict the effects of a given HF exposure scenario on all electronics equipment. Several evaluations of the impact of HF on electronics equipment have been performed relative to the thermal decomposition of Halon 1301, where decomposition products include HF and HBr. One of the more notable was a NASA study where the shuttle orbital electronics were exposed to 700, 7000, and 70,000 ppm HF and HBr.⁴⁰ In these tests, exposures up to 700 ppm HF and HBr caused no failures. At 7000 ppm, severe corrosion was noted; there were some operating failures at this level.

Dumayas exposed IBM-PC-compatible multifunction boards to environments produced by a range of fire sizes as part of an evaluation program on halon alternatives.⁴⁷ He found no loss of function of these boards following a 15-min exposure to postfire extinguishment atmosphere up to 5000 ppm HF, with unconditioned samples stored at ambient humidity and temperature conditions for up to 30 days. Forssell et al.⁴⁸ exposed multifunction boards for 30 min in the postfire extinguishment environment; no failures were reported up to 90 days posttest. HF concentrations up to 550 ppm were evaluated.

While no generic rule or statement can be made at present, it appears that short-term damage (<90 days) resulting in electronics equipment malfunction is not likely for exposures of between 500 to 1000 ppm HF for up to 30 min. This result, however, is dependent on the characteristics of the equipment exposed, postexposure treatment, exposure to other combustion products, and relative humidity. Important equipment characteristics include its location in the space, existence of equipment enclosures, and the sensitivity of the equipment to damage.

All HCFC and HFC clean agents form more thermal decomposition products than Halon 1301, given similar fire sizes and discharge times. The primary variable controlling the quantity of thermal decomposition products is the size of the fire at the time of agent discharge. Through evaluation of the fire size at the time of system actuation, using engineering methods described in Section 4, Chapter 1, and subsequent design of the detection system, the potential hazard posed can be managed adequately.

Hanauska⁴⁰ and Hanauska et al.⁴¹ have indicated that the degree of thermal decomposition products of agents can be managed safely. Full-scale testing with typical Class A fuel packages, in conjunction with typical detection system installation,⁴⁸ has shown that the level of thermal decomposition products is acceptable in typical computer/electronics spaces. For installation in hazard areas where very rapidly developing large fires are likely, the degree of thermal decomposition formation should be

Table 4-7.19 Potential Human Health Effects of Hydrogen Fluoride in Healthy Individuals²⁰

Exposure Time	Hydrogen Fluoride (ppm)	Reaction
2 min	<50	Slight eye and nasal irritation
	50-100	Mild eye and upper respiratory tract irritation
	100-200	Moderate eye and upper respiratory tract irritation, slight skin irritation
	>200	Moderate irritation of all body surfaces, increasing concentration may impair escape
5 min	<50	Mild eye and nasal irritation
	50-100	Increasing eye and nasal irritation, slight skin irritation
	100-200	Moderate irritation of skin, eyes, and respiratory tract
	>200	Definite irritation of tissue surfaces, will impair escape at increased concentrations
10 min	<50	Definite eye, skin, and upper respiratory tract irritation
	50-100	Moderate irritation of all body surfaces
	100-200	Moderate irritation of all body surfaces, escape-impairing effects likely
	>200	Escape-impairing effects will occur, increasing concentrations can be lethal without medical intervention

evaluated in the context of the hazard posed by the fire and the performance of alternative fire protection systems.

Hydraulic Flow Characteristics

All halocarbon replacement agents exhibit two-phase flow behavior. Since all, except HFC-23, are used in cylinders pressurized to 360 or 600 psig, they are also multiple-component flows. Inert gas mixtures are single-phase gas flows with one or more components. As in the case of engineered Halon 1301 systems, all flow calculation procedures used must be listed or approved by the authority having jurisdiction, and be within the limitations of the flow calculation method determined during the engineered system approval process.

The characteristic that differentiates two-phase pipe flow from incompressible fluid (e.g., water) pipe flow is the existence of gas and liquid phases simultaneously in the pipe network. This aspect, coupled with the relatively short flow times, results in significant challenges to correctly predicting the flow. Among the important factors are the change in density of the fluid with pressure, the release of nitrogen in the cylinder and pipe as the fluid pressure and temperature change, differences in agent mass delivered caused by the flow time imbalances between nozzles, and preferential distribution of phases (and subsequently agent mass) at tee splits.

The need for accurate flow predictions is driven by three design requirements:

1. Control of agent discharge time
2. Maintenance of adequate nozzle flow and pressure to ensure agent distribution and mixing at the listed coverage area
3. Delivery of adequate, but not excessive, agent quantities to different rooms within the same protected area, when such rooms are flooded simultaneously

In addition, agent flow rate and thermodynamic state properties are necessary for estimating compartment pressurization levels during agent discharge.

For pre-engineered systems, limits on discharge time and nozzle pressure are built into the limits on piping system geometry. Agent distribution is handled by constraining pre-engineered systems to balanced flow conditions (i.e., the same agent mass is distributed from each nozzle). For adequate design of engineered systems, accurate methods for predicting these elements are required.

Figure 4-7.13 is an idealized plot of cylinder and nozzle pressure during discharge. Throughout the discharge process the amount of agent vapor and liquid, as well as dissolved and gaseous nitrogen, varies. As the pressure decreases in the cylinder and piping system, more agent is vaporized and nitrogen is released from the solution in the agent. The formation of additional vapor and nitrogen bubbles lowers the average density of the fluid. The rapid vaporization of agent is more pronounced in low boiling point/high vapor pressure agents. The fluid temperature also varies with time and along the length of the piping network. The fluid temperature also impacts the degree of agent vaporization and nitrogen release as well as liquid agent density. The discharge process can be divided into five sections.

Figure 4-7.13. Idealized cylinder and nozzle pressure time curves for halocarbon agents.

The first is the process of filling the pipe with agent. The rate at which this process occurs is driven by the speed of the agent interface moving through the network. This speed is determined by either the sonic velocity at the agent interface or the discharge of displaced air through the nozzle. This phase determines the time at which the agent discharges from each nozzle. For systems with high degrees of imbalance in terms of flow path length or large pipe volume differences between nozzles, there can be significant delay in agent reaching one nozzle before another. This delay has a dramatic effect on the distribution of mass from each nozzle.

Once the agent reaches the nozzle and is compressed in the pipeline, the so-called nozzle peak pressure is reached. At this moment, agent is discharging from each nozzle.

The next step in the discharge process is the so-called quasi-steady agent flow regime. This step is generally the longest portion of the discharge, particularly for systems with low pipe volume to agent volume ratios. This period of the discharge process is the basis for the simplified pressure drop calculations embodied in NFPA 12A for balanced Halon 1301 systems.

The next milestone during the discharge process is cylinder liquid runout, where no liquid agent remains in the cylinder. At this moment, an interface between liquid agent and nitrogen/agent vapor forms and travels through the network.

When the trailing liquid/vapor interface reaches the first nozzle, nozzle liquid runout occurs. This runout is important in two ways. First, liquid runout occurs at different times during the discharge for each nozzle and can significantly impact the quantity of agent flowing from any given nozzle. Second, it is possible in many circumstances to discharge sufficient vapor/gas mixture from the first nozzle at NLRO (nozzle liquid runout) to reduce the pressure in the piping below that necessary to flow the remaining agent in the network. This aspect is

especially important for low vapor pressure agents and for nozzle designs requiring relatively high minimum operating pressures.

Once all of the nozzles have been cleared of liquid agent, the system is discharging a combination of nitrogen and agent vapor. This regime is usually ignored since most (>95 percent) of the agent has already been delivered through the nozzles.

The importance of the pipe filling and nozzle runout with these alternatives is relatively more critical with low vapor pressure alternatives due to (1) the inability of the agent to deliver significant pressure to the system by boiling and (2) the higher fluid densities that occur in the piping relative to Halon 1301.

Figures 4-7.14(a) through (d) illustrate the stages of the agent discharge network.

Flow regime: If the flow velocity of the agent in the piping is not high enough, the flow may separate into two distinct phases in the piping. This occurrence causes severe problems at tee splits and in evaluating pressure drops. Therefore, minimum flow rates that ensure a homogeneous mixture of agent liquid and vapor/nitrogen bubbles must be maintained. Various flow regimes are illustrated in Figures 4-7.15 and 4-7.16 for horizontal and vertical pipe, respectively. One of the objectives of approval testing of flow calculation procedures is to ensure

Figure 4-7.14(a). Initial conditions.

Figure 4-7.14(b). Valve open, pipe filling.

that homogeneous flow regimes are maintained in the piping throughout the discharge process. In Figures 4-7.15 and 4-7.16, these are denoted as dispersed bubble and bubble flow regimes, respectively.

Flow division at tees: For a single-component, single-phase flow condition, the flow split at a tee junction is determined by the flow rate of the nozzles downstream of the tee. For two-phase fluids, flow distribution occurs at tees that are sensitive to the velocity of the flow along each branch of the tee, the orientation of the tee, the pressure at the tee, and the phase distribution of the fluid (gas or liquid) entering the tee.

The primary cause of preferential flow splits at tees is the inertia of the liquid versus vapor/gas phase. This condition is most readily envisioned for side-flow tees where one branch of the flow is required to turn 90 degrees. Gas/vapor bubbles with lower momentum relative to the liquid agent will make this change of direction more readily. This change results in relatively less mass flow down the side-flow branch at approximately the same volumetric flow rate or velocity. For bullhead tees, the same problem applies, except that it is more subtle and involves velocity differences through each branch of the tee. For evenly split (50 percent/50 percent) flows, the velocity is identical in both directions, resulting in no flow split correction; as the split becomes greater the velocity

Figure 4-7.14(c). *Quasi-steady flow, liquid throughout network.*

Figure 4-7.14(d). *Cylinder liquid runoff.*

differences are greater, and inertial effects of the gas/vapor relative to the liquid cause significant redistribution of mass through each branch of the tee.

The dependence was understood for Halon 1301 and described in detail by Williamson.⁴⁹ Similar processes occur in all two-phase flows including air/water, steam/water, and refrigerant flows. In the context of clean agent system design calculations, this flow distribution is dealt with using empirical factors that redistribute the flow relative to the pure pressure-driven flow distribution which would occur without preferential phase distribution at tees.

Figures 4-7.17 and 4-7.18 illustrate these correction factors for Halon 1301 flows in bullhead and side-flow tees, respectively.⁴⁹ All of the halocarbon agent flow predictions require similar treatment. Side-flow tees and bullhead tees require independent empirical correction factors. One of the most important limitations to any flow calculation procedure is the maximum flow split allowed for each type of tee. For a bullhead tee, as one moves farther away from 50 percent/50 percent splits, the correction factor becomes greater, and at some point usually in the range of 80 percent/20 percent, it becomes so large that the prediction becomes unreliable. For side-flow tees, allowable flow splits, ranges between 75 percent/25 percent and 90 percent/10 percent are typical. This correction

of flow splits at tees is one reason that final approval of engineered system designs should be constrained to calculation methods that have undergone testing within the range of flow splits required.

Pressure drop due to friction loss: The pressure drop caused by friction in the pipeline is calculated differently for two-phase fluids. The presence of agent vapor and gas affects the pressure drop per unit length of pipe. There are numerous methods for dealing with two-phase fluid pressure drop.^{50,51} Those typically used for fire suppression agent calculations involve either (1) correcting the pressure drop estimated for single-phase fluid as a function of liquid to vapor/gas volume fraction or (2) empirical correlations of the pressure drop to average fluid density. Figure 4-7.19 illustrates the dependence of pressure drop on liquid volume fraction. In all cases for purposes of design of fire protection systems, the pressure drop is calculated on the basis of a homogeneous flow assumption where changes in the liquid fraction are seen as density changes in the homogeneous fluid.

Testing and approval of design methods: The approval or listing of a two-phase flow calculation procedure is part of the approval granted for engineered systems. Since some aspects of two-phase flow calculations are em-

Figure 4-7.15. Horizontal pipe flow regimes.⁵²

Figure 4-7.16. Vertical pipe flow regimes.⁵²

pirically based (e.g., flow regime, pressure drop, and flow splits) and all calculation procedures have some bounds on their validity, testing is performed to verify the predictions and establish the limits of the calculation procedure. These limitations are crucial in helping to ensure that system designs do not exceed verified limits of calculation.

One of the most rigorous approval procedures used in verifying design methods is outlined by Underwriters Laboratories Inc.³⁵ UL 1058, *Halogenated Agent Extinguishing System Units*, was used for evaluating engineered Halon 1301 systems, but the same approach is taken for all clean agent alternatives. Design method limitations are described by the following ten parameters:

1. Percent of agent in piping (maximum)
2. Minimum and maximum discharge times
3. Minimum pipeline flow rates
4. Variance of piping volume to each nozzle
5. Maximum variance of nozzle pressures within a piping arrangement
6. Maximum ratio of nozzle diameter to inlet pipe diameter
7. Arrangement most likely to exhibit vapor time-imbalance condition at nozzle
8. All types of tee splits, including through tees, bullhead tees, and so forth
9. Minimum and maximum container fill density
10. Minimum and maximum flow split for each type of tee

Figure 4-7.17. Bullhead-tee-flow split corrections for Halon 1301.⁴⁹

Figure 4-7.18. Side- and through tee-flow split corrections for Halon 1301.⁴⁹

Figure 4-7.19. Pressure drop versus liquid volume fraction.⁵¹

These parameters are related to the important attributes of the agent discharge process previously discussed. Full-scale testing is performed to evaluate the performance of the design method. The limits on flow calculation method performance are as follows:

1. Actual versus predicted discharge time ± 1 s
2. Actual versus predicted nozzle pressure ± 10 percent
3. Actual versus predicted mass flow through a nozzle, $-5 + 10$ percent

Testing in conjunction with a particular manufacturer’s hardware is important. Ensuring that pressure drop through a particular valve assembly is calculated properly and nozzle orifice discharge coefficient evaluation are two critical hardware-dependent verifications.

Several generic flow calculation routines have been developed.^{37,53-56} Of these, two are directed at single-nozzle systems with very short discharge times⁵⁵ or relatively simple balanced networks.⁵⁴ It is not recommended that any generic calculation procedure be used for final design purposes, unless it has been tested with the specific hardware to be installed and the system is within the limitations derived by tests.

In order to preserve a 10-s discharge time, the mass flow rate of these clean agents must be higher than Halon 1301. The increased density of some of the alternative agents in the piping, caused by lower vapor pressures and nitrogen solubility differences, may result in high enough mass flow rates to retrofit existing Halon 1301 systems. While agent cylinders and nozzles will require replacement, it is often possible to preserve the existing Halon 1301 pipe network. Preservation often requires the use of lower fill density cylinders to increase the average system pressure throughout the discharge time. Any such retrofit using existing Halon 1301 piping must be carefully evaluated with respect to hydraulic performance, with particular care given to preserving minimum required nozzle pressures and flow divisions at tees.

Nozzle Area Coverage and Height Limitations

One of the most important requirements of a gaseous total flooding fire suppression system is the ability of the system to deliver a uniform concentration of agent throughout the protected enclosure. The nozzle design and minimum nozzle pressure are critical in ensuring this distribution of agent. The performance of the nozzle is evaluated by full-scale approval testing, such as UL 1058.³⁵ The basic testing performed to evaluate nozzles is as follows:

1. Establish minimum nozzle pressure and maximum nozzle height by ensuring extinguishment of heptane fires located throughout a space with a height equal to the maximum allowable, at the minimum allowable nozzle pressure.
2. Establish maximum nozzle coverage area by extinguishing tests in a plenum at the minimum height (generally less than 0.5 m) at the maximum nozzle coverage area (on the order of 100 m²) and minimum nozzle operating pressure.

There are substantial differences between hardware manufacturers relative to minimum nozzle pressure, maximum ceiling height, and maximum average coverage. All nozzle orientations should be evaluated. In general, maximum nozzle heights are on the order of 4 to 5 m, nozzle area coverage on the order of 9 to 10 m², and minimum nozzle pressure between 3 and 6 bar. It is critical to

ensure that the nozzle spacing, height, and minimum pressure limits are not exceeded for a particular manufacturer's hardware in a specific design.

The flow, mixing, and distribution of an agent from a nozzle into an enclosure can be predicted theoretically for relatively simple nozzle designs using sophisticated computer models.⁵⁴ Further development of such methods for complex nozzle designs and compartment geometries may eventually form the basis of a design procedure. At present, however, the primary means of ensuring adequate nozzle performance is the hardware approval process and real-scale testing.

Since many of the halocarbon replacements have lower vapor pressures than Halon 1301, there is often a much higher percentage of liquid at the nozzle. This liquid makes the task of vaporizing and mixing the agent in the compartment more difficult. In general, nozzle designs used for Halon 1301 systems are not adequate for the halocarbon replacement agents. Due to the increased liquid fraction at the nozzle, it is critical to ensure that no unenclosed openings exist along the trajectory of the nozzle orifices. Increased liquid fraction may result in significant preferential loss of agent through these openings. This condition further emphasizes the need for third-party approval testing of nozzle performance. In any retrofit situation, the nozzles will need to be replaced even if the piping is adequately sized to deliver adequate agent flow rates.

Compartment Pressurization

The rapid discharge of agent into a compartment will cause rapid changes in the compartment pressure. Depending on the agent and rate of discharge, the initial pressure change may be negative. Figure 4-7.20 is a plot of compartment pressure versus time for the discharge of HFC-227ea into a 28-m³ room with a 360-cm² (56-in.²) leakage area.³⁷ Immediately after discharge, the pressure in the compartment drops below ambient to a minimum of -0.3 kPa; at approximately 1.5 s after discharge began,

Figure 4-7.20. Pressure measured in 28-m³ enclosure during C₃F₇H discharge, with nominal 15-s discharge time and 5-cm pan of n-heptane.³⁷

the pressure then begins to increase to a maximum of approximately 0.14 kPa after nozzle liquid runout. Similar results were obtained for FC-3-1-10. HFC-23 discharge exhibited much higher compartment overpressurization, without the marked initial negative pressure. The maximum overpressure for HFC-227ea and FC-3-1-10 discharge was similar to that of Halon 1301.

As the halocarbon agent is discharged into the space, it vaporizes rapidly, cooling the compartment and lowering the pressure. As the agent/air mixture gains heat from the walls or other objects in the space, the pressure recovers and, as additional agent is added, the pressure increases over ambient as mass is added to the compartment.

The expected maximum and minimum compartment pressure during discharge will be a function of the following:

1. Thermodynamic state of the agent at the nozzle
2. Nozzle design
3. Compartment volume and wall surface area
4. Size of fire
5. Initial conditions in space
6. Leakage area from compartment
7. Agent flow rate

For inert gases, significant compartment overpressurization can occur during discharge, unless adequate free vent area is provided. Calculation of required open area for venting is a part of the design manual for IG-541 systems.⁵⁷

No generalized design procedure for calculating under/overpressurization has been established. Forssell and DiNenno³⁷ have developed a procedure for estimating the compartment pressure as a function of agent, agent flow rate, agent thermodynamic state at the nozzle, compartment volume, and surface area and leakage area. The method has not been sufficiently tested for general application.

Agent Hold Time and Leakage

Traditionally, total flooding gas systems were required to maintain a minimum concentration for a specified time period (10 to 20 min) after discharge. The minimum required hold time was based on the following:

1. Soak time required for deep-seated Class A fuels
2. Response time of emergency personnel
3. Prevention of reflash due to presence of hot surfaces and other reignition sources, particularly in flammable and combustible liquid applications

Currently, there is no specified minimum hold or soak time for clean agents. The variables described above will vary between installations, and there is no significant database on the performance of these agents on deep-seated fires other than wood cribs. The designer will be required to specify the minimum soak time consistent with the requirements of the hazard being protected.

The ability of a compartment to maintain adequate agent concentrations is a function of the leakage of the compartment. Historically, this was done with Halon 1301 through the use of discharge tests. Discharge testing for

this purpose was rendered unnecessary by the introduction of door fan pressurization leakage tests. Appendix B of NFPA 2001 describes a complete procedure for evaluating agent hold time as a function of compartment leakage measured by the door fan pressurization method.

The only difference between alternative agents and Halon 1301 in this regard is the density of the agent/air mixture, which is the driving force for leakage in quiescent environments. The mixture density can be estimated as follows:¹

$$\rho_m = V_d \frac{C}{100} + \left[\frac{\rho_a(100 - C)}{100} \right]$$

where

ρ_m = clean agent/air mixture density (kg/m³)

ρ_a = air density (1.202 kg/m³)

C = clean agent concentration (%)

V_d = agent vapor density at 21°C (kg/m³)

Agent vapor densities at 21°C are given below:

FC-3-1-10	9.85 kg/m ³ (0.615 lb/ft ³)
HBFC-22B1	5.54 kg/m ³ (0.346 lb/ft ³)
HCFC Blend A	3.84 kg/m ³ (0.240 lb/ft ³)
HFC-124	5.83 kg/m ³ (0.364 lb/ft ³)
HFC-125	5.06 kg/m ³ (0.316 lb/ft ³)
HFC-227ea	7.26 kg/m ³ (0.453 lb/ft ³)
HFC-23	2.915 kg/m ³ (0.182 lb/ft ³)
IG-541	1.43 kg/m ³ (0.089 lb/ft ³)
Halon 1301	6.283 kg/m ³ (0.392 lb/ft ³)

All agents, except inert gases, have higher mixture densities than Halon 1301 at 5 percent when used at their design concentrations. This will require slightly more leak-tight enclosures to maintain the same hold time.

Summary

A wide range of inert gas and halocarbon total-flooding clean agents has been introduced over the past several years. More will be commercialized in the near future. The use of an agent must be consistent with applicable environmental regulations. The selection of an agent is driven by its fire performance characteristics, agent and system space and weight concerns, toxicity (particularly for use in occupied areas), and the availability of approved system hardware.

The design of clean agent systems must be carefully done in accordance with third-party listing and approval limitations on both agent and hardware. Given the relative lack of experience with systems employing these new agents, particular care in design, installation, inspection, testing, and maintenance is warranted. Design and installation standards, such as NFPA 2001 form the minimum requirements for these new technologies.

As generalized design methods and more detailed requirements evolve, the ability to design and install systems on a performance basis will increase. A critical part of the installation process is post-installation inspection

and testing. NFPA 2001 contains requirements for the approval and post-installation inspection and test of clean agent systems. Bearing in mind the relative complexity of these systems and the importance of the detection system and enclosure integrity, post-installation inspection and testing should be rigorously performed.

CHAPTER 8

Fire Temperature-Time Relations

T. T. Lie

Introduction

The intensity and duration of fire in buildings can vary in a wide range, and several studies have been carried out to investigate the determining factors. At present it is possible to estimate the temperature course of fire in enclosures under various conditions, provided the values of the parameters that determine it are known.

Several of these parameters, however, such as amount and surface area of the combustible materials, are unpredictable as they change with time and often vary from compartment to compartment in a building. It is not possible, therefore, to know at the time a building is erected the temperature course of a fire to which objects in that building might be exposed during its service life.

It is possible, however, to indicate for any enclosure a temperature-time curve that, with reasonable likelihood, will not be exceeded during the lifetime of the building. Such curves are useful as a basis for the fire-resistive design of buildings. They can also facilitate studies of fire resistance of building components exposed to fires of various intensity and duration.

In this chapter, analytical expressions will be given that describe characteristic temperature curves as a function of the significant parameters for various fire conditions commonly met with in practice.

Expressions will also be given for the standard fire curve used in North America, and for the fire curve adopted by the International Organization for Standardization (ISO).

Fire Temperatures

The temperature course of a fire in an enclosure may be divided into three periods:

1. The growth period
2. The fully developed period
3. The decay period

These periods are illustrated in Figure 4-8.1, where an idealized fire temperature course is shown. During the growth period, heat produced by the burning materials is accumulated in the enclosure. As a result, other materials may be heated so severely that they also ignite. At this stage of the fire, the gas temperatures rise very quickly to high values. The rather sudden ignition of materials in all parts of the room is called *flashover*. After the flashover, the fully developed period starts. Because the temperatures in the enclosure are relatively low in the growth period, their influence on the fire resistance of structural members is negligible. In fire resistance studies, therefore, the growth period can be disregarded. Actual risk of failure of structural members or fire separations begins when the fire reaches the fully developed stage. In this stage, temperatures of about 1000°C or higher can be reached, and the heat transferred from the fire to structural members may substantially reduce their strength. This risk also exists in the decay period.

Figure 4-8.1. Idealized temperature course of fire.

Dr. T. T. Lie is a research officer with the Institute for Research in Construction, National Research Council of Canada. He has carried out research related to fire resistance design, which includes evaluation of the fire resistance of building constructions by calculation and testing.

Parameters Determining the Fire Temperature Course

The most important parameters that determine the temperature course of a fire were first shown by Kawagoe and Sekine¹ and by Odeen,² who estimated the heat balance for fires in enclosed spaces. Usually part of the heat produced during a fire in an enclosure will be absorbed by the walls and contents, a part by the gases, and a part will be lost by radiation and convection from windows. (See Figure 4-8.2.) There is also loss of chemical energy that could have been released as heat because of outflow of unburned gases, which burn outside the enclosure. In addition, there is loss of unburned particles.

To be able to determine the temperature course, it is necessary to know at each moment during a fire, the rate at which heat is produced and the rate at which heat is lost to exposed materials and surroundings. Several of the parameters that determine heat production and heat losses, such as material properties, room dimensions, wall construction, window area, and emissivity of the flames and exposed materials, can be determined with reasonable accuracy. Others that are known approximately are the amount of gases that burn outside the room, the loss of unburned particles through windows, and the temperature differences in the room.

There are several parameters, however, whose magnitude cannot be predicted. Usually they change with time, and therefore, their value at the time of occurrence of a fire is determined by chance. Such parameters include the amount, surface area, and arrangement of the combustible contents, velocity and direction of wind, and

the outside temperature. The influence of wind³ and that of fire load can be substantial. Surveys show, for instance, that the variability of fire loads in various types of buildings is such that deviations in the order of 50 percent or more from the most probable fire load are common.⁴ As a consequence, variability of fire load alone may easily cause deviations from the most probable temperature course of hundreds of degrees centigrade in temperature and 50 percent or more in fire duration.

Possible Fire Severities

Owing to the substantial influence of uncertain factors, it is impossible to predict accurately the temperatures to which building components will be exposed during their service life. Even if the analysis to predict fire temperature courses in enclosures is perfect, it is very improbable that a certain predicted temperature course will occur.

The fire temperature to which building components will most likely be exposed during the use of a building is the relatively low temperature of a fire that has been extinguished before it reaches the fully developed stage. There is a small although not insignificant chance of occurrence of a fully developed fire. In this case, and assuming that the fire cannot be influenced by action of the fire brigade, the fire will be controlled either by the surface area of the materials that can participate in the burning or by the rate of air supply through the openings.^{2,5}

Whether the fire will be largely controlled by surface area or ventilation depends on the amount of combustible contents. Unless its quantity, surface area, and arrangement are controlled, or the size of the windows and floor area made such that the possibility of a ventilation-controlled fire becomes remote,^{6,7} the type of fire that may occur is unpredictable. According to statistical data, combustible contents of 10 to 60 kg per m² of floor area are normal, and there is a considerable probability of enclosures having a combustible content of 40 to 100 kg/m.^{2,4} It is probable that in the latter range, as confirmed by experiments,^{5,8} the fire will be mainly ventilation controlled, even when large window openings are present. It is likely that the greater the space behind the windows, or to a certain extent, the deeper the enclosure, the more material or surface area it will contain and therefore the greater will be the probability of a ventilation-controlled fire. Usually a ventilation-controlled fire is the more severe fire, and because of the substantial probability of its occurrence, it is common to base fire resistance requirements for buildings on the assumption that fire severities will be controlled by ventilation.

Characteristic Temperature Curves

It is possible to indicate for any enclosure a characteristic temperature-time curve whose effect, with reasonable likelihood, will not be exceeded during the lifetime of the building. Such curves are useful as a basis for the fire-resistance design of buildings. They can also facilitate studies of fire resistance of building components exposed to fires of different severity.

- Q_R = Radiation losses
- Q_I = Heat content of inflowing air
- Q_L = Heat content of outflowing gases
- Q_W = Heat losses to the walls
- Q_C = Heat produced by combustion
- Q_G = Rise of the heat content of the gases in the enclosure

Figure 4-8.2. Heat balance for an enclosure during a fire.

There are several reports which present the temperature course of fires in fully developed and decay periods.^{1,2,7,9,10} In all of these studies a procedure is followed in which the fire temperatures are determined by solving a heat balance for the enclosure under consideration.

For the fully developed period and ventilation-controlled fires, there is reasonable agreement in the temperatures found in the various studies, except for rather shallow rooms of limited size. In the latter case, the amount of combustible gases that burn outside may increase in such a way with increasing ventilation that the temperature decreases.⁷

There is less agreement in the results of the various studies for the decay period, partly due to the complexity of the processes that determine the temperature in that period. So far, rates of decay of temperature can only be established empirically or by making conservative or highly idealized assumptions. Because of the different approaches in deriving the rates of decay, there is a rather wide spread in the results of the various studies. Fortunately the influence of temperature variation in the decay period on the maximum temperatures reached in building components is relatively small.¹¹ For the purpose of deriving a temperature-time curve that, with reasonable probability, will not be exceeded during the lifetime of the building, it will be sufficient to use a curve that only approximately reflects the effect of heating in the decay period. This approach is further explained in Figure 4-8.3.

In Figure 4-8.3, curve A illustrates a fire temperature curve derived theoretically for a certain building. The probability of occurrence of a fire with a more severe effect than shown by the curve is once in 50 years. Curve B illustrates a fire temperature curve for the same building, but it is assumed that the rate of burning remains constant until all combustible materials are consumed, whereupon the fire temperature drops linearly to room temperature. Although curve B differs in shape from curve A, their heating effect is approximately the same. If curve B is used instead of curve A, the probability of occurrence of a more severe fire than that represented by the relevant curve may change somewhat, for instance, from once in 50 years to somewhat more or less than 50 years. In practice this means that virtually the same fire safety will be provided whether curve A or curve B is used for the fire-resistance

design of a building. The use of curve B instead of curve A has the advantage that it is easier to define.

Expressions for Characteristic Temperature Curves

In the following, analytical expressions are given that describe characteristic temperature curves as a function of the significant parameters for various fire conditions commonly met with in practice. For the fully developed period, the derivation of these curves will be based on the temperature curves for ventilation-controlled fires calculated according to the method described by Kawagoe and Sekine.¹

The temperatures attained in ventilation-controlled fires are described (in addition to the thermal properties of the material bounding the enclosure) by a parameter, known as the opening factor F

$$F = \frac{A\sqrt{H}}{A_T} \tag{1}$$

where A is area of the openings in the enclosure, H is height of the openings, and A_T is area of the bounding surfaces (walls and floor and ceiling). The method of calculating $A\sqrt{H}$ for openings of unequal height is described in References 9 and 11.

The rate of burning, R , of the combustible materials in the enclosure is given by

$$R = 330A\sqrt{H} \tag{2}$$

and, thus, if Q is the fire load per unit area of the surfaces bounding the enclosure, the duration of the fire, τ , is determined by

$$\tau = \frac{QA_T}{330A\sqrt{H}} = \frac{Q}{330F} \tag{3}$$

For given thermal properties of the material bounding the enclosure, the heat balance can be solved for the temperature as a function of the opening factor F . Besides depending on F , the temperature course is also a function of the thermal properties of the material bounding the enclosure.

In this study, two materials have been chosen as representative bounding materials: one with thermal properties resembling those of a heavy material (high heat capacity and conductivity) and one representing those of a light material (low heat capacity and conductivity). The thermal properties of these materials are given in Table 4-8.1. In practice, materials with a density of approximately 1600 kg/m² or more, for example, normal-weight concretes, sand lime brick, and most clay bricks, can be considered as belonging to the group of heavy material. Those with a density of less than 1600 kg/m², for example, lightweight and cellular concretes and plasterboard, can be regarded as belonging to the group of light materials.

Using the method described in Reference 11, the temperature course of fires in enclosures has been calculated for the two chosen bounding materials and for various values of the opening factor.¹² The conditions for which the calculations have been performed are shown in Table 4-8.1 and the results of the calculations in Figures 4-8.4 and 4-8.5. The curves in these figures were used as a basis for the derivation of temperature curves for fire-resistance

Figure 4-8.3. Temperature curves for fire resistance design.

Table 4-8.1 Thermal Properties of the Enclosure

Factor	Description
k	Thermal conductivity of bounding material: 1.16 W/m-K for a heavy material ($\rho \geq 1600 \text{ kg/m}^3$), 0.58 W/m-K for a light material ($\rho < 1600 \text{ kg/m}^3$)
ρc	Volumetric specific heat of bounding material: $2150 \times 10^3 \text{ J/m}^3\cdot\text{K}$ for a heavy material ($\rho \geq 1600 \text{ kg/m}^3$), $1075 \times 10^3 \text{ J/m}^3\cdot\text{K}$ for a light material ($\rho < 1600 \text{ kg/m}^3$)
A_T	Total inner surface area bounding the enclosure, including window area: 1000 m ²
H	Window height: 1.8 m
ε	Emissivity for radiation transfer between hot gases and inner bounding surface of the enclosure: 0.7
a_c	Coefficient of heat transfer by convection between fire and inner bounding surface area: 23 W/m ² -K
a_u	Coefficient of heat transfer between outer bounding surface area and surroundings: 23 W/m ² -K
c	Specific heat of combustion gases: 1340 J/N·m ³ °C
G	Volume of combustion gas produced by burning 1 kg of wood: 4.9 N·m ³ /kg
q	Heat released in the enclosure by burning 1 kg of wood: $10.77 \times 10^6 \text{ J/kg}$
T_0	Initial temperature: 20°C
V	Volume of enclosure: ^a 1000 m ³
Δx	Thickness of elementary layers of bounding material: 0.03 m
Δt	Time increment: 0.0004167 hr
D	Thickness of bounding material: 0.15 m

^aIt can be shown that the influence of the volume of the enclosure on the fire temperature is negligible.

design. It was found that these temperature curves could be reasonably described by the expression

$$T = 250(10F)^{0.1/F^{0.3}} e^{-F^{2t}} [3(1 - e^{-0.6t}) - (1 - e^{-3t}) + 4(1 - e^{-12t})] + C \left(\frac{600}{F} \right)^{0.5} \quad (4)$$

where T = the fire temperature in °C, t = time in hr, F = opening factor in m^{1/2}, and C = a constant taking into account the influence of the properties of the boundary material on the temperature. $C = 0$ for heavy materials ($\rho \geq 1600 \text{ kg/m}^2$), and $C = 1$ for light materials ($\rho < 1600 \text{ kg/m}$).

The expression is valid for

$$t \leq \frac{0.08}{F} + 1 \quad (5)$$

and

$$0.01 \leq F \leq 0.15 \quad (6)$$

If $t > (0.08/F) + 1$, a value of $t = (0.08/F) + 1$ should be used. If $F > 0.15$, a value of $F = 0.15$ should be used.

The temperature-time curves evaluated from Equation 4 and those obtained by solving the heat balance for the enclosure are shown in Figures 4-8.6 and 4-8.7 for various values of the opening factor.

It is seen that with the aid of the analytical expression, temperature curves can be developed that reasonably describe the curves derived from solving the heat balance.

Figure 4-8.4. Temperature-time curves for ventilation-controlled fires in enclosures bounded by dominantly heavy materials ($\rho \geq 1600 \text{ kg/m}^3$), calculated for various opening factors by solving a heat balance for the enclosure.

Figure 4-8.5. Temperature-time curves for ventilation-controlled fires in enclosures bounded by dominantly light materials ($\rho < 1600 \text{ kg/m}^3$), calculated for various opening factors by solving a heat balance for the enclosure.

As discussed previously, the temperatures in the decay period are more difficult to calculate due to the complexity of the processes that determine the temperature in this period. On the other hand, if the temperature variations are not very large, the influence of such variations in the decay period on the temperature attained in exposed building components is in general relatively small. Therefore, describing the temperature course in the decay period by a temperature-time relation that approximately reflects the decrease of temperature in this period is sufficient.

According to experimental data of Kawagoe⁸ the rate of temperature decrease of a fire with a fully developed period of less than 1 hr is roughly 10°C per min, and that of a fire with a fully developed period of more than 1 hr is 7°C per min. The Swedish code assumes a rate of decrease of 10°C per min irrespective of the duration of the fully developed period of the fire.⁹ A comparison with semi-empirical data developed by Magnusson and Thelander-sson⁹ shows that the assumption of a rate of decrease of 10°C per min is too fast for fires of long duration and too slow for fires of short duration.

Figure 4-8.6. Comparison between temperature-time curves obtained by solving a heat balance and those described by an analytical expression for ventilation-controlled fires in enclosures bounded by dominantly heavy materials ($\rho \geq 1600 \text{ kg/m}^3$).

Figure 4-8.7. Comparison between temperature-time curves obtained by solving a heat balance and those described by an analytical expression for ventilation-controlled fires in enclosures bounded by dominantly light materials ($\rho < 1600 \text{ kg/m}^3$).

According to Harmathy,⁷ who studied several experimental fires of relatively short duration,^{13,14} the rate of decrease of temperature for such fires is in the order of 15 to 20°C per min.

In general, the longer the duration of the fully developed period, the lower the rate of decrease of temperature. Using this information the following expressions have been derived for the temperature course of fire in the decay period:

$$t = -600 \left(\frac{t}{\tau} - 1 \right) + T_\tau \quad (7)$$

with the condition

$$T = 20 \quad \text{if } T < 20^\circ\text{C} \quad (8)$$

In the above equations T = fire temperature, τ = time at which the decay starts as given by Equation 3, t = time under consideration ($t > \tau$), and T_τ = temperature given by Equation 4 at the time $t = \tau$.

The temperature curves obtained from Equations 4 and 7 are illustrated in Figure 4-8.8 for various fire loads

and an opening factor of $0.05 \text{ m}^{1/2}$. In Figure 4-8.9 the influence is shown of the openings on the fire temperature course. It can be seen that the fire load determines the duration of the fire, whereas the openings determine both the duration and the intensity of the fire. In Figure 4-8.10

Figure 4-8.8. Characteristic temperature curves for various fire loads, Q , (opening factor, $F = 0.05 \text{ m}^{1/2}$, heavy bounding material).

Figure 4-8.9. Influence of opening factor on fire temperature course.

Figure 4-8.10. Comparison of design temperature curves derived from analytical expressions with temperatures measured during an experimental fire (fire load per unit internal area of the bounding surfaces $Q = 18.75 \text{ kg/m}^3$, opening factor $F = 0.047 \text{ m}^{1/2}$, heavy bounding material).

a characteristic temperature curve is compared with the temperatures measured at several places in a room during an experimental fire.¹ It is seen that the curve developed from the analytical expression reasonably characterizes the temperatures obtained during the experimental fire. It is somewhat conservative but satisfactory to use as a design curve for fire resistance.

Standard Fire Curve

In studies of fire resistance, it is common to expose building elements to heating in accordance with a standard temperature-time relation. The standard temperature-time curves used in various countries are shown in Figure 4-8.11. It can be seen that there are no significant differences between the various standard curves. The values of the curve adopted by ISO¹⁵ are given in Table 4-8.2. Those used in North America¹⁶ are given in Table 4-8.3.

There are also analytical expressions for several of the standard curves. The expression that describes the ISO curve is

$$T - T_0 = 345 \log_{10}(8t + 1) \quad (9)$$

where

t = time (min)

T = fire temperature (°C)

T_0 = initial temperature (°C)

For the curve used in North America, several analytical expressions exist.¹⁷ One of the expressions is of the form of a sum of exponential functions:

$$T - T_0 = a_1(1 - e^{a_4 t}) + a_2(1 - e^{a_5 t}) + a_3(1 - e^{a_6 t}) \quad (10)$$

where

$a_1 = 532$ for °C, 957 for °F

$a_2 = -186$ for °C, -334 for °F

$a_3 = 820$ for °C, 1476 for °F

$a_4 = -0.6$

$a_5 = -3$

$a_6 = -12$

The extreme deviation from the values given in Table 4-8.2 are -26°C at 45 min, +48°C at 3.5 hr, and -78°C at 8 hr.

Table 4-8.2 Standard Temperature-Time Relation According to ISO 834¹⁵

Figure 4-8.11. Standard fire temperature-time relations used in various countries for testing of building elements.

Table 4-8.3 Standard Fire Temperature-Time Relation Used in North America (NFPA No. 251)¹⁶

Time (min)	Temperature Rise of Fire (°C)
0	0
5	556
10	659
15	718
30	821
60	925
90	986
120	1029
180	1090
240	1133
360	1193

This form is suitable for use in analytical heat flow calculations because when it is used as a boundary condition, the heat transfer equations are integrable.

A set of expressions that more accurately approximate the values given in Table 4-8.2 is

$$T - T_0 = a_1 \tanh a_4 t + a_2 \tanh a_5 t + a_3 \tanh a_6 t, \quad (11)$$

$t < 2$

$$T - T_0 = 906.7 + 41.67t, \quad t \geq 2 \text{ for } ^\circ\text{C} \quad (12)$$

$$T - T_0 = 1632 + 75t, \quad t \geq 2 \text{ for } ^\circ\text{F} \quad (13)$$

where

$$a_1 = 580 \text{ for } ^\circ\text{C}, 1044 \text{ for } ^\circ\text{F}$$

$$a_2 = -276.8 \text{ for } ^\circ\text{C}, -498.2 \text{ for } ^\circ\text{F}$$

$$a_3 = 714.4 \text{ for } ^\circ\text{C}, 1286 \text{ for } ^\circ\text{F}$$

$$a_4 = 0.8429$$

$$a_5 = 0.9736$$

$$a_6 = 8.910$$

The maximum deviation of the temperature after 20 min, given by Equations 11, 12, and 13, from the values tabulated in Table 4-8.2 is -7°C at 40 min.

Another temperature-time relation, given in Reference 18, has the form

$$T - T_0 = a[1 - \exp(-3.79553\sqrt{t})] + b\sqrt{t} \quad (14)$$

where

$$a = 750 \text{ for } ^\circ\text{C}, 1350 \text{ for } ^\circ\text{F}$$

$$b = 170.41 \text{ for } ^\circ\text{C}, 306.74 \text{ for } ^\circ\text{F}$$

$$t = \text{time (hr)}$$

This expression is frequently used and is a reasonably accurate approximation of the relation between temperature and time given in Table 4-8.2.

Nomenclature

- A area of the openings in the enclosure (m^2)
- A_T area of the internal bounding surfaces (m^2)
- C constant
- F opening factor ($\text{m}^{1/2}$)
- H height of openings in the enclosure (m)
- Q fire load per unit area of the internal bounding surfaces (kg/m^2)
- R rate of burning (kg/hr)
- T fire temperature ($^\circ\text{C}$)
- T_τ fire temperature at the time τ ($^\circ\text{C}$)
- t time (hr)
- τ time at which the temperature starts to decline (hr)

CHAPTER 9**Analytical Methods for
Determining Fire Resistance
of Steel Members**

James A. Milke

Introduction

Traditionally, fire resistance has been evaluated by subjecting a structural member to a standard test for a specified duration.¹ All members performing acceptably are rated and listed for the duration period of the test (e.g., 1 hr, 2 hr). Assemblies not listed are assumed to be unable to meet the test criteria and, thus, have no rating, unless proved otherwise. Providing proof of acceptable performance can be accomplished in one of three manners:

1. Conduct the standard test.¹
2. Conduct a special experiment.²
3. Apply an analytical technique.³

The standard test can involve an appreciable turnaround time in order to specify, schedule, and analyze the results of the test. An experimental program can require a substantial amount of effort in order to obtain accurate data. The costs involved in sponsoring a standard test or experimental program can be appreciable. In the case of archaic structural assemblies, materials may no longer be available to reconstruct the design for possible testing.

Because of these drawbacks, calculation methods have been developed to analyze structural designs for fire conditions. The calculation methods have been formulated based on analyses of data from standard tests, experimental programs, and theoretically based investigations.

Analytical methods for fire resistance must consider three basic aspects of the problem:

1. Fire exposure
2. Heat transfer
3. Structural response

The fire exposing the structure must be characterized using methods described in other chapters of this hand-

book for the case of a real fire, or by assuming the fire exposure specified in the standard test. The thermal response of the structural member can be addressed using principles of heat transfer. Heating within the member is treated by conduction heat transfer analysis (radiation and convection heat transfer may also need to be considered, if voids or porous insulation materials are present within the assembly). Typically, radiative and convective boundary conditions are present. Finally, the structural response is examined by comparing some or all of the following: deflections, strains, and stress levels to established limits.

The following types of calculation methods are available to assess the fire resistance of steel structural members:

1. Empirical correlations
2. Heat transfer analyses
3. Structural analyses

Empirical correlations are based on the analysis of data resulting from performing the standard test numerous times. A limitation of the empirical correlations is that they can only be applied when considering the fire exposure, loading, and span provided in the standard test. If other conditions apply, then another approach is needed.

The second group of calculation methods consists of heat transfer analyses. The heat exposure conditions may be those associated with the standard test or a specified fire. The purpose of the heat transfer analysis is to determine the time required for the structural member to attain a predetermined critical temperature or to provide input to a structural analysis. The temperature endpoint criteria cited by ASTM E119¹ are often accepted as the critical temperatures. Typically, inaccuracies of this method are related to the temperature dependence of the material properties or the description of the heating conditions.

Many of the structural analysis-based calculations are similar to those conducted for structural engineering purposes, except the material properties are evaluated at elevated temperatures and thermal expansion is considered. In structural analyses, the loading and end conditions must be known or assumed. Limitations result from

James A. Milke is an associate professor in the Department of Fire Protection Engineering at the University of Maryland. His recent research activities have included the impact of fires on the structural response of steel and advanced composite members.

Figure 4-9.1. ASTM E119 standard time-temperature curve.¹

uncertainties in characterizing the end conditions and the material properties at elevated temperatures.

This chapter provides an overview of the available calculation methods for determining the fire resistance of steel structural members. The basis of each method will be presented along with sample applications.

Standard Test for Fire Resistance of Structural Members

The standard test method in the United States for determining the fire resistance of columns, floor and roof assemblies, and walls is ASTM E119.^{*1} Basically, the test involves subjecting the structural component to a heated furnace environment for the desired duration. If the endpoint criteria are not reached prior to the end of the test period, the assembly passes the test and is rated.

Gas burners are used to heat the furnace in testing laboratories throughout North America. The furnace is heated so that the temperature inside the furnace follows the time-temperature curve illustrated in Figure 4-9.1. In principle, the time-temperature curve is intended to relate to a severe exposure from a room fire. Thus, the applicability of the test method to examine the fire resistance of exterior structural members exposed to fires outside of the building is questionable.⁴

Assemblies may be tested with or without load. If tested under load, the assembly is subjected to maximum

design stress levels, based on common structural analysis procedures for ambient temperature design. Floor and roof assemblies and bearing walls are always tested under load. Columns are tested with or without a loading. Steel beams and girders may be tested without load if the design loading cannot be achieved in the laboratory.

Structural assemblies may be restrained or unrestrained against thermal expansion. The effect of restraint on the fire resistance of assemblies has been investigated by Bletzacker.⁴ The degree of restraint in structural members varies with the geometry, connection method, and framing system, among other factors. The descriptions presented in Table 4-9.1 relate actual construction conditions to the restrained and unrestrained designation noted in the ASTM E119 test method.

The minimum dimensions of the structural components for testing are specified in ASTM E119. A maximum set of dimensions is established by the size of available test furnaces. While the test is large-scale, the test cannot be considered full-scale, given the stipulation of the maximum permissible dimensions. The consequence of not testing full-scale members means that continuous beams, actual floor/roof ASTM assemblies, and long columns are not tested. Consequently, this test is only comparative in nature and cannot be used to assess actual performance.

The ASTM E119 endpoint criteria for building assemblies consider structural integrity, temperature, passage of flame, ignition of cotton waste, and in some cases, response to the hose stream. For the tests without loading, the structural integrity endpoint criterion is relaxed to require that the component only remains in place. The structural integrity criterion addresses the need for members to remain in place (supporting self-weight of member) and to continuously support any applied loads. The ignition-of-cotton-waste endpoint addresses the ability of the structural assembly to prevent the transmission of flame and hot gases to the side not exposed to the furnace fire.

The temperature endpoint criteria are noted in Table 4-9.2. In principle, the endpoint temperatures are based on the maximum allowable reduction in load-bearing capacity of the structural member, based on the reduction in strength experienced at elevated temperature and the maximum permissible loads stipulated by structural design standards.

Fire Resistance of Steel Members

Several calculation techniques are available to determine the fire resistance of steel members, including steel columns, beams in floor and roof assemblies, and trusses.⁷⁻¹⁰ Three types of techniques are available: empirically derived correlations, heat transfer analyses, and structural analyses.

The equations and models do not eliminate the need for all future testing. Testing is still required, at least to validate the calculation techniques and assess the interaction and mechanical behavior of the constituents of the assembly, such as the steel structural member, insulating materials, or other components. However, the calculation techniques can be used to extend the application of test results and reduce the number of required tests. In addi-

^{*}Versions of the test method are also published as NFPA 251⁵ and UL 263.⁶

Table 4-9.1 *Restrained and Unrestrained Construction Systems (from ASTM E119 Table X3.1)¹*

Wall bearing:		
Single span and simply supported end spans of multiple bays: ^a		
Open-web steel joists or steel beams, supporting concrete slab, precast units, or metal decking		unrestrained
Concrete slabs, precast units, or metal decking		unrestrained
Interior spans of multiple bays:		
Open-web steel joists, steel beams or metal decking, supporting continuous concrete slab		restrained
Open-web steel joists or steel beams, supporting precast units or metal decking		unrestrained
Cast-in-place concrete slab systems		restrained
Precast concrete where the potential thermal expansion is resisted by adjacent construction ^b		restrained
Steel framing:		
Steel beams welded, riveted or bolted to the framing members		restrained
All types of cast-in-place floor and roof systems (such as beam-and-slabs, flat slabs, pan joists, and waffle slabs) where the floor or roof system is secured to the framing members		restrained
All types of prefabricated floor or roof systems where the structural members are secured to the framing members and the potential thermal expansion of the floor or roof system is resisted by the framing system or the adjoining floor or roof construction ^b		restrained
Concrete framing:		
Beams securely fastened to the framing members		restrained
All types of cast-in-place floor or roof systems (such as beam-and-slabs, flat slabs, pan joists, and waffle slabs) where the floor system is cast with the framing members		restrained
Interior and exterior spans of precast systems with cast-in-place joints resulting in restraint equivalent to that which would exist in condition III(1)		restrained
All types of prefabricated floor or roof systems where the structural members are secured to such systems and the potential thermal expansion of the floor or roof systems is resisted by the framing system or the adjoining floor or roof construction ^b		restrained
Wood construction:		
All types		unrestrained

^aFloor and roof systems can be considered restrained when they are tied into walls with or without tie beams, the walls being designed and detailed to resist thermal thrust from the floor or roof system.

^bFor example, resistance to potential thermal expansion is considered to be achieved when:

1. Continuous structural concrete topping is used
2. The space between the ends of precast units or between the ends of units and the vertical face of supports is filled with concrete or mortar, or
3. The space between the ends of precast units, and the vertical faces of supports, or between the ends of solid or hollow core slab units, does not exceed 0.25% of the length for normal-weight concrete members or 0.1% of the length for structural lightweight concrete members.

Table 4-9.2 *ASTM E119 Temperature Endpoint Criteria¹*

tion, experimental methods are essential in determining the material properties at elevated temperature of the protection materials.

Steel Material Properties

The principal material properties of interest are yield strength, ultimate strength, modulus of elasticity, coefficient of thermal expansion, density, specific heat, and thermal conductivity. The effect of temperature on steel properties has been examined by many researchers.¹¹ For steel, all of the properties, except for density, are strongly influenced by temperature.

The thermal properties of ASTM A36 steel are provided in the following correlations:^{7,12,13,14}

$$k = -0.022T + 48 \quad \text{for } 0 \leq T \leq 900^\circ\text{C}$$

$$k = 28.2 \quad \text{for } 900^\circ\text{C} < T$$

$$c_s = 0.51T + 420 \quad \text{for } 0 \leq T \leq 650^\circ\text{C}$$

$$c_s = 8.65T + 4870 \quad \text{for } 650^\circ\text{C} < T \leq 725^\circ\text{C}$$

$$c_s = -10.9T + 9340 \quad \text{for } 725^\circ\text{C} < T \leq 800^\circ\text{C}$$

$$c_s = 579 \quad \text{for } 800^\circ\text{C} < T$$

$$\rho = 7860 \text{ kg/m}^3$$

Figure 4-9.2. Temperature effects on properties of ASTM A36 steel.^{12,15}

The influence of temperature on the mechanical properties of A36 steel is presented in Figure 4-9.2. At 538°C (1000°F), the yield strength is approximately 60 percent of the value at normal room temperature. The American Institute for Steel Construction's *Specification for the Design, Fabrication, and Erection of Structural Steel for Buildings*¹⁶ limits the maximum permissible design stress to approximately 60 percent of the yield strength. Thus, for structural members at 538°C (1000°F) designed to carry the maximum permissible stress, the applied stress is approximately the same as the strength of the member. It should also be noted that at 538°C (1000°F) the modulus of elasticity has decreased appreciably from the value at normal room temperature.

Mathematical expressions describing the relationship of the yield strength, modulus of elasticity, and coefficient of thermal expansion on temperature are^{7,17,18}

For $0 < T \leq 600^\circ\text{C}$,

$$\sigma_{yT} = \left[1 + \frac{T}{900 \ln(T/1750)} \right] \sigma_{y0}$$

$$E_T = \left[1 + \frac{T}{2000 \ln(T/1100)} \right] E_0$$

For $T > 600^\circ\text{C}$,

$$\sigma_{yT} = \frac{340 - 0.34T}{T - 240} \sigma_{y0}$$

$$E_T = \frac{690 - 0.69T}{T - 53.5} E_0$$

$$\alpha_T = (0.004T + 12) \times 10^{-6}$$

where

σ_{yT} = yield strength at temperature T (MPa) (psi)

σ_{y0} = yield strength at 20°C (68°F) (MPa) (psi)

E_T = modulus of elasticity at temperature T (MPa) (psi)

E_0 = modulus of elasticity at 20°C (68°F) (MPa) (psi)

α_T = coefficient of thermal expansion at temperature T (m/m°C)

T = steel temperature (°C)

$$\theta = \begin{cases} \frac{T' - 68}{1800} & T' \text{ in } ^\circ\text{F} \\ \frac{T' - 20}{1000} & T' \text{ in } ^\circ\text{C} \end{cases}$$

T' = steel temperature

In addition to the changes in material properties that occur at elevated temperatures, the crystalline structure of steel also changes, as noted in Figure 4-9.3.¹⁹ However, for the low-carbon steels typically used in building construction, significant changes in crystalline structure only begin to occur at temperatures in excess of 650°C (1200°F),²⁰ above the temperature typically associated with failure.

Creep, the time-dependent deformation of a material, may be significant in structural steel at temperatures in excess of 460°C (860°F).²¹ The rate of creep increases approximately 300 times for ASTM A36 structural steel, when the steel temperature is increased from 460 to 520°C (860 to 968°F). Since creep is a complex phenomenon depending on the stress level, rate of heating, and other factors, often it is included implicitly in the mechanical properties to simplify the fire resistance calculations.^{15,20} In-depth discussions of creep have been prepared by Harmathy.^{22,23}

Methods of Protection

The basic intent of the various methods of protection is to reduce the rate of heat transfer to the structural steel. This is accomplished by using insulation, membranes, flame shielding, and heat sinks.

Insulation

Insulation of the steel is achieved by surrounding the steel with materials that preferably have the following characteristics:²⁴

1. Noncombustibility and the added attribute of not producing smoke or toxic gases when subjected to elevated temperatures
2. Thermal protective capability when tested in accordance with the standard fire test ASTM E119
3. Product reliability giving positive assurance of consistent uniform protection characteristics
4. Availability in a form that permits efficient and uniform application
5. Sufficient bond strength and durability to prevent either dislodgement or surface damage during normal construction operations
6. Resistance to weathering or erosion resulting from atmospheric conditions

In addition to the insulating qualities of the protection materials, chemical reactions may occur in the insulation, further reducing the rate of heat transfer. The chemical reactions include calcination, ablation, intumescence, thermal hydrogeneration, and sublimation.

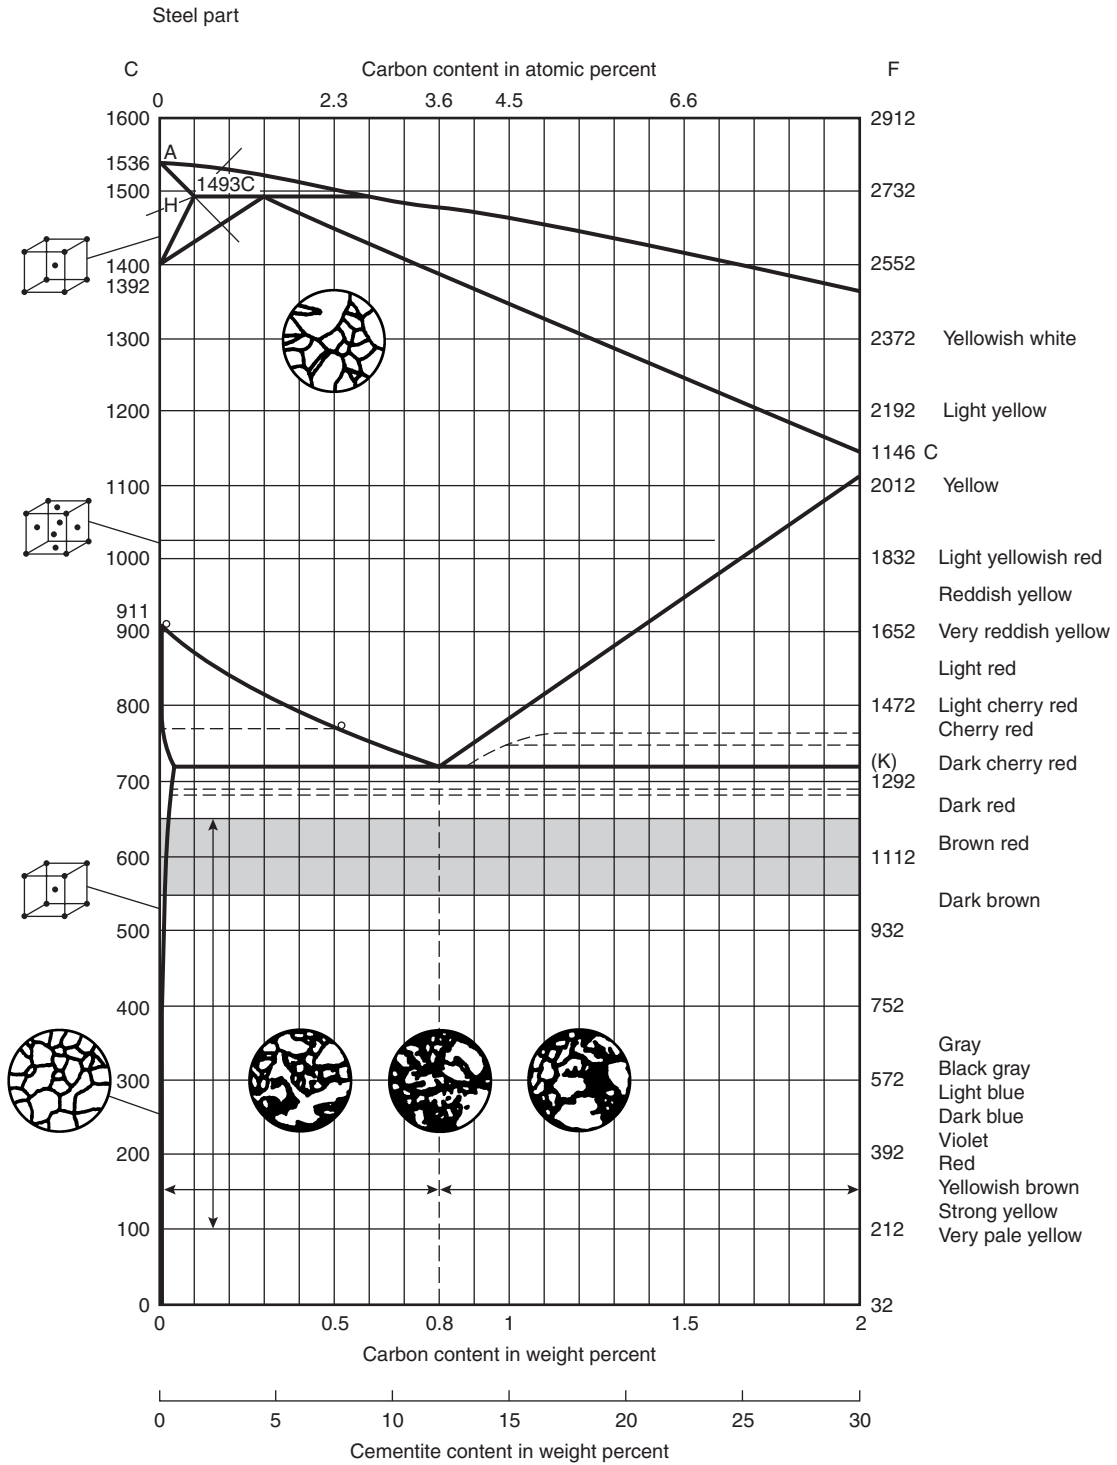

Figure 4-9.3. Influence of elevated temperatures versus carbon content in steel.¹⁹

Insulating methods include the use of board products, spray-applied materials, and concrete encasement. A brief review of each method is presented below.

Board products: Four types of board products are commonly used to protect structural steel: gypsum board, fiber-

reinforced calcium silicate board, vermiculite-sodium silicate board, and mineral fiber board. In each case, the means of attachment of the boards surrounding the steel is a critical parameter affecting the performance of the assembly. Two commonly used methods of attachment of gypsum wallboard with and without steel covers are illustrated in

Figure 4-9.4. Detailed descriptions of the attachment mechanisms for the other board products are provided elsewhere.²⁵⁻²⁷ Also, board products can be used in wall assemblies to provide an envelope around steel trusses.

Spray-applied materials: Several types of spray-applied materials are commonly used. These include cementitious plasters, mineral fibers, magnesium oxychloride cements, and intumescent. Sufficient data has been obtained to characterize spray-applied cementitious and mineral fiber materials for the purpose of estimating the fire endurance of structural steel protected with these materials. An illus-

tration of a steel column protected by a spray-applied material is presented in Figure 4-9.5.

Concrete encasement: Concrete encasement of steel members to surround and insulate the steel is illustrated in Figure 4-9.6. As indicated in Figure 4-9.6, the concrete is cast to fill in all re-entrant spaces. Alternatively, concrete column covers may be used, as illustrated in Figure 4-9.7. The concrete is assumed to act only to thermally protect the steel. Some empirical correlations implicitly account for the load-bearing capacity of the concrete and possible steel-concrete composite action.

Corner Joint Details (A)

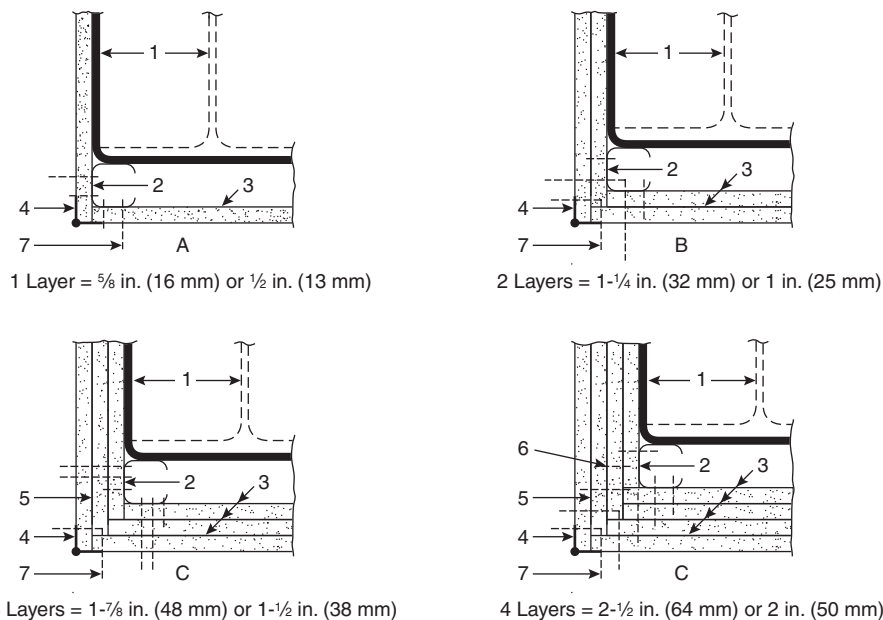

Figure 4-9.4. Attachment mechanisms of gypsum wallboard to steel columns.²⁵

Figure 4-9.5. (a) Sprayed insulation; (b) Metal lath and plaster encasement.²⁴

Membrane: Suspended ceiling assemblies are used as membranes to protect structural steel in floor and roof assemblies. The ceiling panels and tiles comprising the ceiling assembly may consist of gypsum, perlite, vermiculite, or mineral fibers.

The membrane method of protection is illustrated in Figure 4-9.8. Heat transfer to the structural steel is reduced due to the air space above the membrane and the insulating characteristics of the membrane. Also, membranes help prevent the direct impingement of flame on the structural steel.

Flame shield: Flame shields are intended to reduce the incident radiant heat flux on the steel by preventing direct flame impingement. The effectiveness of flame shields to protect exposed spandrel beams was first examined by Seigel.^{2,28} In this instance, 14-gage sheet steel was used as the flame shield.

Heat sinks: The heat sink approach delays the heating of steel by absorbing heat transferred through the steel. The heat sink approach usually involves liquid- or concrete-

Figure 4-9.6. Steel column with concrete encasement.²⁴

filling of the interior of hollow steel members (tubular and pipe sections). Liquid-filling can be used to provide a sufficient level of protection for the columns, without any externally applied coating. The liquid used for protection is an aqueous solution. Additives are provided primarily for antifreeze, corrosion protection, and biological reasons.

A diagram of a typical design for a liquid-filled column fire protection system is presented in Figure 4-9.9. The components of this system include the hollow structural steel columns, piping to connect the columns, a water storage tank, and associated valves.

The system operates on the principle that heat incident on the column is removed by circulation of the liquid. If sufficient heat is delivered to the liquid, boiling can be expected, which enhances the efficiency of the heat-removal process. In many tests with liquid-filling, steel temperatures have been observed to be well below those required for failure, as long as the column remains full of the liquid.

Another heat-sink approach consists of filling the interior of hollow steel columns with concrete. If the concrete is reinforced, load transfer from the steel to the concrete can be expected as the steel weakens with increasing temperature. Calculation methods to determine the fire resistance of concrete-filled steel columns are available.^{10,12}

Figure 4-9.7. Concrete-protected structural steel columns. (a) Square shape protection with a uniform thickness of concrete cover on all sides; (b) Rectangular shape with varying thickness of concrete cover; and (c) Encasement having all re-entrant spaces filled with concrete.

Membrane method of protection,²⁴ (a) Cross-section of a floor-ceiling system with conventional sheet steel fusible-link damper for protecting typical ceiling outlets in galvanized sheet ducts; (b) Sprayed contact fireproofing applied directly to the underside of formed-steel decking and to a supporting steel beam.

Empirically Derived Correlations

Numerous, easy-to-use, empirically derived correlations are available to calculate the fire resistance of steel columns, beams, and trusses. The correlations are based on data from performing the standard test numerous times on variations of a particular assembly. Curve-fitting techniques are used to establish the various correlations. In some cases, a best-fit line has been drawn for the data points, whereas in other cases, lines were placed to provide conservative estimates of the fire endurance by connecting the two lowest points.²⁹

Steel Columns

The correlations to estimate the fire endurance of unprotected and protected steel columns are given in Table 4-9.3. Present in each of the equations is W/D for wide-flange sections and A/P for hollow sections. The W/D

and A/P ratios are comparable. The W/D ratio is the weight per lineal foot to the heated perimeter of the steel at the protection interface (or the perimeter of the steel if unprotected). The A/P ratio is the cross-sectional area divided by the heated perimeter. Essentially, the W/D ratio relates to the product of the density of the steel and the A/P ratio.

The relevance of the W/D and A/P ratios was first noted by Lie and Stanzak.³⁰ W/D ratios for commonly used wide-flange and tubular shapes for columns and beams are available elsewhere.^{25,31,32} The two factors in the W/D ratio that affect the rate of heat transfer to the steel (and consequently the rise in temperature of the steel) are (1) shape of the fire protection system, D , and (2) steel mass per unit of length, W .

The parameter that characterizes the shape of the fire protection system is D , the heated perimeter expressed in inches, which is defined as the inside perimeter of the steel at the fire protection material interface. Figure 4-9.10 illustrates the method for determining D in four typical

Figure 4-9.9. Schematic layout of a typical piping arrangement used in a liquid-filled column fire-protection system.⁴

cases. As can be seen from the figure, the heated perimeter depends on the size of the column and also on the profile of the protection system. Two different commonly used profiles are: (1) contour profile, where all surfaces of the steel column are in contact with the protection material and (2) box profile, where a rectangular box of protection material is built around the column.

A large value of W refers to a column with a large weight per lineal foot. A given amount of energy will raise the temperature of the massive column to a lesser degree than that of a light column. Less surface area is available for heat transfer if the heated perimeter, D , is small, thereby inhibiting the temperature rise in the steel. The greater the W/D ratio, the greater the inherent fire resistance of the assembly is.

Because steel elements with larger W/D ratios are inherently more fire resistant, substituting shapes with greater W/D ratios for shapes identified in the listed designs in the *UL Fire Resistance Directory*³ is permitted while maintaining the same thickness of protection. However, such substitution yields inefficient designs, because shapes with large W/D ratios actually require less fire protection material than shapes with small W/D ratios for the same level of fire resistance.

The equation for gypsum wallboard protection is non-linear. The weight of the gypsum wallboard is included because the heat capacity of gypsum has a considerable

Figure 4-9.10. Heated perimeter for steel columns.²⁵

Table 4-9.3 Empirical Equations for Steel Columns^{20,26,27}

Member/Protection	Solution	Symbols
Column/Unprotected	$R = 10.3 (W/D)^{0.7}$, for $W/D < 10$ $R = 8.3 (W/D)^{0.8}$, for $W/D \geq 10$ (for critical temperature of 1000°F)	R = fire endurance time (min) W = weight of steel section per linear foot (lb/ft) D = heated perimeter (in.)
Column/Gypsum Wallboard	$R = 130 \left(\frac{hW/D}{2} \right)^{0.75}$ where $W' = W + \left(\frac{50hD}{144} \right)$	h = thickness of protection (in.) W' = weight of steel section and gypsum wallboard (lb/ft)
Column/Spray-applied materials and board products—wide flange shapes	$R = [C_1(W/D) + C_2]h$	C_1 & C_2 = constants for specific protection material
Column/Spray-applied materials and board products—hollow sections	$R = C_1 \left(\frac{A}{P} \right) h + C_2$	C_1 & C_2 = constants for specific protection material The A/P ratio of a circular pipe is determined by $A/P \text{ pipe} = \frac{t(d-t)}{d}$ where d = outer diameter of the pipe (in.) t = wall thickness of the pipe (in.) The A/P ratio of a rectangular or square tube is determined by $A/P \text{ tube} = \frac{t(a+b-2t)}{a+b}$ where a = outer width of the tube (in.) b = outer length of the tube (in.) t = wall thickness of the tube (in.)
Column/Concrete cover	$R = R_0(1 + 0.03m)$ where $R_0 = 10(W/D)^{0.7} + 17 \left(\frac{h^{1.6}}{k_c^{0.2}} \right) \cdot \left\{ 1 + 26 \left[\frac{H}{\rho_c c_c h(L+h)} \right]^{0.8} \right\}$ $D = 2(b_f + d)$	R_0 = fire endurance at zero moisture content of concrete (min.) m = equilibrium moisture content of concrete (% by volume) b_f = width of flange (in.) d = depth of section (in.) k_c = thermal conductivity of concrete at ambient temperature (Btu/hr·ft·°F) h = thickness of concrete cover (in.)
Column/Concrete encased	for concrete-encased columns use $H = 0.11W + \frac{\rho_c c_c}{144} (b_f d - A_s)$ $D = 2(b_f + d)$ $L = (b_f + d)/2$	H = thermal capacity of steel section at ambient temperature (= 0.11 W Btu/ft·°F) c_c = specific heat of concrete at ambient temperature (Btu/lb·°F) L = inside dimension of one side of square concrete box protection (in.) A_s = cross-sectional area of steel column (in. ²)

impact on the fire resistance of the assembly. The thickness of wallboard required to achieve a particular level of fire resistance as a function of the W/D ratio of the column is presented in Figure 4-9.10.

Based on an elementary heat transfer analysis, Stanzak and Lie conducted a parametric analysis that resulted in correlations of the following form to estimate the thickness of material required to achieve a particular level of fire resistance:^{25,27}

$$R = (C_1 W/D + C_2)h$$

where

R = fire endurance (hr)

W = steel weight per lineal foot (lb/ft)

D = heated perimeter of the steel at the insulation interface (in.)

h = thickness of insulation (in.)

The constants C_1 and C_2 need to be determined for each protection material. The constants take into account the thermal conductivity and heat capacity of the insulation material. Constants for some materials are included in listings in the *UL Fire Resistance Directory*.³

Considering the equation for the concrete cover column protection method (see Table 4-9.3), R_0 is the fire endurance of the assembly if the concrete has no moisture content. However, because the fire resistance of concrete-cover over steel columns is known to increase by approximately 3 percent for each 1 percent of moisture, R_0 is multiplied by the $(1 + 0.03m)$ factor where m is the equilibrium moisture content of concrete. The parameters h and L noted in the equation are shown in Figure 4-9.7. If the protection thickness or column dimensions are not the same in the vertical and horizontal directions, average values are used for h and L .

The heat capacity of the concrete must be accounted for in the determination of H if all re-entrant spaces are filled. (See Figure 4-9.7.) If specific data on the concrete's thermal properties are not available, values given in Table 4-9.4 may be used. Typical densities for normal-weight and lightweight concrete are 145 and 110 lb/ft³ (2320 and 1760 kg/m³). Also, the typical equilibrium moisture content (by volume) for normal-weight concrete is 4 percent and lightweight concrete is 5 percent.

Many of the equations cited in Table 4-9.3 are limited to a range of shapes or protection thickness. Before applying any equation from this table, users should consult the original reference and confirm that the equation is being applied properly.

EXAMPLE 1:

Determine the thickness of spray-applied cementitious material to obtain a 2-hr fire endurance when applied to a $W 12 \times 106$ column.

SOLUTION:

From UL X772, the applicable equation is

$$R = (63W/D + 36)h$$

Solving for h ,

$$h = \frac{R}{63W/D + 36}$$

where

$$R = 2 \text{ hrs} = 120 \text{ min}$$

$W/D = 1.44 \text{ lb/ft}\cdot\text{in.}$ for a $W 12 \times 106$ with contour profile protection

Table 4-9.4 Thermal Properties of Concrete at 70°F

	Normal-Weight Concrete	Structural Lightweight Concrete
Thermal conductivity (k) ^a	0.95	0.35
Specific heat (c) ^b	0.20	0.20

^aExpressed as Btu/hr·ft·°F

^bExpressed as Btu/lb·°F

Substituting,

$$h = \frac{120}{63 \times 1.44 + 36} = 0.95 \text{ in.}$$

EXAMPLE 2:

Determine the fire endurance of a $W 8 \times 28$ column encased in lightweight concrete (density of 110 lb/ft³ [176.2 kg/m³]) with all re-entrant spaces filled. The concrete cover thickness is 1.25 in. (31.8 mm).

SOLUTION:

From Table 4-9.3, the appropriate equation is

$$R = R_0(1 + 0.03m)$$

where

$$R_0 = 10(W/D)^{0.7} + 17(h^{1.6}/k_c^{0.2})\{1 + 26[H/\rho_c c_c h(L + h)]^{0.8}\}$$

Referring to Figure 4-9.7,

$$h_2 = h_1 = h = 1.25 \text{ in. (31.8 mm)}$$

$$b_f = 6.535 \text{ in. (166 mm)}$$

$$d = 8.060 \text{ in. (204.7 mm)}$$

$$W/D = 0.67 \text{ lb/ft}\cdot\text{in. (39.3 kg/m}^2\text{)(contour profile)}$$

$$A = 8.25 \text{ in.}^2 \text{ (0.0053 m}^2\text{)}$$

From Table 4-9.4,

$$k_c = 0.35 \text{ Btu/hr}\cdot\text{ft}\cdot\text{°F}$$

$$c_c = 0.20 \text{ Btu/lb}\cdot\text{°F}$$

$$\rho_c = 110 \text{ lb/ft}^3$$

$$L = \frac{1}{2}(b_f + d) = 7.30 \text{ in.}$$

$$H = 0.11W + \frac{\rho_c c_c}{144}(b_f D - A_s)$$

$$H = 0.11 \times 28 + \frac{110 \times 0.20}{144}(6.535 \times 8.060 - 8.25) = 9.87$$

$$R_0 = 10(0.67)^{0.7} + 17\left(\frac{1.25^{1.6}}{0.35^{0.2}}\right)$$

$$\times \left\{ 1 + 26 \left[\frac{9.87}{110 \times 0.2 \times 1.25(7.30 + 1.25)} \right]^{0.8} \right\}$$

$$R_0 = 99 \text{ min}$$

Assuming a moisture content of 5 percent for lightweight concrete,

$$R = 99(1 + 0.03 \times 5) = 114 \text{ min}$$

Steel Beams

As in the case of columns, the W/D ratio is an important parameter affecting the fire resistance of a beam. Beams with larger W/D ratios may be substituted for

beams with lesser W/D ratios for an equivalent rating with no change in the protection thickness. However, as with columns, designs resulting from the direct substitution of larger beams without reducing the protection thickness may be inefficient.

In 1984, an empirically derived correlation was developed to calculate the required thickness of spray-applied material protection.³¹ Correlations of the form for steel columns are not possible, given the deck's role as a heat sink. Thus, the thickness of protection for steel beams is determined based on the following scaling relationship:

$$h_1 = \left(\frac{W_2/D_2 + 0.6}{W_1/D_1 + 0.6} \right) h_2 \quad (1)$$

where

h = thickness of spray-applied fire protection (in.)

W = weight of steel beam (lb/ft)

D = heated perimeter of the steel beam (in.) (See Figure 4-9.11)

and where the subscripts

1 = substitute beam and required protection thickness

2 = the beam and protection thickness specified in the referenced tested design or tested assembly

Limitations of this equation are noted as follows:

1. $W/D \geq 0.37$
2. $h \geq 3/8$ in. (9.5 mm)
3. The unrestrained beam rating in the referenced tested design or tested assembly is at least 1 hr

It should be noted that the above equation only pertains to the determination of the protection thickness for a beam in a floor or roof assembly. All other features of the assembly, including the protection thickness for the deck, must remain unaltered.

EXAMPLE 3:

Calculate the thickness of spray-applied fire protection required to provide a 2-hr fire endurance for a $W 12$

Figure 4-9.11. Heated perimeter for steel beams.³¹

$\times 16$ beam to be substituted for a $W 8 \times 17$ beam requiring 1.44 in. (36.6 mm) of protection for the same rating.

SOLUTION:

The beam substitution correlation, presented as Equation 1, is used.

$$h_1 = \left(\frac{W_2/D_2 + 0.6}{W_1/D_1 + 0.6} \right) h_2$$

where

$$W_2/D_2 = 0.54 \quad \text{for } W 8 \times 17$$

$$W_1/D_1 = 0.45 \quad \text{for } W 12 \times 16$$

$$h_2 = 1.44$$

$$h_1 = \left(\frac{0.54 + 0.6}{0.45 + 0.6} \right) \times 1.44 = 1.6 \text{ in.}$$

Steel Trusses

There are three types of trusses used in buildings: transfer, staggered, and interstitial trusses. Because of the inherent features of each type of truss, some fire protection systems are more appropriate than others.³³

A load-transfer truss (see Figure 4-9.12) supports loads from more than one floor. The loads may be suspended

Figure 4-9.12. Vierendell truss providing support from above and below.³³

from a transfer truss or the transfer truss can be used to eliminate columns on lower floors.

A staggered truss is illustrated in Figure 4-9.13. Generally, staggered trusses are used in residential occupancy buildings. Staggered trusses carry loads from two floors.

Interstitial trusses are used to create deep floor/ceiling concealed spaces containing mechanical and electrical equipment, as shown in Figure 4-9.14. Interstitial trusses support only those loads from the equipment enclosure and the floor above. Interstitial trusses are typically used in health-care facilities with heavy mechanical equipment needs.

Three methods of fire protection are often used for trusses: membrane, envelope, and individual element protection. Some fire protection methods are more appropriate than others for the specific truss types. The fire protection methods typically used for each truss type are indicated in Table 4-9.5. Membrane protection is accomplished through the use of a fire-resistant ceiling assembly. Design parameters for such an assembly can be determined from listings of fire-rated designs.^{3,34} No empirical correlations are available to assess the design of membrane protection systems.

The envelope means of protection is illustrated in Figure 4-9.15. The truss is enclosed in layers of a board product, with the number of layers determined by the required fire endurance. Some practical rules of thumb based on test results are noted in Table 4-9.6.

Figure 4-9.13. A typical truss and positionings in a staggered truss system.³³

Figure 4-9.14. Hospital interstitial truss system.³³

Table 4-9.5 Typical Fire Protection Methods for Steel Trusses

Truss Type	Fire Protection Method		
	Membrane	Envelope	Individual Element
Transfer		X	X
Staggered		X	X
Interstitial	X	X	X

Table 4-9.6 Practical Guidelines for Thickness of Gypsum Wallboard for Steel Truss Envelope Protection³³

Fire Endurance	Gypsum X	Wallboard Type
60	5/8" (16 mm)	5/8" (16 mm)
120	1 1/4" (32 mm)	—
180	—	1 1/2" (38 mm)

Individual element protection is generally accomplished using a spray-applied material. Since critical truss elements perform structurally as columns, that is, in tension or compression (as opposed to bending), the applicable equations for determining the thickness of spray-applied material for columns is used. In order to use these equations, the W/D ratio must be calculated for each element. Unlike columns and beams, the ratio may not be readily available. The diagrams in Figure 4-9.16 are provided for assistance in calculating the heated perimeter.

Figure 4-9.15. Staggered truss protection with envelope protection.³³

Heat Transfer Analyses

Heat transfer analyses are applied to determine the time period required to heat structural members to a specified critical temperature or to provide temperature data as input to the structural analysis of the heated member. The time required to heat the member to a specified critical temperature is often defined as the fire endurance time of the member.

The critical temperature of a structural member can be determined by referring to the temperature endpoint criteria cited in ASTM E119¹ or by a structural assessment, as is discussed later in this chapter.

The available types of heat transfer analyses can be grouped into the following categories:

1. Numerical methods
2. Graphical solutions
3. Computer programs

Numerical Methods

Many numerical methods are available to estimate the temperature rise in steel structural elements. The equations are derived from simplified heat transfer approaches.

Unprotected steel members: The temperature in an unprotected steel member can be calculated using a quasi-steady-state, lumped heat capacity analysis. This method assumes that the steel member is at a uniform temperature. The equation for temperature rise during a short time period, Δt , is²¹

$$\Delta T_s = \frac{\alpha}{c_s(W/D)} (T_f - T_s)\Delta t \tag{2}$$

where

- ΔT_s = temperature rise in steel (°F)(°C)
- α = heat transfer coefficient from exposure to steel member (Btu/ft²·s·R)(W/m²·K),
- D = heat perimeter (ft)(m) (see Figure 4-9.16)
- c_s = steel specific heat (Btu/lb·°F)/(J/kg·°C)
- W = steel weight per lineal foot (lb/ft)/(kg/m)
- T_f = fire temperature (R)(K)
- T_s = steel temperature (R)(K)
- Δt = time step (s)

where

$$\alpha = \alpha_r + \alpha_c$$

α_r = radiative portion of heat transfer

$$\alpha_r = \frac{C_1 \epsilon_f}{T_f - T_s} (T_f^4 - T_s^4)$$

where $C_1 = 4.76 \times 10^{-13}$ Btu/s·ft²·R⁴ (5.77×10^{-8} W/m³·K⁴) and ϵ_f , the effective emissivity, can be evaluated from Table 4.97.

α_c = convective portion of heat transfer

$$9.8 \times 10^{-4} \text{ to } 1.2 \times 10^{-3} \text{ Btu/ft}^2\cdot\text{s} \text{ (20 to 25 W/m}^2\cdot\text{K)}$$

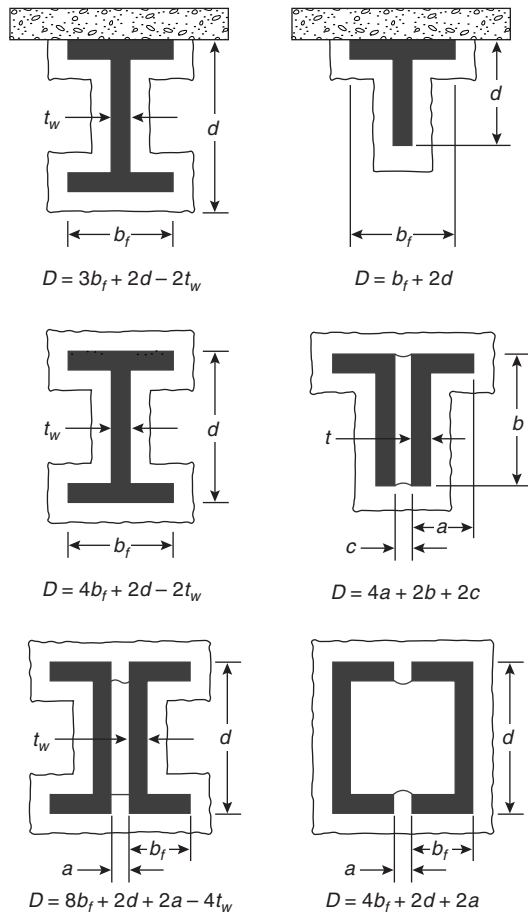

Figure 4-9.16. Heated perimeter for steel truss shapes.³³

The quasi-steady assumption dictates that the time step should be small, that is, on the order of 10 s.⁵⁹

Equation 2 is successively applied up to the time duration of interest. Correlations for the time-temperature curve associated with standard fire resistance tests are included by Lie, in another chapter of this handbook. For the ISO 834 test, T_f at any time, t , can be estimated by the following expression:²¹

$$T_f = C_T \log_{10} (0.133t + 1) + T_0 \quad (3)$$

where

$$C_T = 620 \text{ with } T_f, T_0 \text{ in } ^\circ\text{F}$$

$$345 \text{ with } T_f, T_0 \text{ in } ^\circ\text{C}$$

Protected steel members: For protected members, the thermal resistance provided by the insulating material must be considered. If the thermal capacity of the insulation layer is neglected,²¹

$$\Delta T_s = \frac{k_i}{c_s h W/D} (T_f - T_s) \Delta t \quad (4)$$

where all parameters are as defined in Equation 2, and

Table 4-9.7 Effective Emissivity³⁵

Type of Construction	Resultant Emissivity
1. Column exposed to fire on all sides	0.7
2. Column outside facade	0.3
3. Floor girder with floor slab of concrete, only the underside of the bottom flange being directly exposed to fire	0.5
4. Floor girder with floor slab on the top flange	
Girder of 1 section for which the width-depth ratio is not less than 0.5	0.5
Girder of 1 section for which the width-depth ratio is less than 0.5	0.7
Box girder and lattice girder	0.7

k_i = thermal conductivity of insulation material (Btu/ft·s·°F) (W/m·°C)

h = protection thickness (ft) (m)

Malhotra suggests that the thermal capacity of the insulation material may be neglected if the following inequality is true (see parameter definitions for Equation 2):²¹

$$c_s W/D > 2c_i \rho_i h$$

If the thermal capacity must be accounted for, as in the case of gypsum and concrete insulating materials, then

$$\Delta T_s = \frac{k_i}{h} \left[\frac{T_f - T_s}{c_s (W/D) + 1/2c_i \rho_i h} \right] \Delta t \quad (5)$$

where all parameters are as defined for Equation 2, and c_i = specific heat of insulating material (Btu/lb·°F) (J/kg·°C) ρ_i = density of insulating material (lb/ft³) (kg/m³)

An evaluation of the predictive capability of the lumped heat capacity approach using Equation 5 for protected steel sections was conducted by Berger for steel columns protected with a spray-applied cementitious material.³⁶ The analysis consisted of comparing predicted versus measured temperatures for steel columns exposed to the standard fire exposure. A comparison of the predicted versus measured times for the steel column to reach 538°C is provided in Table 4-9.8. A comparison of the predicted temperature with that measured for one protected steel column assembly is provided in Figure 4-9.17.

Predictions of temperature rise in steel beams by the lumped heat capacity approach are prone to be inherently less accurate than those for steel columns.³⁷ As noted previously, a steel beam in contact with a slab only has three sides exposed to a fire and also will lose heat to the slab.³⁸ Consequently, the temperature of a steel beam exposed to fire is likely to vary appreciably from the bottom flange to the top flange, stretching the validity of the uniform temperature assumption. Nonetheless, for many engineering applications, the lumped heat capacity approach can provide a conservative estimate of the average temperature

Table 4-9.8 Comparison of Predicted Time from Lumped Heat Capacity Analysis and Measurements for Protected Steel Column to Reach 538° C

Shape	<i>h</i> (cm)	Test (min)	Calc. (min)
W 6 × 16	1.9	58	56
	3.8	112	119
	7.6	210	251
W 8 × 28	3.5	122	121
	8.3	291	298
	9.5	355	352
W 10 × 49	1.9	70	62
	5.6	217	220
W 12 × 106	3.8	200	203
W 14 × 228	1.4	123	140
W 14 × 233	2.9	225	251

Figure 4-9.17. Predicted steel column temperature.³⁶

rise of a steel beam.³⁹ Heat losses to the slab may be compensated for by reducing the effective flame emissivity to 0.5.³⁵ However, if the temperature gradient across the beam is important, another analytical approach will need to be applied.³⁷

Exterior steel columns and steel spandrel beams: A design guide is available for calculating the exposure of exterior steel columns and steel spandrel beams.⁴⁰ The guide is based on research by Law and basic radiation heat transfer principles.⁴¹ A similar calculation procedure is available in the Eurocodes.⁹

The temperature of the steel member is calculated from a steady-state conduction analysis. The exposure boundary conditions consist of radiant heating from a fully developed room fire and flames emitting from windows near the steel member. For this method, a specific design is considered unacceptable if the steel temperature exceeds 1000°F.

Liquid-filled columns: The design calculations for liquid-filled columns are based on the thermal capacity of the liquid. The design of a liquid-filled column fire protection system consists of three major steps:

1. Heat transfer analysis
2. Determination of volume of liquid required
3. Pipe network design

The heat transfer analysis is used to assess the impact of fire exposure on the liquid-filled column. The heat transfer analysis considers radiation and convection heat transfer from the fire to the column surface, conduction through the column wall, and convection with localized boiling into the liquid. Both temperature of the steel column and total amount of heat transferred to the liquid causing evaporation are determined as a result of this analysis.

The liquid volume calculation is important to ensure the column remains full of liquid for the entire fire exposure period. Since heat transferred to the liquid will cause some evaporation, a supplemental amount of liquid must be provided in a storage tank.

The final step in the design method is a hydraulic analysis of the tubular column and pipe network. This analysis assesses the ability of the liquid to circulate based on friction losses, elevation changes, and buoyancy of the heated liquid.

A comprehensive design aid for liquid-filled columns is available.⁴² Since the procedure is rather lengthy, it will not be reviewed here.

Graphical Solutions

Because heat transfer analyses can be very tedious and may involve the use of complex computer programs, graphic solutions have been formulated to simplify the estimation of steel temperature. Graphs of the temperature of protected steel members have been developed by Malhotra,²¹ Jeanes,¹² Lie,¹⁵ and others.

The series of graphs developed by Malhotra,²¹ presented in Figure 4-9.18, for estimating the temperature of steel members exposed to the standard exposure are based on the lumped heat capacity approach described in the previous section. Steel temperatures are plotted versus the D/A ratio (analogous to the inverse of W/D) for selected time periods of exposure and thermal resistances of the insulating material. Time periods of 30 to 120 min are noted in the graphs. The range of thermal resistances of the insulating material covered by these graphs is 0.01 to 0.30 $(W/m^2 \cdot ^\circ C)^{-1}$ (0.003 to 0.10) $(Btu/ft^2 \cdot hr \cdot ^\circ F)^{-1}$.

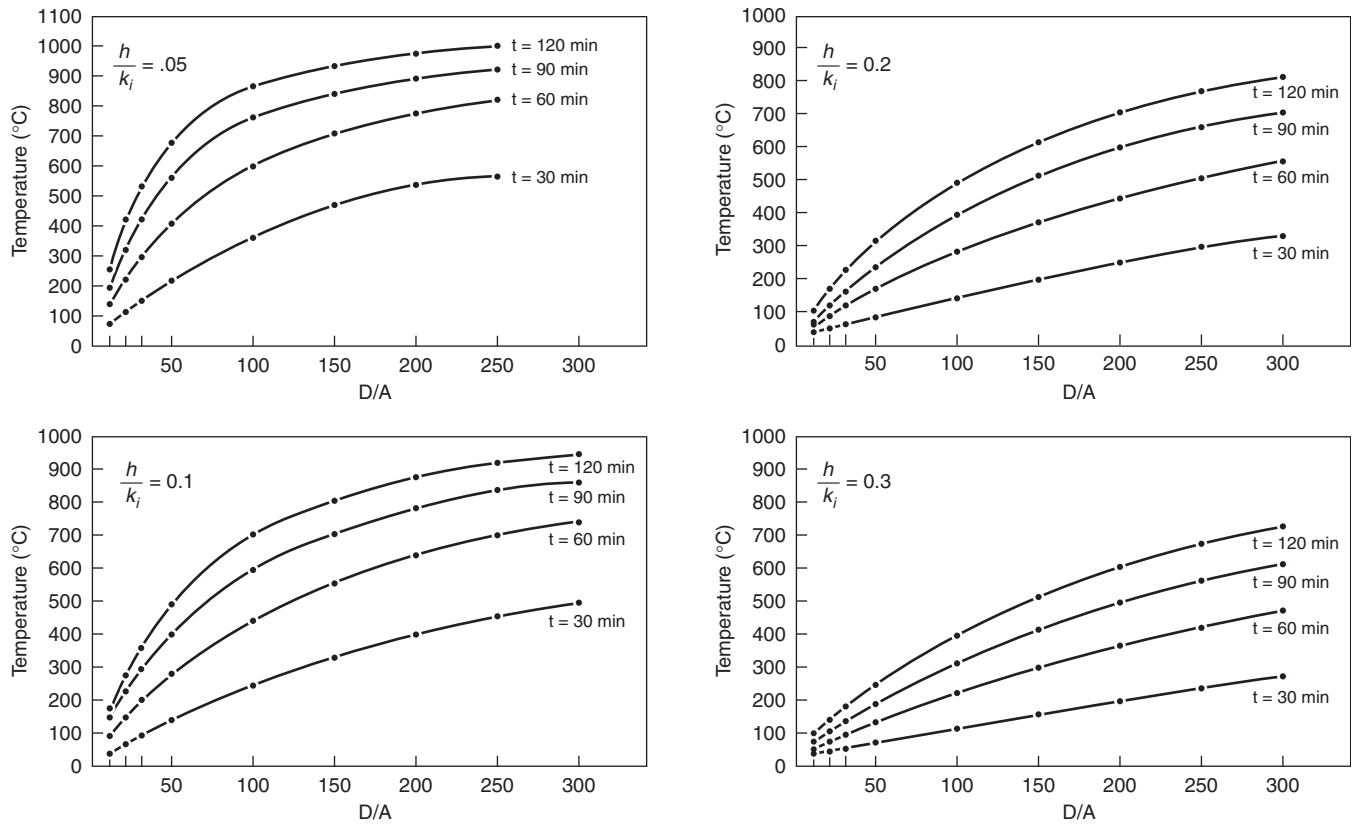

Figure 4-9.18. Relationship of heated area to steel weight with temperature.²¹

Based on the application of FIRES-T3, a heat transfer computer program which will be described in the next section, Jeanes formulated a series of time-temperature graphs of protected steel beams.¹² The steel beams are protected by a proprietary specific spray-applied cementitious material with a range of thicknesses of 0.5 to 1.5 in. (12.7 to 38.1 mm). Graphs are available for a variety of common wide-flange beam shapes.¹² Examples of these graphs are presented in Figure 4-9.19 with graphs addressing the average and single-point steel temperatures relating to the maximum endpoint criteria from ASTM E119.¹ Average and single-point steel temperatures are represented by the dashed lines. These graphs can be used to determine the thickness of protection material required to provide a desired level of fire resistance. Alternatively, the fire endurance can be estimated for a particular steel beam and insulation thickness design which has not been tested.¹²

Information from numerous applications of FIRES-T3 examining the time-temperature response of steel beams protected with a spray-applied cementitious material exposed to the standard fire exposure is summarized in Figure 4-9.20. Using this graph, the fire endurance of protected steel beams with a W/D ratio of 0.4 to 2.5 lb/ft-in. can be determined for thicknesses of the spray-applied protection between 1.3 to 3.8 cm (0.5 to 1.5 in.).

Lie provides graphical representations of the exact solutions of the governing differential equations for the temperature of protected steel members exposed to the

standard fire.¹⁵ The heat transfer is assumed to be one-dimensional through the insulation layer. A uniform temperature throughout the steel cross section is assumed. The two graphs presented in Figure 4-9.21 are applicable to a wide range in the Fourier number, Fo, for the insulation layer. In order to use the graphs, the following dimensionless parameters must be defined:

$$Fo = \frac{at}{h^2}$$

$$N = \frac{\rho_i c_i h}{c_s (W/D)}$$

$$\theta = \frac{T - T_0}{T_m - T_0}$$

where

- a = thermal diffusivity of insulation (ft²/hr) (m²/hr)
- t = heating time (hr)
- h = thickness of insulation (ft) (m)
- ρ_i = density of insulation (lb/ft³) (kg/m³)
- c_i = specific heat of insulation (Btu/lb·°F)
- c_s = specific heat of steel (Btu/lb·°F)
- T = temperature of steel at time t (°F) (°C)
- T₀ = initial temperature of steel (°F) (°C)
- T_m = mean fire temperature (°F) (°C)

Average Section Temperature of Steel Beam, W12 x 14 ($W/D = 0.40$), for Various Thicknesses of Direct-Applied Fire Protection

Maximum Steel Beam Temperature, W12 x 14 ($W/D = 0.40$), for Various Thicknesses of Direct-Applied Fire Protection

Figure 4-9.19. Predicted steel beam temperature by FIRES-T3.¹²

Figure 4-9.20. Fire endurance of steel beams versus fire protection thickness for average section temperature of 1000° F (538° C). (Based on FIRES-T3 analysis of ASTM E119 fire exposure.)¹²

Figure 4-9.21. Dimensionless steel temperature versus Fourier numbers.¹⁵

The mean fire temperature associated with a heating time, t , for these graphs is calculated from the standard time-temperature curve, where

$$T_m = \begin{cases} 150(\ln 480t - 1) - 30/t, & T^\circ\text{C} \\ 270(\ln 480t) - 238 - 54/t, & T^\circ\text{F} \end{cases}$$

EXAMPLE 4:

Determine the fire resistance of a $W 24 \times 76$ steel beam based on the temperature endpoint criteria noted in ASTM E119. The beam is protected with 0.50 in. (12.7 mm) of spray-applied cementitious material, by three methods:

1. Graphical approach from Jeanes¹²
2. Graphical approach by Lie¹⁵
3. Quasi-steady-state approach by Malhotra²¹

SOLUTION:

A $W 24 \times 76$ steel beam has a W/D ratio of 1.03 lb/ft-in. or 12.36 lb/ft². The material properties are evaluated at mean temperatures expected during the exposure. The fire resistance can be assessed using the temperature endpoint criteria in ASTM E119. Mean temperatures of 500°F (260°C) and 750°F (400°C) are selected (arbitrarily) for the steel and insulation, respectively, to determine the thermal properties. The following material property values are assumed:¹²

	Steel	Insulation
Thermal conductivity (Btu/ft·hr·°F)	25.6	0.067
Specific heat (Btu/lb·°F)	0.132	0.304
Density (lb/ft ³)	490	15

Jeanes's graph: Using Figure 4-9.21 with a W/D of 1.03 lb/ft-in. and an insulation thickness of 0.50 in. (12.7 mm), the fire endurance is estimated to be 1.33 hr or 80 min.

Lie's graph: Evaluating the dimensionless parameters,

$$Fo = \frac{\alpha t}{h^2}$$

where

$$\alpha = \frac{k_i}{\rho_i c_i} = \frac{0.067}{15 \times 0.304} = 0.0147 \text{ ft}^2/\text{hr}$$

$$Fo = \frac{0.0147t}{(0.5/12)^2} = 8.47t \quad (t \text{ in hr})$$

Referring to Figure 4-9.22 and using a trial and error approach with a critical temperature selected as 1000°F (538°C), the fire endurance time is estimated as approximately 75 min.

Quasi-steady-state approach: First, a check is performed to determine if the thermal capacity of the insulation material must be considered.

Figure 4-9.22. Comparison of calculated and measured steel temperatures.⁴³

$$c_s W/D > 2c_i \rho_i h$$

$$0.132 \times 12.36 > 2 \times 0.304 \times 15 \times 0.50/12$$

$$1.63 > 0.38$$

Disregarding the thermal capacity of the insulation, Equation 4 is used to predict the steel temperature rise for each time step.

$$\Delta T_s = \frac{0.067/3600}{0.0132 \times 0.50/12 \times 12.36} (T_f - T_s)\Delta t$$

$$= 2.74 \times 10^{-4}(T_f - T_s)\Delta t$$

Time	Steel Temperature (°C)	Fire Temperature (°C)	Fire-Steel Temperature (°C)	W/m ² ·K k/h	ΔT _s (°C)
10	20.0	46	26	9.13	0.1
20	20.1	72	51	9.13	0.2
30	20.3	96	76	9.13	0.3
40	20.5	120	99	9.13	0.3
50	20.8	143	122	9.13	0.4
3220	534.2	888	353	9.13	1.2
3230	535.3	888	353	9.13	1.2
3240	536.5	888	352	9.13	1.2
3250	537.7	889	351	9.13	1.2
3260	538.9	889	350	9.13	1.2
3270	540.1	890	350	9.13	1.2
3280	541.2	890	349	9.13	1.2

Thus, the fire endurance is 54 min.

The fire endurences calculated by the three methods can be compared as follows:

Jeanes (FIRES-T3)	80 min
Lie	75 min
Quasi-steady-state	54 min

The agreement between the fire endurance times determined by Jeanes’s and Lie’s graphs is very good. The significantly reduced fire endurance calculated using the quasi-steady-state approach is attributable to the approximate nature of the lumped heat capacity method assuming an adiabatic surface at the beam–slab interface.

Computer-Based Analyses

Several computer-based analyses are available to estimate the temperature rise of steel members. The analyses range from a spreadsheet procedure to perform the iterative calculations for the quasi-steady-state approach to finite element models.

Spreadsheets are one example of providing a framework to perform the iterative, quasi-steady calculations.^{36,37,44} Typically, the spreadsheet procedures mimic the quasi-steady analysis procedure described previously, including the evaluation of material properties at a mid-range temperature for the exposure of interest. Although temperature-dependent material properties can be included within the spreadsheet framework, the accuracy implied by considering temperature-dependent properties is not consistent with the first-order nature of the quasi-steady approach.

Another framework for conducting computer-based analyses includes the numerous mathematical-equation-solver software packages. This software can be used to

conduct the iterations associated with the quasi-steady approach or to solve the partial differential equations exactly.

Harmathy and Lie developed a two-dimensional finite difference model to predict the temperature rise in protected steel columns.⁴³ The two-dimensional network is formulated over the cross-section of the insulation layer, assuming the temperature to be independent of length. The steel is assumed to be a perfect conductor (i.e., the temperature is uniform throughout the steel). Heat transfer via radiation is considered across any air spaces enclosed by the insulation and steel.

The boundary conditions included by Harmathy are those associated with the ASTM E119 test.¹ To simplify the model, convection is disregarded, since convection comprises a minor portion of the heat transfer process in the furnace test. A flame emissivity of 0.9 is selected. A comparison between the calculated and experimental steel temperatures is presented in Figure 4-9.22. As is evident, the agreement is very good for three insulating materials.

Pettersson et al.³⁵ include a finite difference formulation to predict the temperature rise of steel beams protected with a suspended ceiling exposed to a specified fire. The formulation uses a one-dimensional approximation accounting for conduction through the suspended ceiling and floor slab (above the beam), and radiation and convection in the air space between the slab and beam. The temperature of the steel is assumed to be uniform. The assembly is divided into several elements as depicted in Figure 4-9.23.

A system of simultaneous equations is derived for the temperature rise in each of the assembly elements. A numerical integration technique such as Runge-Kutta is used to obtain the solution. A comparison of the calculated versus experimentally observed temperatures for a steel beam is presented in Figure 4-9.24.

General heat-transfer finite-element programs have been available for many years.⁴⁵ FIRES-T3, TASEF-2, SAFIR, and SUPER-TEMPALC, among others, have been

Figure 4-9.23. Division of the floor slab into elements.³⁵

Figure 4-9.24. Calculated (--) and measured (—) steel temperature-time ($\theta_s - t$) curve for a floor girder IPE 140 with insulation in the form of a suspended ceiling of 40-mm-thick mineral wool slabs of density $\gamma = 150 \text{ kg/m}^3$. The figure also gives the calculated (—o—) and measured (—x—) temperature-time curve for the top of the 50-mm-thick concrete floor slab.³⁵

developed specifically to address the heating of assemblies with steel structural members exposed to fire conditions.⁴⁶⁻⁴⁸

TASEF-2 examines the conduction heat transfer through assemblies.⁴⁶ Assemblies may include internal voids, in which convection and radiation heat transfer modes are considered. Two time-temperature curves are available: (1) the ISO 834 standard time-temperature curve and (2) a time-temperature curve from a ventilation-controlled fire.

SUPER-TEMPCALC can also be used to analyze the conduction heat transfer through assemblies with air gaps. Numerous fire curves are included within the software.

FIRES-T3 was specifically developed to examine the heating of structural members exposed to fire conditions.⁴⁷ FIRES-T3 has been applied successfully to predict the temperature rise in protected steel beams and columns.^{12,49} Almand used a finite-difference heat-transfer model to estimate the protection thickness of spray-applied cementitious material required for tubular steel columns.⁵⁰

The input data requirements for the heat transfer computer models can be grouped into two categories:

1. A description of the assembly
2. A description of the fire exposure

The information necessary to describe the assembly includes geometric factors (dimensions, shape of member) and material property values (thermal conductivity, specific heat, and density). The fire exposure is characterized in terms of the temperature of the surrounding environment and appropriate heat transfer coefficients. The geometry of the assembly is established by formulating an element mesh for the assembly of interest. Required material property data consists of the density, specific heat, and thermal conductivity of the steel and insulation. Material property data is available for a limited number of insulation materials.^{12,51} The exposure associated with the ASTM E119 test¹ may be selected as the fire exposure to be simulated by FIRES-T3.^{12,49} A pre-processor routine for FIRES-T3 was recently developed by Stubblefield and Edwards.⁵² TASEF and SUPER-TEMPCALC also includes a post-processor to generate graphs of the output.

For models using an explicit transient solution technique, such as FIRES-T3, caution must be exercised in selecting the time step and mesh size to obtain correct results that are numerically stable. TASEF-2 internally determines a numerically stable time step. Most heat transfer models do not address the effects of phase changes or chemical reactions that may influence the heating process. Phase changes and chemical reactions have been accounted for by altering the value of the material properties. Milke addressed the evaporation of free water in a spray-applied cementitious material by increasing the specific heat in a narrow temperature region around 100°C (212°F).⁴⁹

Agreement between the predicted and experimental average steel temperatures is quite good in both applications of FIRES-T3 by Jeanes and Milke. A comparison of the temperature history for a steel column protected with a spray-applied cementitious material subjected to the ASTM E119 test is presented in Figure 4-9.25. A similar comparison is presented in Figure 4-9.26 for steel beams protected with the same material.¹²

FIRES-T3 has also been used to conduct a preliminary analysis of the heating of partially protected steel columns (i.e., where a portion of the spray-applied protection is missing).⁵³ The analysis indicated that even a small portion of missing protection significantly decreased the fire resistance of the column, especially for cases involving small columns. Results of the analysis are indicated in Figure 4-9.27.

Structural Analyses

The structural analysis methods calculate one of three parameters: deflection, critical temperature, or critical load. In several of the methods, all three of the parameters may be considered, since they are interrelated. Algebraic equations, graphs, and computer programs are available to perform a structural analysis for the purpose of addressing fire resistance.

General Discussion of Three Parameters Addressed in Structural Analysis

Deflection: The total deflection and rate of deflection can be calculated for loaded and heated steel beams by

Figure 4-9.25. Comparison of predicted and measured average steel column temperature.⁴⁷

considering all sources of strain. The total strain comprises components of the elastic and plastic strains due to the applied loads, thermal strain (due to thermal expansion), and creep strain.

The calculated deflection and rate of deflection can be compared with established maximum limits of each. The Robertson-Ryan criteria have been widely accepted for this purpose.^{20,54,55} However, calculation of the deflection of unheated beams is difficult except for simple loadings, geometries, and end conditions. Adding the thermal expansion and creep components further complicates the calculation, virtually requiring computer solution.

Critical temperature: As mentioned earlier in the chapter, the material properties of steel change with increasing temperature. The most important material properties for critical-temperature calculations are yield strength, ultimate strength, and modulus of elasticity. The critical temperature is defined as the temperature at which the material properties have decreased to the extent that the steel structural member is no longer capable of carrying a specified load or stress level. In this context, the factor of safety of the member is considered to be reduced if the

Figure 4-9.26. Comparison of experimental data and FIRES-T3 analysis.¹²

member reaches unacceptable stress levels, buckling becomes imminent, or deflections exceed maximum limits. The critical temperature can be calculated as long as the dependence of the material properties with temperature is known. There are numerous algebraic equations to calculate the critical temperature of steel structural members.⁵⁶ Often, the critical temperature is defined based on temperature limits stated in the standard test. However, in recent tests steel members experienced temperatures in excess of 800°C (1470°F) without collapse.⁵⁷

Figure 4-9.27. Fire resistance versus percent protection loss for W 10 × 49 column, flange exposure.

Critical load: The critical load is defined as the minimum applied load that will result in failure if the structural member is heated to a temperature, T . The critical load can be expressed as a point load or distributed load. As with critical temperature, the critical load calculation requires the material properties at elevated temperatures. Critical load calculations can be conducted with algebraic equations or with a computer program.

Algebraic Equations: Critical Temperature

Beams

The critical temperature of Grade 250 steel beams with an allowable stress of 20,000 psi (138 Mpa) can be determined using equations by Lie and Stanzak.³⁰ The Lie and Stanzak equations account for creep strain and assume the beam is simply supported and thermally unrestrained.

Similar approaches have been developed by Malhotra,²¹ Vinnakota,⁵⁵ and Kruppa.⁵⁸ Differences in the percent reduction in yield stress or modulus of elasticity are related to design method (elastic or plastic), factor of safety, and end conditions. Equations for the ratio of yield stress at elevated temperature with yield stress at ordinary room temperature are presented in Table 4-9.9. Typical values of Z/S are between 1.13 and 1.15 for I sections,²¹ and 1.5 for rectangular sections.

Another example of the second approach is the analysis of the critical temperature of beams by European Convention for Constructional Steelwork (ECCS).^{56,59} The ECCS guide addresses the maximum allowable reduction in yield strength by considering the applied loading, beam geometry, structural end conditions, and whether the applied loading results in stresses in the elastic or plastic range. Critical temperature calculations based on the ECCS analysis are presented in Table 4-9.10.

EXAMPLE 5:

Determine the critical temperature of a simply supported W 12 × 26 steel beam supporting a 53-in.- (1.35-m-)

Table 4-9.9 Critical Stress Equations²¹

Design Basics	Critical Yield Stress
Elastic design	$\frac{\sigma_{YT}}{\sigma_Y} = \frac{1}{F_e} \frac{Z_e}{Z_p}$
Plastic design	$\frac{\sigma_{YT}}{\sigma_Y} = \frac{1}{F_p}$

where

σ_{YT} = critical yield stress at elevated temperature, T

σ_Y = yield stress at ordinary room temperature

F_e = factor of safety, elastic design

F_p = factor of safety, plastic design

Z_e = elastic section modulus

Z_p = plastic section modulus

thick rectangular slab. The applied moment is 41,750 ft·lb (15,480 N·m). The rectangular slab is 8 ft (2.4 m) wide. The section properties of the beam are

$$Z_e = 33.4 \text{ in.}^3 (547 \times 10^3 \text{ mm}^3)$$

$$I = 204 \text{ in.}^4 (84.9 \times 10^6 \text{ mm}^4)$$

Assume $\sigma_y = 36,000$ psi (248 MPa).

SOLUTION:

Using Lie and Stanzak's equation for a beam,

$$T_{cr} = \frac{70,000}{45.62 - 4.23(I_d/I)} - 460$$

$$I_d = \frac{3^3 \times 96}{12} = 216 \text{ in.}^4$$

$$T = \frac{70,000}{45.62 - 4.23(216/204)} - 460 = 1,240^\circ\text{F}$$

Columns. Lie and Stanzak calculated a critical temperature of 941°F (505°C) for slender, axially loaded columns.³⁰ The calculation was based on the temperature for the onset of elastic buckling for columns under maximum permissible applied stress conditions.

The Euler buckling stress at which elastic buckling is imminent is given by

$$\sigma_{cr} = \frac{\pi^2 E_T}{\lambda^2} \quad (6)$$

where

σ_{cr} = Euler buckling stress (MPa) (psi)

E_T = modulus of elasticity at temperature T (MPa) (psi)

λ = slenderness ratio = Kl/r

r = radius of gyration (ft)(m)

Kl = effective length of column (ft)(m)

Included in the ECCS guide⁵⁹ are dimensionless buckling curves for steel columns at elevated temperatures. These curves are presented in Figure 4-9.28.

Table 4-9.10 Critical Temperature of Steel Beams³⁷

			factor $\frac{kq^*}{q_e}$ resp. $\frac{kq^*}{q_p}$					
			Static System					
			0.3	0.4	0.5	0.6	0.7	
Base of structural design at room temperature	Theory of plasticity	Statically determinate	585	540	490	430	360	
		Statically indeterminate						
	Theory of elasticity	Statically determinate	605	565	525	475	425	
		Statically indeterminate	$\Theta = 1.33$	640	605	575	545	510
			$\Theta = 1.0$	605	565	525	475	425
$\Theta = 1.47$	650		615	590	560	535		
$\Theta = 1.12$	615		580	545	505	465		
$\Theta = 1.47$	650	615	590	560	535			

q_p = Ultimate plastic load
 q^* = Applied load
 k = Load multiplier
 Θ = Factor addressing plastic reserve of beam from redistribution of moments.

Figure 4-9.28. Dimensionless buckling curves for steel columns.⁵⁹

Equation 6 is only valid for columns that buckle in the elastic range. Generally, slender columns having a slenderness ratio in excess of approximately 90 can be expected to buckle elastically. Buckling stresses for stout columns (slenderness ratio less than 90) are in the plastic range, requiring a more complex analysis. The failure mode for columns with a slenderness ratio between 80 and 100 cannot be reliably predicted.⁶⁰ The tangent mod-

ulus can be used instead of the modulus of elasticity in Equation 6 for stout columns. However, predictions of the critical temperature using Equation 6 may not be accurate, due to residual stresses from the steel fabrication process.⁶⁰ Thus, for stout columns, a conservative estimate for the critical temperature of steel columns may be obtained by determining the temperature at which the yield stress is equal to the applied stress.

General

Malhotra has observed that critical temperatures determined from the structural analysis algebraic equations will be somewhat low when compared to experimental data.²¹ Thus, the following correction factors, V , are suggested by Malhotra to improve the prediction capabilities of the approach:

1. Columns: $V = 0.85$
2. Statically determinate beams: $V = 0.77 + 0.15 \frac{P_s}{P_u}$
3. Statically indeterminate beams: $V = 0.25 + 0.77 \frac{P_s}{P_u}$

where

P_s = service (applied) load (N or N/m) (lb or lb/ft)
 P_u = load to induce ultimate stress at midspan (N or N/m) (lb or lb/ft)

EXAMPLE 6:

Determine if the following steel column is expected to buckle if it achieves an average temperature of 1100°F (593°C). The column is simply supported, 15 ft (4.6 m) long and has an applied load of 12,000 psi (82.8 MPa). Assume the yield stress is 36,000 psi (248.4 MPa) and the modulus of elasticity is 30,000,000 psi. The characteristics of the column are

$$A = 8.23 \text{ in.}^2 \text{ (5310 mm}^2\text{)}$$

$$I = 21.6 \text{ in.}^4 \text{ (8.99} \times 10^6 \text{ mm}^4\text{)}$$

$$Kl = 180 \text{ in. (4572 mm)}$$

At 1100°F (593°C):

$$E_T = 1 + \frac{T}{2000 \ln(T/1100)}$$

$$E_o = 15.6 \times 10^6$$

SOLUTION:

Calculate the slenderness ratio to determine the failure mode.

$$\lambda = \frac{Kl}{r} = 110$$

Since the slenderness ratio exceeds 90, the column is susceptible to buckling. The buckling stress at 1100°F (593°C) is 12,700 psi (87.6 MPa). Thus, the column does not buckle due to the applied load and elevated temperature.

Critical Stress

Columns: Sample expressions for determining the critical stress for steel columns³⁰ are noted below.

$$P_{cr}^2 - P_{cr} \left[\sigma_{yT} + \pi^2 E_T \left(4.8 \times 10^{-5} + \frac{1}{\lambda^2} \right) \right] + \sigma_{yT} A \frac{\pi^2 E_T}{\lambda^2} = 0$$

where

P_{cr} = critical point load (N) (lb)

σ_{yT} = yield stress at temperature T (Pa) (psi)

E_T = modulus of elasticity at temperature T (Pa) (psi)

$$\lambda = Kl/r$$

In order to improve the prediction capabilities of the critical stress approach for slender columns, the modulus of elasticity should be replaced by the reduced modulus of elasticity.¹⁵ The reduced modulus is defined as

$$E_r = \frac{4EE_T}{(\sqrt{E} + \sqrt{E_T})^2}$$

where

E_i = tangent modulus

In addition, the 0.2 percent proof stress may be replaced by the 0.5 percent proof stress in the yield stress parameter.⁶¹

Results of a buckling analysis on concrete-filled square hollow sections are provided in Figure 4-9.29.

Beams: The expressions for the critical loads for beams assume at failure that the beam is in a state of full plasticity at the location of the maximum moment.⁶¹ Obviously, in order to calculate the critical stress, the material property-temperature relationships must be known.

The critical distributed load for a simply supported beam is⁵⁵

$$q_{cr} = \frac{8\sigma_{yT}Z_p}{L^2}$$

where

q_{cr} = critical distributed load (N/m) (lb/ft)

Z_p = plastic section modulus (m³) (in.³)

L = span of beam (m) (ft)

σ_{yT} = yield stress at elevated temperature (MPa) (psi)

Considering a cantilever beam with a point load applied one-third of the span from the fixed end, plastic hinges can be expected at the point of load application and at the fixed end. The critical load can be determined by

$$P_{cr} \frac{7.5\sigma_{yT}Z}{L}$$

The above equations in this section do not account for creep strain. Based on an analysis of the deflection history of heated, loaded beams, Pettersson et al. include a load ratio, β , to determine the critical distributed stress.³⁵

$$q_{cr} = \beta \frac{8\sigma_{yT}Z}{L^2}$$

where the yield stress is evaluated at ordinary room temperature, relaxing the need to know the yield stress-temperature relations. β is defined as the ratio of the load causing a maximum allowable deflection under fire conditions to the load inducing stresses equal to the yield stress at ordinary room temperature. Thus, the parameter β takes into account the dependence of both the yield stress and creep on temperature. Graphs of β are available for a variety of thermal restraint and structural end conditions.

The Eurocodes include a method of analysis using algebraic equations to consider the moment capacity of steel beams which have a temperature gradient through the depth of the beam.⁹ The method involves dividing the beam into small isothermal sections and treating these isothermal sections as a composite beam (see Figure 4-9.30). In this case, the moment capacity of the beam is given as

$$M_{cap} = \sum_{i=1}^n \sigma_i A_i z_i$$

where

M_{cap} = moment capacity (N·m) (lb·ft)

σ_i = applied stress in isothermal element (Pa) (psi)

A_i = area of isothermal element (m²) (ft²)

z_i = distance from neutral axis to centroid of isothermal element (m) (ft)

Figure 4-9.29. Design graphs for ISO fire resistance requirements R60 and R90. For the concrete-filled square hollow structural section 400 × 10, the axial buckling load is a function of the buckling length, of the concrete quality, and of the percentage μ of reinforcement; this design diagram is based on a simple calculation model.⁸

Computer Programs

Several finite element computer models are available to assess the structural response of fire-exposed structural members or frames. Sullivan et al. indicate that most of the existing finite element models used for structural fire protection analyses were developed originally for research applications.⁶²

FASBUS-II is an example of a finite element model developed in the United States to evaluate the structural response of complex building assemblies such as floor assemblies consisting of a two-way concrete slab, steel deck, and steel beam.⁶³ Input for FASBUS-II includes the temperature distribution, temperature-dependent mechanical properties, geometry, end conditions, and loading. The output of FASBUS-II includes deflections, rotations,

Figure 4-9.30. Isothermal sections of beam.

and stresses in the components of the assembly, which then need to be compared to performance limits.

Sullivan et al. and Franssen et al. provide extensive reviews and comparisons of existing finite element models for structural fire protection applications.^{62,64} According to Sullivan et al. all of the models make the following assumptions:

- Plane sections remain plane (Navier-Bernoulli hypothesis).
- Perfect composite action is assumed for steel-concrete assemblies, disregarding any slippage between the steel and concrete.
- Torsion is disregarded.
- Moisture effects are disregarded.
- Large displacements are not accurately modeled.

Traditionally, analysis of the response of the structure exposed to fire has been limited to an analysis of the response of single members. However, in structural frames comprising many members, load transfer or membrane action may occur to permit the steel member to maintain its integrity, despite achieving a temperature in excess of that typically associated with failure.

Load transfer allows stronger members to support additional loads not capable of being carried by heated, weak members. In order to capture this phenomenon, a frame analysis is required.⁴⁴ Numerous software packages are available to conduct the frame analysis. Results of a frame analysis are presented in Figures 4-9.31 and 4-9.32.

The frame analyses range from algebraic-equation-based methods to finite element analyses. Pettersson et al.

Figure 4-9.31. Deformations measured and calculated by a numerical model for a composite frame.⁸

Figure 4-9.32. Fire resistance times measured and calculated by a numerical model for columns, beams, or frames of any cross section types (bare steel, protected steel, composite).⁶

include a frame analysis via algebraic equations used to determine displacement.³⁵ The frames consist of beams supported by one or two columns at mid-span. The analysis assumes that each beam or column has a uniform temperature (though the temperature of the beam is not required to be that of a column). A pinned connection between the structural members is assumed. The analysis considers the compatibility of the deformation of each member by requiring that the change in length of the column is equal to the beam deflection at the point of contact.

Schleich et al. describe the application of CEFICOSS for a frame analysis.^{65,66} The frame consists of a single beam and column, where one end of the column is connected to an end of the beam. Reasonable agreement is indicated between predicted and measured results.

El-Rimavi et al. describe the application of another finite element model, NARR2, for the evaluation of a large building frame involving numerous beams and columns.⁶⁷ The large frame is divided into several sub-frames for computational ease. Good agreement is noted

between predictions of deflections and force resultants obtained involving simulations of the full building frame and subframes. Slightly greater failure temperatures were determined for semi-rigid connections as compared to rigid connections.

Nomenclature

- a characteristic dimension
- A cross-section area of steel tube, steel column
- A_s cross-section area of steel column
- b characteristic dimension
- b_f width of flange
- c characteristic dimension
- c_c specific heat of concrete
- c_i specific heat of protection material
- c_s specific heat of steel
- C_1 constant

C_2	constant
d	outer diameter of steel pipe
d	depth of section
D	heated perimeter of steel section
E_0	modulus of elasticity at ambient temperature
E_r	reduced modulus
E_t	tangent modulus
E_T	modulus of elasticity at temperature T
F	factor of safety
F_e	factor of safety, elastic design
F_p	factor of safety, plastic design
$ Fo$	Fourier number
h	thickness of protection material
H	thermal capacity of steel section at ambient temperature
k	thermal conductivity of steel
k_c	thermal conductivity of concrete
k_i	thermal conductivity of protection material
K	end condition factor
l	unsupported length of column
L	inside dimension of one side of square concrete box protection
L	span of beam
m	moisture concrete of concrete
N	ratio of thermal capacity of protection material to that of steel
P	perimeter of steel tube
P_{cr}	critical point load
P_s	service (applied) load
P_u	ultimate load
q_{cr}	critical distributed load
r	radius of gyration
R	fire resistance
R_0	fire resistance with zero moisture content of concrete
t	wall thickness of steel pipe
t	time
t_w	width of web
Δt	time step
T	steel temperature
T_f	fire temperature
T_m	mean fire temperature
T_0	ambient temperature
T_s	steel temperature
ΔT_s	change in steel temperature
V	correction factor
W	weight of steel section per unit length
Z_e	elastic section modulus
Z_p	plastic section modulus

Greek

α	thermal diffusivity (when used with Fourier number)
α	heat transfer coefficient

α_c	convective heat transfer coefficient
α_r	radiative heat transfer coefficient
α_T	coefficient of thermal expansion at temperature T
β	ratio of distributed load causing maximum allowable deflection to distributed load inducing yielding
ϵ_f	fire emissivity
λ	slenderness ratio
θ	dimensionless temperature
ρ	density
ρ_i	density of insulation material
σ_{cr}	critical stress for buckling
σ_{y0}	yield strength at ambient temperature
σ_{yT}	yield strength at temperature T

CHAPTER 10

Analytical Methods for Determining Fire Resistance of Concrete Members

Charles Fleischmann and Andy Buchanan

Introduction

Concrete structures have a reputation for good behavior in fires. Many reinforced concrete buildings, which have experienced severe fires, have been repaired and put back into use. Concrete is noncombustible and has a low thermal conductivity. Concrete tends to remain in place during a fire, protecting the reinforcing steel, with the cool inner core continuing to carry the load. Catastrophic failures of reinforced concrete structures in fires are rare, but some occasionally occur.¹

Analytical methods developed to predict the fire resistance of structural assemblies can be divided into two groups: (1) standard and (2) nonstandard fire exposure. For the case of the standard fire exposure, a large database exists from referenced standard tests. The analytical methods use empirically based correlations and minimum dimensions to determine the fire resistance. For nonstandard fire exposure, the analysis is more complicated, requiring both heat transfer and structural analyses. Analytical methods are an alternative to conventional methods that require destructive testing of exemplar systems in accordance with standard testing procedures, for example, ASTM E119 or ISO 834.

Fire resistance calculations typically use the same acceptance criteria specified in standard test methods, that is, heat transmission and structural integrity. The analysis can be broadly divided into two parts: (1) heat transfer and (2) structural analysis. Heat transfer calculations are used to evaluate the unexposed surface temperature and the temperature distribution throughout the member, in order to evaluate material strength. The structural integrity analysis applies the strength theory² used to de-

sign reinforced concrete members. The reduced strength of the concrete and steel resulting from elevated temperature is taken into account by using experimental results for the compressive and yield strengths as a function of temperature. This procedure is known as the rational design method.

As the fire protection field advances into performance-based engineering, techniques like the rational design method are more likely to be used. In the rational design approach, a design time-temperature curve, based on the expected fire, is specified. The engineer then performs the heat transfer analysis to determine the temperature profile and unexposed surface temperature. Knowing the temperature distribution of the member, a structural analysis is conducted to determine the fire endurance.

This chapter presents an overview of the analytical methods for calculating the fire resistance of concrete structural members and provides a description of the mechanical properties for concrete and steel at elevated temperatures. A brief discussion of heat transfer for a concrete assembly is given, along with temperature profiles from ASTM E119 test results. The structural calculations for simply supported and continuous members are explained. A simple example is shown to further demonstrate the basics of the design concept. Fire resistance for columns and walls is also presented. A more comprehensive discussion of the rational design method can be found elsewhere.¹⁻⁵

Material Properties of Concrete and Steel

Most of the material properties for concrete and steel change significantly at elevated temperatures. In order to accurately predict the structural fire endurance of concrete members, these changes must be taken into account. Temperature-dependent values of strength, modulus of elasticity, and thermal expansion have been presented in a graphical format to aid in the design process. The thermophysical properties required for a heat transfer analysis, that is, thermal conductivity and specific heat, also change

Charles Fleischmann is a senior lecturer in the Department of Civil Engineering, University of Canterbury, in Christchurch, New Zealand.

Andy Buchanan is an associate professor in the Department of Civil Engineering, University of Canterbury, in Christchurch, New Zealand.

significantly. The thermophysical properties have been investigated at elevated temperatures by Harmathy and others.⁶⁻¹⁰

Strength

The strength of the reinforcing steel changes significantly with temperature, and must be taken into account in any structural calculation. Figure 4-10.1 shows the strength-temperature relationship for hot-rolled, cold-drawn, and high-strength alloy steels. Yield strength versus temperature relationship is given for hot-rolled steel, used for reinforcing bars. Tensile strength versus temperature relationship is shown for the cold-drawn steel and high-strength alloy steel, used for prestressing bars, wire, or strands. The change from yield strength to tensile strength for the two steel types relates to the design parameters used for reinforced versus prestressed concrete assemblies.

Like steel, the strength of concrete is also diminished at elevated temperatures. Figure 4-10.2 shows the strength-temperature relationship for carbonate, siliceous, and sand-lightweight aggregate concretes. The compressive strength is not only a function of temperature but is also affected by the applied load.

The results shown in Figure 4-10.2 were obtained from specimens loaded to 40 percent of their compressive strength during the heating process. Once the test tem-

perature of interest was reached, the specimens were loaded to failure. Figure 4-10.2 illustrates that the compressive strength of concrete remains relatively unchanged up to 500°C (900°F). Above 500°C (900°F), the compressive strength of the siliceous aggregate concrete starts to decrease rapidly and is considered ineffective at temperatures above 650°C (1200°F), where the compressive strength has been reduced by approximately 50 percent of the value at normal temperatures. However, for carbonate and lightweight aggregates, compressive strength remains relatively unchanged up to 650°C (1200°F) and is not considered to be ineffective until it reaches a temperature of 650°C (1400°F). The experimental method used may influence the reported compressive strength. Specimens heated without compressive loads and then loaded to failure while hot have lower compressive strengths than those heated while loaded.⁴

Modulus of Elasticity

The modulus of elasticity for steel decreases as the temperature increases, as shown in Figure 4-10.3. Figure 4-10.4 shows the modulus of elasticity-temperature curve for three different concrete aggregates. In each case, the modulus of elasticity of concrete is greatly reduced at elevated temperatures. This large reduction of the elastic modulus is helpful in reducing induced thermal stresses in concrete members due to fire.⁴

Figure 4-10.2. Strength-temperature relationships for carbonate, siliceous, and sand-lightweight aggregate concretes.¹³

Figure 4-10.3. Modulus of elasticity for hot-rolled steel at elevated temperatures.¹⁴

Thermal Expansion

Both concrete and steel expand when heated. This thermal expansion can actually increase the fire resistance. The effects of thermal expansion are discussed later in this chapter. Figure 4-10.5 shows the coefficient of thermal expansion for concrete and steel. The values for the steel were calculated using the following equation taken from the *Manual of Steel Construction*:¹⁶

$$\begin{aligned} \alpha_C &= (11.0 + 0.0062\theta_C) \times 10^{-6} \\ \alpha_F &= (6.1 + 0.0019\theta_F) \times 10^{-6} \end{aligned} \tag{1}$$

Figure 4-10.4. Modulus of elasticity, at elevated temperatures, for carbonate, siliceous, and lightweight concretes.¹⁵

where

- α = coefficient of thermal expansion (in/in °F) ($\Delta l/l$ °C)
- θ_C = temperature (°C)
- θ_F = temp

Figure 4-10.5. Thermal expansion of concrete and steel at elevated temperatures.⁴

Figure 4-10.6. Fire endurance of concrete slabs—effect of thickness and type of aggregate, based on heat transmission.⁴

Heat Transmission

The temperature of the unexposed side of concrete floors, roofs, and walls are usually limited to prevent ignition of combustibles in contact with the unexposed surface. In ASTM E119 the criteria are 121°C (250°F) average and 163°C (325°F) single-point temperatures. These criteria often govern the fire resistance of the assembly. In addition to the unexposed surface temperature, the temperature distribution throughout the member is required in order to evaluate the material strengths in the structural calculations.

The temperature distribution within concrete slabs exposed to the ASTM E119 time-temperature curve is illustrated in Figures 4-10.8 through 4-10.10. These data apply to any slab thickness, as long as the slab is at least 25 mm (1 in.) thicker than the point in question.

Heat is mainly transferred through a solid concrete member by conduction. The temperature of the unexposed side of the slab is a function of the slab thickness and the type of aggregate used. The fire endurance versus slab thickness is presented in Figure 4-10.6 for three types of concrete typically used in building construction. The data are based on actual fire tests of concrete slabs.⁴ For the normal-weight concretes used in the fire tests, the maximum aggregate size was 20 mm (3/4 in.) and the air content was about 6 percent. The maximum aggregate size for the structural lightweight concretes was slightly less than 20 mm (3/4 in.) and the air content was about 7 percent. Although the slab thickness and type of aggregate are the main factors that affect heat transmission through the concrete, other factors do have some impact. These factors include moisture content, unit weight, air content, and maximum aggregate size. Within the usual range of values, water-cement ratio, strengths, and age have been shown to have insignificant effects on the heat transfer process.⁴

Floor and roof slabs are often composites of materials, for example, a concrete base slab with overlays or undercoatings of either insulating materials or other types of concrete. Research has been conducted on two-course composite assemblies. An example of a composite slab of normal and lightweight concrete is shown in Figure 4-10.7. Similar plots for different composite assemblies can be found in Reference 17.

The temperature on the unexposed side is not the only temperature of concern. The temperature distribution within the member is used to determine the temperature of the reinforcing or prestressing steel. The temperature of the reinforcing bars is approximately equal to the temperature of the concrete at the level of the center of the bar;⁴ that is, the presence of the steel is neglected in the heat transfer analysis. Thus, temperature distribution is primarily affected by the type of concrete, shape of the member, and exposure conditions. During fire tests, slabs and walls are typically heated on one side only; beams are heated from one, two, or three sides; and columns are heated on all four sides. Data on the temperature distribution within concrete members are available from results of fire tests. Figures 4-10.8, 4-10.9, and 4-10.10 show the temperatures within a slab exposed to the standard ASTM E119 fire for carbonate, siliceous, and sand-lightweight aggregates, respectively.

The temperature distribution within a 150 × 300 mm (6 × 12 in.) rectangular concrete beam exposed to the ASTM E119 standard time-temperature curve is illustrated in Figure 4-10.11. Because the temperature distribution is a function of the beam size, it is not practical to present a complete set of figures. A procedure has been developed in which the temperature distribution can be constructed.⁴ With the advent of fast, affordable computers, such empirical techniques are rapidly being

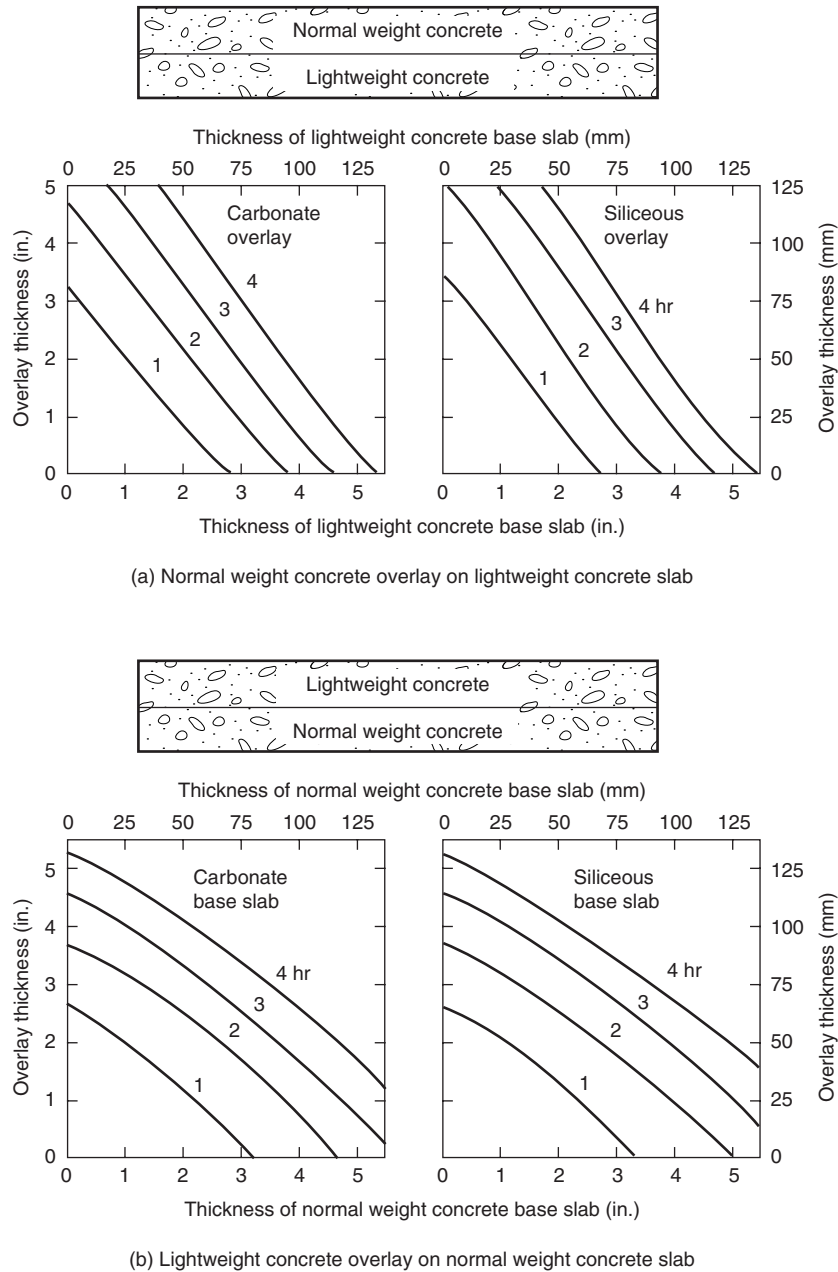

Figure 4-10.7. Fire endurance of base slabs and overlays of normal weight or lightweight concretes, based on heat transmission.¹⁷

replaced by complete numerical modeling of the temperature distribution. Computer models such as FIRES T3,¹⁸ TASEF-2,¹⁹ and SAFIR²⁰ can accurately predict the temperature distribution in various types of concrete members. These models are capable of handling one-, two-, or three-dimensional heat transfer, with time-dependent nonlinear boundary conditions, and temperature dependent thermal properties. None of these models incorporate mass transfer or moisture migration, and thus require modification to the thermal properties to ac-

count for latent heat absorption of the water. All three programs use a finite-element technique to solve the energy equation and thus require a skilled operator. Recent improvements to SAFIR include element generation, significantly simplifying the input, and reducing time required. Although these models are not necessary for typical analysis assuming a standard time-temperature curve, with the increased emphasis on performance-based design and more realistic time-temperature curves, the use of such models is likely to increase in the future.

Simply Supported Slabs and Beams

Simply supported, unrestrained members are not typically cast in place. However, a discussion of simply supported members will make the discussion of continuous members easier to understand. A simply supported, reinforced concrete slab is illustrated in Figure 4-10.12.

The slab is supported by "frictionless" rollers, so that the slab is free to expand without resistance but should not deflect at the support. The load, w , is evenly distributed over the surface of the slab, and the reinforcing steel runs the entire length of the slab. Considering these conditions without a fire, the moment diagram for the slab is illustrated in Figure 4-10.12(b). The moment strength of the slab will be constant along the entire length:

$$M_n = A_s f_y \left(d - \frac{a}{2} \right) \quad (2)$$

where

A_s = area of the reinforcing steel

f_y = yield stress of the reinforcing steel

d = distance from the extreme compression fiber to the centroid of the reinforcing steel

a = depth of the equivalent rectangular stress block²

$$a = \frac{A_s f_y}{0.85 f'_c b} \quad (3)$$

f'_c = compressive strength of the concrete

b = width of the beam or slab

(a) Simply supported one-way slab

(b) Normal conditions (no fire)

(c) At 2 hr of fire exposure

Figure 4-10.12. Applied moments and reduced moment strength diagrams for simply supported one-way slab.⁴

During exposure to a fire, the temperature of the reinforcing steel will increase. As the temperature of the steel increases, the yield strength decreases. (See Figure 4-10.12(c).) This reduction in the steel strength causes a reduction of the moment strength of the slab:⁴

$$M_{n\theta} = A_s f_{y\theta} \left(d - \frac{a_\theta}{2} \right) \quad (4)$$

where θ denotes the effects of elevated temperature.

The reduced moment strength diagram is shown in Figure 4-10.12(c).

With a reduction in the yield stress, $f_{y\theta}$, there is a corresponding reduction in the size of the equivalent stress block, a_θ .⁴

$$a_\theta = \frac{A_s f_{y\theta}}{0.85 f'_c b} \quad (5)$$

Typically, the temperature at the top of a slab remains relatively unchanged from normal conditions even after 2 hr of fire exposure, since the concrete is a good insulating medium. (See Figures 4-10.8 through 4-10.10.) Thus, the values for f'_c and d are not affected. However, if the temperatures in the compression zone exceed 480°C (900°F) for a siliceous aggregate or 650°C (1200°F) for a carbonate aggregate, the concrete compressive strength, f'_c should be reduced. (See Figure 4-10.2.)

As previously noted, the compressive strength of concrete is reduced significantly at a critical temperature, selected here as 650°C (1200°F) for a siliceous aggregate or 760°C (1400°F) for a carbonate aggregate. To account for this substantial reduction in strength, regions of concrete in the compression zone at temperatures above the critical temperature are neglected in the design process. As a result, the depth and/or width of the compression zone are reduced by subtracting the area of the concrete, which is heated in excess of the critical temperature.

For a simply supported slab it is unlikely that the compression zone would be heated to above the critical temperature without the steel failing first, but it should be noted that, if the section of concrete is reduced, the value of d in Equation 4 must be adjusted accordingly.

Flexural failure occurs when the moment strength is reduced to the applied service load moment, M , at the center of the span⁴

$$M = \frac{wL^2}{8} \quad (6)$$

where

M = applied service load moment

L = length of the span

w = applied live load plus dead load, with "factor of safety" = 1.0

The factor of safety used in fire endurance calculations is equal to 1.0, which yields the actual applied moment. The factors of safety used in structural design (1.7 live load, 1.4 dead load, etc.) do not apply to fire endurance calculations.³

As indicated in Equation 4, the structural fire endurance of a simply supported one-way slab or beam is a function of the load intensity, strength-temperature

characteristics of the reinforcing steel, and the depth of protection given to the reinforcement by the concrete cover. There is no benefit of continuity or restraint of thermal expansion with a simply supported slab, the total slab depth, based on heat transmission, h_t , required to obtain the desired fire rating is probably as small or smaller than the total slab thickness, h_s , required for gravity loads.⁴ Therefore, there is no advantage of doing a structural fire endurance analysis for unrestrained, simply supported structural members.⁴

Continuous Unrestrained Flexural Members

Continuous unrestrained members have a considerably longer fire endurance than simply supported members because of their ability to redistribute the applied moments. Figure 4-10.13(a) shows an interior span of a continuous unrestrained slab. The applied moment diagram for a normal condition, with no fire, is shown in Figure 4-10.13(b). The maximum positive moment occurs near the center of the span, and the maximum negative moments are located over the supports.

When the slab is exposed to fire conditions from below, the moments will be redistributed within the slab. This redistribution may be sufficient to cause the negative moment reinforcement to yield. This yielding generally occurs within the first half hour of the fire, based on observation made during standard fire tests.⁴ Figure

Figure 4-10.13. Moment redistribution in interior span of continuous unrestrained one-way slab due to fire exposure.⁴

Figure 4-10.14. Redistributed applied moment diagram at structural endpoint for span of a uniformly loaded continuous one-way slab or beam with unequal end moments.⁴

4-10.13(c) shows the redistribution of moments after 2 hr of fire exposure (2 hr was selected at random). The American Concrete Institute (ACI) warns that increasing the negative reinforcement will increase the attracted negative moment, possibly leading to a compressive failure. It is important that flexural tension governs the design of concrete members. Thus, to avoid compressive failure in the negative moment region, the negative reinforcement should be small enough so that³

$$\frac{A_s f_{y\theta}}{b_\theta d_\theta f'_{c\theta}} < 0.30 \tag{7}$$

Flexural failure of continuous members occurs when three hinges are formed within a span. One of the hinges will form near the midspan and the other two at the adjacent supports. A hinge is formed at the point where the applied moment is equal to the flexural strength at that point.

The flexural strength at any point can be calculated using Equation 4 for simply supported members. Figure 4-10.14 shows the moment diagram for a one-way span with unequal end moments, that is, when the spans are of unequal lengths. This diagram represents the general case and can be used for other conditions, that is, end spans and slabs with equal spans. The member fails when the sum of the flexural strengths is less than the applied moment, $wL^2/8$. The negative moments are calculated at the supports, and the positive flexural strength is calculated at the center of the span. The negative flexural strength is then used in the following equation for the minimum positive flexural strength:⁴

$$\begin{aligned} \text{Minimum required } M_{n\theta} = & \frac{M_{n\theta_1}^- - M_{n\theta_2}^-}{2wL^2} - \frac{M_{n\theta_1}^-}{2} \\ & - \frac{M_{n\theta_2}^-}{2} + \frac{wL^2}{8} \end{aligned} \tag{8}$$

If the minimum positive flexural strength required is less than the positive flexural strength, the member has the calculated fire endurance. The location of the maximum positive moment, X_1 , is calculated from

$$X_1 = \frac{L}{2} + \frac{(M_{n\theta_1}^- - M_{n\theta_2}^-)}{wL} \tag{9}$$

Figure 4-10.15. Redistributed applied moment diagram at structural endpoint for end span of a continuous one-way slab or beam.⁴

Figure 4-10.16. Redistributed applied moment diagram at structural endpoint for symmetrical interior span of a uniformly loaded continuous one-way slab or beam.⁴

End Span

Equations 8 and 9 can be modified and used for the end span of a continuous member. (See Figure 4-10.15.) For the end span, $M_n = 0$, leaving

$$\text{Minimum required } M_{n\theta}^+ = \frac{(M_{n\theta}^-)^2}{2wL^2} - \frac{M_{n\theta}^-}{2} + \frac{wL^2}{8} \quad (10)$$

$$X_1 = \frac{L}{2} - \frac{M_{n\theta}^-}{wL} \quad (11)$$

Interior Span with Equal End Moments

Equations 8 and 9 can also be modified for spans with equal end moments, as indicated in Figure 4-10.16. For this case, $M_{n\theta 1}^- = M_{n\theta 2}^-$, changing Equation 8 to

$$\text{Minimum required } M_{n\theta}^+ = \frac{wL^2}{8} - M_{n\theta}^- \quad (12)$$

Equation 9 becomes

$$X_1 = \frac{L}{2} \quad (13)$$

The location of the points of inflection, X_0 , is dependent on the magnitude of the negative flexural strengths and can be calculated using

$$X_0 = \frac{L}{2} - \sqrt{\frac{2M_{n\theta}^+}{w}} \quad (14)$$

The negative moment reinforcement must be extended a sufficient distance beyond the point of inflection to allow the bar strength to become fully developed. Design criteria for the development length are outlined in the *ACI Building Code Requirements for Reinforced Concrete*.² It is further recommended that at least 20 percent of the maximum negative moment reinforcement in the span extends throughout the entire length of the span.

Fire Endurance of Concrete Structural Members Restrained against Thermal Expansion

When a fire occurs beneath an interior portion of a floor or roof slab, the heated portion of the slab tends to expand. As this portion of the slab expands, the surrounding cooler portions resist the expansion and exert a resistive force on the heated portion of the slab. This resistive force is referred to as the *thermal thrust force*.

Most U.S. fire tests of floor slabs are conducted with the specimen mounted within a restraining frame which restricts the thermal expansion.²² The amount of restraining force provided by the restraining frame varies from one laboratory to another, based on factors such as frame design, specimen design, and specimen tightness.

Prior to 1960, no research had been conducted to measure the magnitude of the thermal thrust force. In 1960, the Portland Cement Association (PCA) began operation of its floor furnace.²³ This furnace allowed for both variable and monitored restraint during the fire test. Restraining the slab against expansion greatly affects the thermal thrust, as indicated in Figure 4-10.17. Notice

Figure 4-10.17. Maximum thrust for allowed expansion of reference specimens.²⁵

that with no expansion allowed, the thermal thrust force would be very high, which would cause compression failure of the concrete. However, with only a slight increase in the allowed expansion, there is a significant decrease in the thermal thrust force. It should also be noted that the thermal thrust force developed in lightweight concrete is considerably less than is developed within normal-weight concrete. This condition is believed to be due to the lower modulus of elasticity and the lower coefficient of expansion of the lightweight concrete.⁴

As a result of the fire research done at PCA, the thermal thrust force was found to vary with the initial modulus of elasticity and the heated perimeter.²⁴ The heated perimeter, S , is defined as that portion of the perimeter of a section of the specimen, normal to the direction of the thermal thrust, that is exposed to fire. Having assembled a large database of "reference specimens," the thermal thrust from these specimens can be used to predict the thermal thrust within a concrete member:²⁵

$$\frac{T_1}{A_1 E_1} = \frac{T_0}{A_0 E_0} \frac{Z_0}{Z_1} \tag{15}$$

where

$$Z_0 = A_0 / S_0$$

$$Z_1 = A_1 / S_1$$

S_0 = heated perimeter of the reference member

S_1 = heated perimeter of the member in question

T_1 = maximum thermal thrust of the member in question

T_0 = maximum thermal thrust of the reference member

A_0 = cross-sectional area normal to the direction of thermal thrust of the reference member

A_1 = cross-sectional area normal to the direction of thermal thrust of the member in question

E_0 = modulus of elasticity of the member in question

E_1 = modulus of elasticity of the reference member

The parameter $T/(AE)$ is dimensionless, thus the units used for T , A , and E must be consistent.

Nomographs, presented in Figure 4-10.18, are used to solve Equation 15.

For any given partially restrained expansion of a concrete member exposed to fire, there is a compatible thermal thrust developed in the fire-exposed portion. The effect of the thermal thrust on the structural behavior of a reinforced concrete slab is the same as that of a prestressing force along the line of action of the thrust. In structural fire endurance calculations, the flexural strength is the primary interest, for which case the thermal thrust can be considered a "fictitious reinforcement" along the line of an action of the thrust.²⁶

The moment due to the thermal thrust, referred to as the thrust moment, is equal to the thrust force multiplied by the distance between the line of action of the thermal thrust and the centroid of the compression block²⁵

$$M_T = T \left(d_t - \Delta - \frac{a_\theta^+}{2} \right) \tag{16}$$

where

$$a_\theta^+ = \frac{T + A_s^+ f_y^+}{0.85 f_c' b_\theta} \tag{17}$$

T = magnitude of the thermal thrust

d_t = distance from extreme compression fiber to the line of action of the thermal thrust, T

Δ = deflection of the slab at the point in question

M_T = thrust moment strength

The line of action of the thermal thrust must act below the resultant of the equivalent rectangular stress block in order to contribute to the fire endurance of the slab. Results from fire tests have shown that the line of action for the thermal thrust is near the bottom of the mem-

Figure 4-10.18. Nomographs relating thrust parameter, strain parameter, and ratio of cross-sectional area to heated perimeter.²⁵

ber throughout the fire test in most cases, particularly when the thrust is small.²⁵ Although the line of action acts near the bottom, the actual position changes during the fire test. The exact location of the line of action depends on the shape of the member, type of concrete, amount of reinforcement, stiffness of the restraining frame, and the amount of expansion permitted. Table 4-10.1 is used to locate the line of action of the thermal thrust for floor systems developing a minimal restraint to thermal expansion. The guidelines presented in Table 4-10.1 are based on results from standard fire tests.²⁵

In order to calculate the thrust moment, the deflection must be estimated. Since the deflections at the supports are assumed to be zero, the only other deflection of interest is at the midspan. The midspan deflection can be approximated using the following equation derived from the deflection equation for simply supported members²⁵

$$\Delta_1 = \frac{L_1^2 \Delta_0}{3500 y_{b1}} \tag{18}$$

where

Δ_1 = deflection for the member (in.)

Δ_0 = deflection for the reference member (in.) (see Figure 4-10.19)

L_1 = length of the span of the member (in.)

Table 4-10.1 Location of Thermal Thrust Line³

Type of Construction	Fire Exposure (hr)	Location of Thrust Line at Supports ^a
Solid slab	2	25 mm (1 in.)
	3	32 mm (1¼ in.)
	4	38 mm (1½ in.)
Slab-and-joint	≤ 2	0.1h
	2-4	0.15h

^aDistance above bottom of member where h = overall depth of the joist and slab.

Figure 4-10.19. Idealized midspan deflection, Δ_0 , of reference specimens with minimal restraint.⁴

y_{b1} = distance from the centroidal axis to the extreme fiber (in.)

In SI units, Equation 18 becomes

$$\Delta_1 = \frac{L_1 \Delta_0}{88,900 y_{b1}}$$

where Δ , L , and y_{b1} are all in mm.

Equation 18 is for members with minimal restraint to thermal expansion. Another equation should be used when the thrust is greater than minimal.⁴

In order to summarize and illustrate how to apply this information to calculate the structural fire endurance for reinforced concrete members, a step-by-step procedure is presented. This procedure was taken from the Concrete Reinforcing Steel Institute (CRSI), *Reinforced Concrete Fire Resistance*. (See Table 4-10.2.)⁴

Example of Continuous One-Way Span

The continuous one-way span example has been included to illustrate the step-by-step procedure for structural analysis for fire endurance that is used. The example problem is for a one-way continuous slab with no thermal restraint assumed. The slab is found to have the desired fire endurance, but the development length of the steel bars required for the negative moment strength is significantly longer than is required for standard gravity loading. The development length is then recalculated assuming minimal thermal restraint.

Given: A one-way, multispan continuous slab supported on beams as shown in Figure 4-10.20. The slab is 100 mm (4 in.) thick with 3.7-m (12-ft) beam spacing. The concrete for the slab is made from siliceous aggregate with a compressive strength of 20.7 MPa (3,000 psi). The slab is subjected to a 3.8 kPa (80 psf) superimposed live load and a 0.25 kPa (5 psf) dead load.

The reinforcement consists of No. 4 bars that meet the requirements of ASTM for A615 Grade 60 (415 MPa). Reinforcing bars are placed in accordance with the 1975 *CRSI Handbook*.²⁷

Problem: Determine if the slab has a 2-hr fire endurance.

Step 1: Determine the required fire rating: 2 hr, as stated in the problem.

Step 2: Determine the total depth of the slab, h_t , based on heat transmission: From Figure 4-10.6, $h_t = 125$ mm (5 in.).

Step 3: Compare h_t vs. h_s : $h_t = 125$ mm (5 in.) > 100 mm (4 in.) = h_s .

Step 4: In this example, the authority having jurisdiction has waived the requirements for heat transmission, as long as the required structural fire endurance is provided.

Step 5: Because 125 mm (5 in.) > 100 mm (4 in.), the fire endurance for the end span must be computed based on continuity only.

Table 4-10.2 Step-by-Step Procedure—Structural Analysis for Fire Endurance

Step No.	Description
1	From the building code governing the project (model, municipal, state, etc.) look up the required fire ratings.
2	Determine the total depths of slabs, h_t , based on heat transmission to provide the required fire ratings.
3	Compare h_t vs. h_s .
4	If $h_t < h_s$, no further fire endurance considerations are necessary.
4a	If the governing building code permits a reduced fire rating for heat transmission as long as the required structural fire rating is provided, then proceed to Step 5.
5	Only if $h_t > h_s$ (or as in step 4a), compute the structural fire endurance, in hours, based on continuity and/or restraint to thermal expansion.
STRUCTURAL FIRE ENDURANCE FOR SIMPLY SUPPORTED OR CONTINUOUS SLABS WITH NO AXIAL RESTRAINT	
6	<i>Solid slabs.</i> Compute the reduced nominal positive and negative flexural strengths, M_{n0}^+ and M_{n0}^- , available at the required fire rating, for example, 3 hr.
7	<i>Interior spans.</i> If the absolute sum of available nominal flexural strengths is equal to or greater than the applied moment, that is, if $M_{n0}^+ + M_{n0}^- \geq wL^2/8$ the fire endurance \geq than the required fire rating.
7a	<i>Exterior spans.</i> Using either the reduced nominal negative or positive flexural strength available at the specified fire endurance, compute the minimum required nominal flexural strength.
8	If the nominal flexural strength available \geq minimum required nominal flexural strength, the structural fire endurance is adequate—go to Step 9.
8a	If the nominal flexural strength available $<$ required nominal flexural strength, the structural fire endurance based on continuity only is not sufficient—go to Step 10.
9	If continuity only is considered in the structural fire endurance calculations, and restraint to thermal expansion is neglected, check the lengths of the top reinforcing bars to make sure the bars are long enough to develop the required nominal negative flexural strength.

The procedure for analyzing continuous beams and joist systems is the same as for the solid slab above, except that isothermal diagrams would be required for determining the available nominal flexural strengths.

STRUCTURAL FIRE ENDURANCE BASED ON RESTRAINT TO THERMAL EXPANSION

- 10 Estimate the deflection Δ_1 , of the heated bay, assuming minimal restraint occurs.
- 11 Locate the line of action of the thermal thrust force at the supports.
- 12 Compute the moment, M_T , which the thermal thrust force has to develop to provide the required additional nominal positive flexural strength for the specified fire endurance.

$$M_T = (\text{Min. req'd } M_{n0}^+ - \text{Available } M_{n0}^-)$$
- 13 Compute the thermal thrust, T_1 , required to produce M_T using Equation 16.
- 14 Compute the thrust parameter, T_1/A_1E_1 .
- 15 Compute the value of $z = A_1/s$.
- 16 With T_1/A_1E_1 and z , determine the strain parameter.
- 17 Compute the expansion, ΔL , by multiplying the strain parameter by the heated length, L_h , of the member.
- 18 Determine if the restraining elements, that is, spandrel or effective edge beams, columns, walls, and so forth, can withstand the thermal thrust, T_1 , with a displacement no greater than the expansion, ΔL .

Structural Fire Endurance Based on Continuity Only

Step 6: Compute the reduced positive and negative moment strengths, M_n^+ and M_n^- , respectively, available after 2 hr.

6a: M_{n0}^+ available at 2 hr.

U^+ for bottom bars, $U^+ = 19 + 6 = 25$ mm (1.0 in.) (See Figure 4-10.21.)

At 2 hr, $U^+ = 25$ mm (1.0 in.), $\theta_s^+ = 630^\circ\text{C}$ (1170°F). (See Figure 4-10.15.)

$f_y = 0.42(60) = 174$ MPa (25.2 ksi). (See Figure 4-10.1.)

Reinforcing is 12.5-mm bars at 215 mm (#4 bars at 9 in.)

$$A_s^+ = 570 \text{ mm}^2/\text{m} \text{ (0.27 in.}^2/\text{ft)}.$$

A_s^+ is calculated from the rebar spacing requirements.

$$a_0^+ = \frac{A_s f_y \theta^+}{0.85 f_c' b} = \frac{570(174)}{0.85(20.7)(1000)} = 5.6 \text{ mm (0.22 in.)} \quad [\text{from Eq. 5}]$$

$$M_{n0}^+ = A_s^+ f_y \theta^+ \left(d^+ - \frac{a_0^+}{2} \right) = \frac{570(174)(75 - 5.6/2)}{1 \times 10^6} \\ = M_{n0}^+ = 7.3 \text{ kN}\cdot\text{m/m (1.64 ft}\cdot\text{kips/ft)} \quad [\text{from Eq. 4}]$$

6b: M_{n0}^+ available at 2 hr

Figure 4-10.20. One-way continuous slab, supported on beams.⁴

Figure 4-10.21. M_n^+ calculation for bottom bars.

The bottom 1 in. has been neglected, because the concrete temperature is above 650°C (1200°F) with a significantly reduced f'_c .

Top bars, $U^- = 100 - (19 + 6) = 75 \text{ mm (3.0 in.)}$ (See Figure 4-10.22.)

At 2 hr, $U^- = 75 \text{ mm (3.0 in.)}$, $\theta = 270^\circ\text{C (520}^\circ\text{F)}$. (See Figure 4-10.9.)

$$f_{y\theta}^- = 0.83 (60.0) = 344 \text{ MPa (49.8 ksi)}. \text{ (See Figure 4-10.1.)}$$

The $f_{y\theta}^-$ stress block, a_{θ}^- , is estimated to be about 16 mm (5/8 in.) with a temperature ranging from 650 to 480°C (1200 to 900°F).

Temperature values are estimated from Figure 4-10.9. The average temperature is approximately 565°C (1050°F).

$$f_c\theta' = 0.65(3) = 13.5 \text{ MPa (1.95 ksi)}. \text{ (See Figure 4-10.2.)}$$

$$d_{\theta} = 4.0 - (0.75 + 0.25 + 1.0) = 50 \text{ mm (2.0 in.)}$$

Figure 4-10.22. M_n^- calculation for top bars.

Reinforcing is 12.5-mm bars at 240 mm (#4 at 10 in.)

$$A_s^- = 510 \text{ mm}^2/\text{m (0.24 in.}^2/\text{ft)}$$

$$a_{\theta}^- = \frac{A_s^- f_{y\theta}^-}{0.85 f_{c\theta}' b} = \frac{510(344)}{0.85(13.5)(1000)} = 15 \text{ mm (0.60 in.)} \quad [\text{from Eq. 5}]$$

$$\left\{ \begin{aligned} M_n^- &= A_s^- f_{y\theta}^- \left(d_{\theta}^- - \frac{a_{\theta}^-}{2} \right) = \frac{510(344)(50 - 15/2)}{1 \times 10^6} \\ &= Mn_{\theta}^- = 7.5 \text{ kN}\cdot\text{m/m} \\ &\quad (1.69 \text{ ft}\cdot\text{kips/ft}) \end{aligned} \right. \quad [\text{from Eq. 4}]$$

Step 7: Calculate the minimum positive moment required at 2 hr.

$$\text{Minimum required } M_{n\theta}^+ = \frac{(M_{n0}^-)^2}{2wL^2} - \frac{M_{n0}^-}{2} + \frac{wL^2}{8}$$

$$w = 0.1(24) + .25 + 3.8 = 6.45 \text{ kN/m (0.44 kips/ft)}$$

$$\text{Minimum required } M_n^+ = \frac{(7.5)^2}{2(6.45)(3.65)^2} - \frac{7.5}{2} + \frac{6.45(3.65)^2}{8}$$

$$\text{Minimum required } M_n^+ = 7.4 \text{ kN}\cdot\text{m/m (1.66 ft}\cdot\text{kips/ft)}$$

Step 8: If the positive moment strength available is greater than the required positive moment strength, structural fire endurance is adequate. Because the moment strength available, 7.3 kN·m/m (1.64 ft·kips/ft), is for practical purposes equal to the required moment strength, 7.4 kN·m/m (1.66 ft·kips/ft), the structural fire endurance for the end span is 2 hr.

Step 9: Check the lengths of the top reinforcing bars to make sure the bars are long enough to develop the required negative moment strength. The length of the top bars under normal conditions, considering only gravity loads and no fire, is taken from the *CRSI Handbook*.²⁷ (See Figure 4-10.23.)

Step 9a: Top bar lengths, at first interior support, neglecting restraint to thermal expansion

Figure 4-10.23. Top bar lengths at 2 hr of fire exposure.

The distance to the point of inflection at first interior support for structural fire endurance is calculated using

$$X_0 = \frac{2M_n^-}{wL}$$

Because the negative reinforcement generally yields early in the fire, as discussed previously, within the first half hour, the value for the negative moment used in Equation 14 should be the maximum negative moment that the beam can support.

$$a = \frac{A_s f_y}{0.85 f_c' b} = \frac{510(415)}{0.85(20.7)(1000)} = 12 \text{ mm (0.47 in.)}$$

$$M_n^- = A_s f_y d - \left(\frac{a}{2}\right) - \frac{510(415)(75 - 12/2)}{1 \times 10^6} \\ = M_n^- = 14.6 \text{ kN}\cdot\text{m/m (3.28 ft}\cdot\text{kips/ft)}$$

The value used for w is left to engineering judgment based on the expected loading during a fire. For this example, the full dead load and one-half the live load is used.

$$w = 0.1(24) + 0.25 + 1.9 = 4.55 \text{ kN/m (0.31 kips/ft)}$$

$$X_0 = \frac{2(14.6)}{4.55 \times 3.65} = 1.75 \text{ m (5 ft 9 in.)}$$

The distance the top bars have to be embedded beyond the point of inflection is given in the ACI *Building Code*.² At least one-third of the bars should be embedded $1/16$ of the clear span, d , or $12d_b$, whichever is greater. In this example, the $1/16$ of the clear span criterion governs (250 mm or 10 in.). Thus, some of the top bars must extend 2.0 m (6 ft 6 in.) into the end span. The length of the top steel, 2.0 m (6 ft 6 in.), is nearly twice the required length for the gravity load (1.2 m or 3 ft 10 in.). The maximum negative moment strength, M_n^- , used in Equation 14, represents the most severe condition for the development length. However, the assumption of frictionless roller bearing supports used in the above example neglected the restraining force, or thermal thrust, T , is developed early in the fire, producing a moment opposite the support moment, which acts to reduce the magnitude of the support moment. The net support moment will then be less than the moment strength, M_n^- , used in the calculation above, thereby overestimating the development length required for the desired fire endurance.⁴

The restraint criteria discussed will be used to determine if there is sufficient restraint developed in the longitudinal direction, to reduce the development lengths to that required for the gravity load.

9b: Top bar lengths, at first interior support, including restraint to thermal expansion

Using $X_0 = 1.2 \text{ m (3.83 ft)}$, the length required for gravity loading, we can determine the net moment at the support required.

$$X_0 = \frac{2M_n^-}{wL} \quad (19)$$

$$M_n^- = \frac{X_0 w L}{2} = \frac{1.2(4.55)(3.65)}{2} \\ = 10 \text{ kN}\cdot\text{m/m (2.25 ft}\cdot\text{kips/ft)}$$

The thermal thrust must produce a moment equal to

$$M_T = 14.6 - 10.0 = 4.6 \text{ kN}\cdot\text{m/m (1.04 ft}\cdot\text{kips/ft)}$$

Early in the fire, T will act at or near the bottom of the slab. (See Table 4-10.1.) T is assumed to act 12 mm (1/2 in.) above the bottom of the slab (taking the fire exposure as approximately one-half hour):

$$d_T = 100 - 12 = 88 \text{ mm (3.5 in.)}$$

$$\Delta = 0 \quad \text{at the support}$$

The depth of the stress block, a_θ^+ , is assumed initially to be zero because the required thrust is small.

$$T = \frac{M_T}{d_T - \Delta - a_\theta^+} = \frac{4.6(1000)}{88 - 0 - 0} = 52.2 \text{ kN/m (3.6 kips/ft)}$$

Recalculating a_θ^+ ,

$$a_\theta^+ = \frac{T}{0.85 f_c' b} = \frac{52.2}{0.85(20.7)} = 3 \text{ mm (0.13 in.)}$$

$$T = \frac{1.14(12)}{3.5 - 0 - 0.13/2} = 53.2 \text{ kN/m (3.65 kips/ft)}$$

Compute the expansion, L , that corresponds to

$$T = 53.2 \text{ kN/m (3.65 kips/ft)}$$

$$E_1 = 25,000 \text{ MPa (3.6} \times 10^6 \text{ psi)}$$

$$A_1 = 1.0(0.1) = 0.1 \text{ m}^2/\text{m (48 in.}^2/\text{ft)}$$

$$\frac{T_1}{A_1 E_1} = \frac{53.2}{0.1(25)} = 21 \times 10^{-6}$$

$$Z = \frac{A_1}{s} = \frac{0.1}{1} = 0.1 \text{ m = 100 mm (4 in.)}$$

$$\frac{\Delta L}{L_h} = 0.006 \text{ (from Figure 4-10.18)}$$

$$L = 0.006 \times 3650 = 22 \text{ mm (0.86 in.)}$$

In order to maintain equilibrium of the horizontal forces and compatibility of the displacements, the restraining elements must withstand $T = 53.2 \text{ kN/m}$ (3.65 kips/ft) and not deflect more than $\Delta L = 22 \text{ mm}$ (0.86 in.). The next step would be to check the strength and stiffness of the restraining elements, that is, the exterior spandrel beams and columns of the exterior support and the plane floor area of the first interior support. In this example, it is not necessary to check the strength and stiffness toward the interior of the structure, because there is considerable restraint from the large unheated floor area and many columns to provide the thrust moment at the first interior support.⁴ However, the spandrel beams and columns at the exterior support should be checked to ensure that there is sufficient strength and stiffness to resist the thrust moment. Determining the strength and stiffness of the spandrel beams and columns requires a long and complex structural analysis and is not shown here. An explanation of the structural analysis of spandrel beams and columns can be found in the literature.⁴

Assuming there is sufficient restraint in the spandrel beams and columns to resist the thrust moment, the required length of the top bars over the first interior support at 2 hr of fire exposure must be determined. Neglecting restraint to thermal expansion,

$$X_0 = \frac{2M_{m0}^-}{wL} = \frac{2(7.5)}{(4.55)(3.65)} = 0.90 \text{ m (2.96 ft)}$$

As previously discussed, at least one-third of the top bars should be embedded 1/16 of the clear span at the point of inflection, X_0 , therefore the top steel should extend 1.1 m (3 ft 8 in.) into the end span. This length is less than the top bar length required for gravity loads, so no adjustment in the length of the reinforcement steel is required to obtain the desired fire endurance.

Reinforced Concrete Columns

Throughout the history of concrete construction reinforced concrete columns have performed well when exposed to fire. The reason for this is threefold:

1. Columns are generally large enough to prevent the center core from losing a significant amount of strength even in prolonged fire exposure.
2. Ties or spirals contain the concrete within the core.
3. The vertical reinforcing bars are generally protected by at least 48 mm (1 7/8 in.) of concrete cover, thereby insulating the steel bars.⁴

Most of the building codes in the United States assign 3- and 4-hr fire resistance to reinforced concrete columns larger than 300 mm \times 300 mm (12 \times 12 in.) for square shapes, or a diameter of at least 300 mm (12 in.) for round columns.

ACI suggests that the information in Table 4-10.3, by Hull and Ingberg,²⁸ be used for designing reinforced con-

Table 4-10.3 Fire Endurance Proposed by Hull and Ingberg⁸

Aggregate Type	Minimum Area of Round or Square Cross Section		Concrete Cover		Fire Endurance Classification (hr)
	(cm ²)	(sq in.)	(mm)	(in.)	
Siliceous	710	110	38	1 1/2	1 1/2
Siliceous	1,290	200	38	1 1/2	2 1/2
Siliceous	1,290	200 ^a	38	1 1/2	3 1/2
Siliceous	1,613	250	64	2 1/2	3
Siliceous	1,613	250 ^a	64	2 1/2	6

Carbonate	1,290	200	38	1 1/2	6

^aMesh in cover.

^bAir-cooled slag.

crete columns for exposure to fire. The information presented in Table 4-10.3 is based on the results of a series of fire tests on concrete columns reported in 1925.²⁸ More detailed tables are available.^{1,44} Detailed assessments of reinforced concrete columns exposed to fires have been made by Anderberg²⁹ and Lie and Irwin.³⁰

Reinforced Concrete Frames

It is not possible to use simple hand methods for accurate structural design of reinforced concrete frame structures exposed to fires. Individual concrete members can be designed by the methods described above, but for moment-resisting frames, a special purpose computer program is necessary for detailed analysis and design. Available programs include FIRES-RC-II,³¹ CONFIRE,³² and SAFIR.²¹

Reinforced Concrete Walls

Typically, the fire endurance of concrete and concrete masonry walls is determined by heat transmission criteria as opposed to structural performance.^{3,4} As a result, estimating the fire resistance of walls can be accomplished using a heat transfer analysis only. For this reason, the discussion of thickness requirements presented in the heat transmission section can be used. The required thickness can be determined graphically or by applying a heat transfer computer model.

The distinction between bearing and nonbearing walls is based on building code structural requirements and not fire endurance. For example, some building codes require bearing walls to be thicker than nonbearing walls. Such a requirement has not been justified by results of a fire test.⁴ ASTM E119 requires that a superimposed load be applied and maintained at a constant magnitude throughout the test of a bearing wall. When testing nonbearing walls, there is no applied load; however, the edges of the

walls may be restrained against thermal expansion, in which case a thermally induced load is applied during the fire test. This thermally induced load is of much greater magnitude than the load applied to bearing walls.⁴

Prestressed Concrete Assemblies

Most of this chapter refers to reinforced concrete. The same principles apply to prestressed concrete, which is often more vulnerable in fires for the following reasons: prestressing steels are much more sensitive to elevated temperatures than mild steel reinforcing bars; prestressed concrete is often manufactured in slender components with thin cover concrete; and some failure modes such as debonding, shear, and spalling are more critical in prestressed concrete.

Procedures are also available to calculate the fire resistance of prestressed concrete members. The reader is directed to *Design for Fire Resistance of Precast Prestressed Concrete*.³³

Composite Steel-Concrete Construction

Composite steel-concrete construction refers to concrete slabs cast on permanent steel-deck formwork and steel beams which act compositely with the concrete slab to resist bending moment, as shown in Figure 4-10.24.

Composite steel-concrete slabs have excellent integrity in fire conditions because even if cracks occur in the concrete slab, the continuous steel deck will prevent any passage of flames or hot gases through the floor. To meet the insulation criterion, it is simply necessary to provide sufficient thickness of slab. A solid slab of uniform thickness requires the same thickness as a normal reinforced concrete slab, but for other profiles it is necessary to evaluate an effective thickness. Generic listings are given in some codes including Eurocode 4,³⁴ and manufacturers of steel decking have proprietary ratings for their products. It is possible to spray the underside of the steel sheeting with spray-on insulation, but this method is rarely economical.

The strength of composite steel-concrete slabs is severely influenced by fire because the steel sheeting, acting

Figure 4-10.24. *Composite steel-concrete construction.*

as external reinforcing, loses strength rapidly when exposed to the fire. However, composite slabs can achieve good fire resistance because of three contributing factors: axial restraint, moment redistribution, and fire emergency reinforcement.

Composite slabs often have different fire resistance ratings for restrained and unrestrained conditions.³⁵ During a fire test, if a composite slab is built into a rigid testing frame which allows almost no axial expansion, the slab can achieve a fire resistance rating with no reinforcing other than the steel sheeting, because of the thermal thrust developed at the supports. Some buildings are sufficiently stiff and strong to provide such restraint to a fire-exposed floor system, but because the amount of restraint is difficult to assess accurately, it is usual to rely on some reinforcing within the slab.

If the nominal reinforcing provided to control shrinkage cracking is placed near the top of the concrete and if the slab is continuous over several supports, it can develop significant negative flexural capacity through moment redistribution and hence retain sufficient load capacity during the fire. If a slab is simply supported, or if moment redistribution is insufficient to resist the applied loads, it is common practice to place *fire emergency reinforcing* in the slab, consisting of steel reinforcing bars in the troughs of the sheeting, with sufficient cover from the bottom surface to control temperatures in the bars. The flexural strength of the slab can be calculated in the usual way using the temperature of the rebars. Further design recommendations are given by ECCS,³⁶ Lawson,³⁷ and EC4.³⁴

Recent Developments

There is continuing international research on fire performance of reinforced concrete. Several recent developments are described below.

Calculation of Temperatures

Recent publications on thermal and mechanical properties of concrete at high temperatures are given by Harmathy,³⁸ Schneider,³⁹ Bazant,⁴⁰ and Neville.⁴¹ A simple, approximate formula for calculating internal temperatures in reinforced concrete members exposed to the standard fire has been developed by Wickström.⁴² Internal temperatures in concrete slabs and beams exposed to realistic fires are given by Wade.⁴³

Eurocodes

The new Eurocodes for structural design have comprehensive chapters on fire design. For reinforced concrete, Eurocode 2⁴⁴ gives minimum dimensions and minimum cover necessary to achieve fire resistance ratings for slabs, walls, beams, and columns. It also provides information on thermal and mechanical properties of concrete at high temperatures, with recommended design methods. The Eurocode describes two overall types of design: a "simplified" calculation method and "general" calculation methods. The simplified calculation method is essentially the same as that described in this chapter. The

general calculation methods include those which provide a more realistic analysis of concrete structures exposed to actual fires, based on fundamental physical behavior including high temperature effects. Complex structures can only be designed using general methods and computer programs for calculating thermal gradients and analyzing the structure at elevated temperatures, for any type of fire exposure. Design of composite steel-concrete slabs in fire conditions is given in Eurocode 4.³⁴

Spalling

The design methods in this chapter are based on the assumption that the concrete remains intact for the duration of the fire. This assumption is invalid if the cover concrete spalls off during the fire, exposing reinforcing steel to the fire temperatures. Experiments and real fire experience have shown that most normal weight concrete members can withstand severe fires without spalling, but spalling does occur sometimes. In some cases spalling is related to the type of aggregate, but it is more often linked to the behavior of the cement paste. It is generally agreed that spalling most often occurs when water vapor is driven from the cement paste during heating, with high pore pressures creating high tensile stresses in the concrete. Susceptibility to spalling results from high moisture content (such as in fresh concrete), rapid rates of heating, slender members, and high stresses at the time of the fire. Recent reviews of concrete spalling are provided by Malhotra⁴⁵ and Phan.⁴⁶ The most promising new development to reduce spalling is the addition of fine polypropylene fibers to the concrete mix so that the polypropylene melts during fire exposure, leaving cavities through which the water vapor can escape.⁴⁷

High-Strength Concrete

There has been considerable recent interest in high-strength concrete as a construction material. High-strength concrete contains additives such as silica fume and water-reducing admixtures which result in compressive strength in the range 50 to 120 MPa (7000 to 18,000 psi). An extensive survey of high-strength concrete properties at elevated temperatures by Phan⁴⁶ shows that they tend to have a higher rate of strength loss than normal concrete at temperatures up to 400°C (750°F), with explosive spalling being a problem in some cases. High-strength concrete is more susceptible to spalling since it has smaller free-pore volume (higher paste density), so that the pores become filled with high pressure water vapor more quickly than in normal weight concrete and the low porosity results in slower diffusion of the water vapor through the concrete. Fire tests on high-strength columns are reported by Aldea et al.⁴⁸ and Kodur.⁴⁷ Design recommendations are given by Tomasson,⁴⁹ who suggests a simple method which ignores concrete above 500°C (950°F) for slabs and beams and above 400°C (750°F) for columns.

Fiber-Reinforced Concrete

Thermal and mechanical properties of steel-fiber reinforced concrete at elevated temperatures are described

by Lie and Kodur.⁴⁹ They show that the presence of steel fibers increases the ultimate strain and improves the ductility of the concrete during fire exposure.

CHAPTER 11

Analytical Methods for Determining Fire Resistance of Timber Members

Robert H. White

Introduction

The fire resistance ratings of wood members and assemblies, as of other materials, have traditionally been obtained by testing the assembly in a furnace in accordance with American Society for Testing and Materials (ASTM) Standard E119.¹ These ratings are also published in listings, such as the Underwriters Laboratories *Fire Resistance Directory*² or the Gypsum Association's *Fire Resistance Design Manual*,³ and in publications of the model building code organizations. The ratings listed are limited to the actual assembly tested and normally do not permit modifications such as adding insulation, changing member size, changing or adding interior finish, or increasing the spacing between members. Code interpretation of the test results sometimes allows the substitution of larger members, thicker or deeper assemblies, smaller member spacing, and thicker protection layers, without reducing the listed rating. A new ASTM standard⁴ provides guidelines on such extension of fire endurance results obtained from the standard ASTM E119 fire test. A fire-endurance design procedure for wood beam and columns and a procedure for wood-frame walls have U.S. and Canadian building code acceptance. In Europe, the new Eurocode 5⁵ provides calculation methods at three levels of complexity. In addition, other procedures and models have been proposed or are being developed.

When attention is given to all details, the fire endurance of a wood member or assembly depends on three items:

1. Performance of its protective membrane (if any)
2. Extent of charring of the structural wood element
3. Load-carrying capacity of the remaining uncharred portions of the structural wood elements

Dr. Robert H. White is project leader for wood preservation and fire research at the USDA, Forest Service, Forest Products Laboratory. His research has primarily been in the areas of wood charring and fire endurance of wood assemblies.

The following sections review the methods available for determining the contribution of each item and discuss the major properties of wood that affect the thermal and structural response of wood assemblies or components.

Contribution of the Protective Membrane

Gypsum wallboard and plywood paneling are two common types of protective membrane, which is the first line of resistance to a fire in wood construction. In a protected assembly, the fire resistance rating is largely determined by the type and thickness of the protective membrane. The effects of the protective membrane on the thermal performance of an assembly are included in Harmathy's ten rules of fire endurance rating.⁶ These ten rules (Figure 4-11.1) provide guidelines to evaluate the relative effects of changes in materials on the fire resistance rating of an assembly. However, there are exceptions to some of these general rules. The rules apply primarily to the thermal performance of the assembly.

The contribution of the protective membrane to the fire resistance rating of a light-frame assembly is clearly illustrated in the component additive calculation procedure discussed in the following subsection. Brief discussions of direct protection of wood members and numerical heat transfer models are also presented.

Component Additive Method

The Component Additive Method (CAM) is a calculation procedure to determine the fire resistance ratings of light-frame wood floor, roof, and wall assemblies. With this procedure, as with Harmathy's rules 1 and 2, one assumes that times can be assigned to the types and thicknesses of protective membranes and that an assembly with two or more protective membranes has a fire resistance rating at least that of the sum of the times assigned

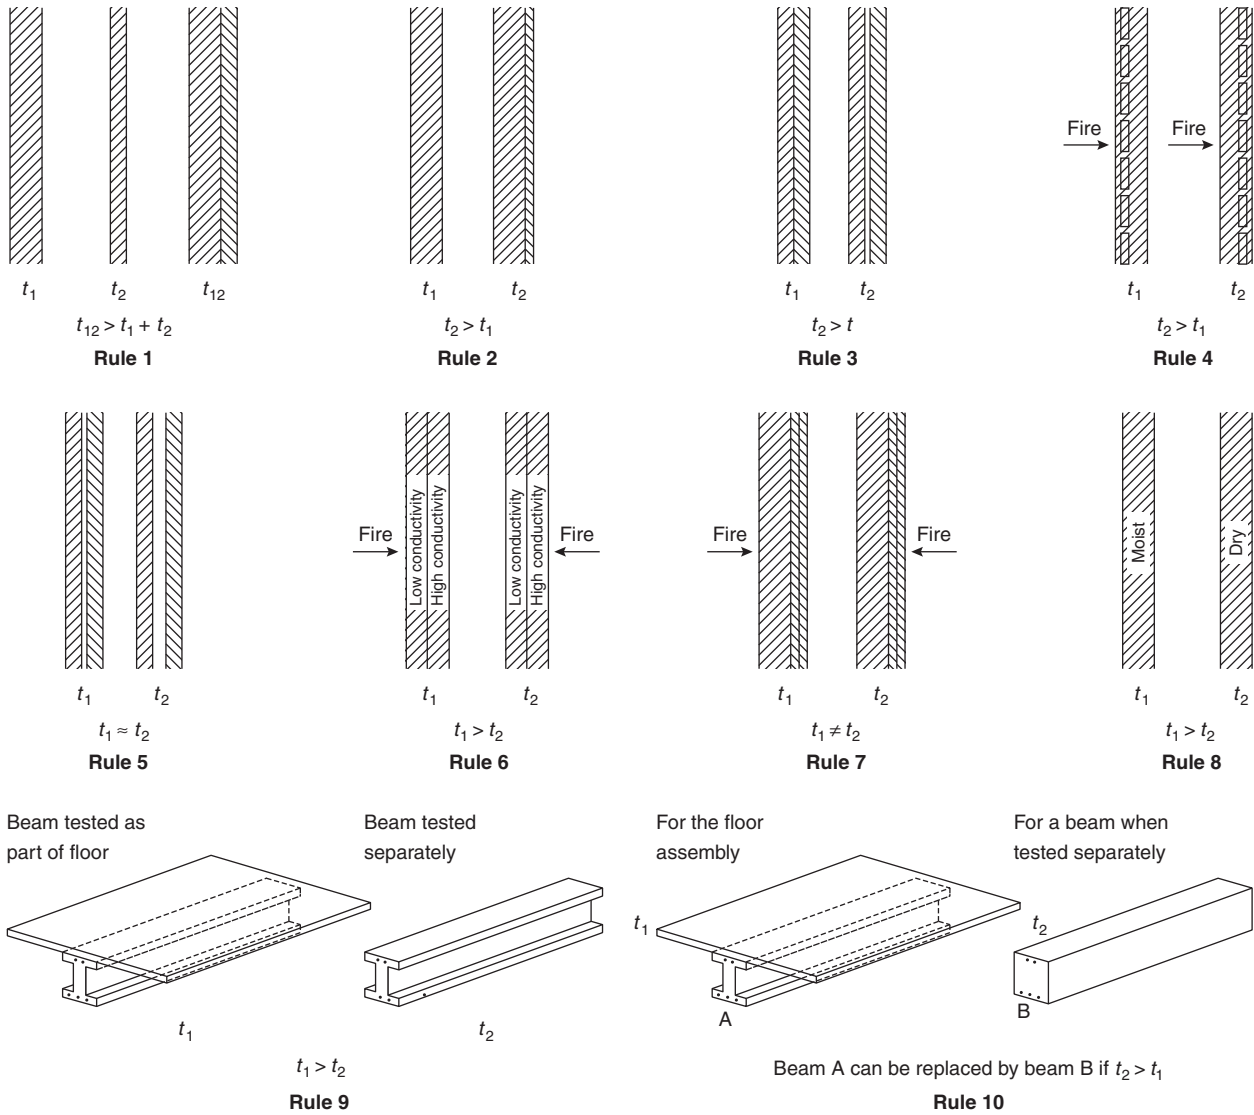

Figure 4-11.1. Harthy's ten rules of fire endurance.⁶

for the individual layers and the times assigned to the framing. CAM was developed by the National Research Council of Canada (NRCC), and has gained code approval in both the United States and Canada.

The times assigned to the protective membranes (Table 4-11.1), the framing (Table 4-11.2), and other factors are added together to obtain the fire resistance rating for the assembly. The times are based on empirical correlation with actual ASTM E119 tests of assemblies. The ratings obtained in these tests ranged from 20 to 90 min. The times given in Table 4-11.1 are based on the membrane's ability to remain in place during fire tests. The type of fasteners and their spacing on the protective membrane can be critical factors in the performance of the membrane in a fire endurance test. Reference should be made to similar tested assemblies. The addition of insulation to a wall assembly can increase its fire resistance. Adding rock wool

Table 4-11.1 Time Assigned to Protective Membranes^a

Description of Finish	Time (min)
9.5-mm (3/8-in.) Douglas fir plywood, phenolic bonded	5
13-mm (1/2-in.) Douglas fir plywood, phenolic bonded	10
16-mm (5/8-in.) Douglas fir plywood, phenolic bonded	15
9.5-mm (3/8-in.) gypsum board	10
13-mm (1/2-in.) gypsum board	15
16-mm (5/8-in.) gypsum board	20
13-mm (1/2-in.) type X gypsum board	25
16-mm (5/8-in.) type X gypsum board	40
Double 9.5-mm (3/8-in.) gypsum board	25
13-mm + 9.5-mm (1/2-in. + 3/8-in.) gypsum board	35
Double 13-mm (1/2-in.) gypsum board	40

^aThe applicable building code should be checked for acceptance of, modification to, and limitations on the procedure. There are specific requirements for the installation of some of the membranes.

Table 4-11.2 Time Assigned for Contribution of Wood Frame^a

Description of Frame	Time (min)
Wood wall studs, 406 mm (16 in.) on center	20
Wood floor and roof joists, 406 mm (16 in.) on center	10

^aMinimum size for studs is nominal 51 mm by 102 mm (2 in. by 4 in.). Wood joists must not be less than nominal 51 mm (2 in.) in thickness. The spacing between studs or joists cannot exceed 406 mm (16 in.) on center. The applicable building code should be checked for acceptance of, modification to, and limitations on the procedure.

or slag mineral wood insulation batts for additional protection to the wood stud wall generally has an assigned time of 15 minutes, which is added to the times for the framing and for the protective membrane to obtain the rating for the wall assembly. Assigned times, if any, for glass fiber insulation depend on the codes. Adding insulation to a floor or roof assembly can decrease its fire resistance, depending on its location within the assembly and the method of attachment.

For asymmetrical wall assemblies, the rating is based on the side with the lesser fire resistance. For exterior walls rated only from the interior and floor/roof assemblies, there are minimal requirements for the membrane on the side or top of the assembly not exposed to the fire, in order to ensure that the wall or floor/roof assembly does not fail because of fire penetration or heat transfer through the assembly. Specific alternative membranes are identified for the face of wood stud walls not exposed to fire (exterior) and for the flooring or roofing over wood joist framing.

The membrane on the side not exposed to fire (the outside or top) may also be any membrane listed in Table 4-11.1 with an assigned time of 15 min or greater.

The application of the method in the building codes is generally limited to 60 or 90 min. Additional information can be found in publications of the American Forest & Paper Association⁷ and the Canadian Wood Council.⁸ The applicable building code should be checked for acceptance of, modifications to, and limitations on the procedure. There are differences between the codes in what is accepted.

CAM gives flexibility, for example, in calculations for plywood and gypsum board combined as an interior finish.

EXAMPLE 1:

The calculated fire resistance rating of a wood stud exterior wall (nominal 2-in. × 4-in. [51-mm × 102-mm] studs, 16 in. [406 mm] on center) with 5/8-in. (16-mm) Douglas fir phenolic-bonded plywood over 1/2-in. (13-mm) type X gypsum wallboard on the side exposed to fire is

From Table 4-11.1:	
16-mm (5/8-in.) Douglas fir plywood, phenolic bonded	15 min
13-mm (1/2-in.) type X gypsum board	25 min
From Table 4-11.2:	
Wood stud framing	20 min
Calculated rating (total)	60 min

Mineral wool insulation could be used to increase the fire rating to 75 minutes.

Other Methodologies

The times assigned to the protective membranes in the component additive method are not the “finish ratings” of the material cited in test reports or listings. A finish rating of a protective membrane is generally defined as the time to reach either an average temperature rise of 139°C (250°F) or a maximum rise of 181°C (325°F), as measured on the plane of the wood framing member nearest the fire. Since the charring of wood is associated with a temperature of 300°C (550°F), another method is to assume that the membrane will protect any wood framing for at least the time of the finish rating of the membrane in a test involving wood framing. The fire rating of the entire assembly with the substituted member is assumed to be at least equal to the finish rating of the protective membrane in the test with the solid sawn wood framing. This approach is described as the *onset of char* method in New Zealand publications.⁹

In a Swedish additive method,¹⁰ the fire separation of nonloaded wall assemblies is calculated as the sum of the contribution to fire resistance from each layer of material:

$$b_{\text{tot}} = b_1k_1 + b_2k_2 + \dots = b_nk_n \quad (1)$$

where

b_{tot} = total fire resistance of the wall

b_n = basic fire resistance of layer n

k_n = coefficient of position indicating where the layer is located in relation to the fire

Direct Protection of Wood Members

The steel industry improves the fire endurance of steel members by directly covering them with fire-resistive panels or coatings. Currently, the marketing of fire-resistive coatings for use on wood is very limited or nonexistent. The fire-retardant coatings marketed for wood are only designed and recognized for use to reduce the spread of flames over a surface (flamespread).

Depending upon its thickness and durability under fire exposure, a coating may merely delay ignition of the wood for a few minutes or may provide an effective insulative layer that reduces the rate of charring. For both fire-retardant coatings and fire-resistive coatings, their performance as a fire-resistant membrane on wood has been evaluated.¹¹⁻¹³ In some full-scale testing of beams, those coated with an intumescent fire retardant produced improvements less than that obtained in earlier tests in a small-scale furnace.¹⁴ Bending of the beams during the fire test resulted in adhesion problems. Tests on coated timber members were also reported in Finland and U.S.S.R.¹⁵ There is limited published data on the protection provided by directly covering a wood member with gypsum board or other nonwood panel products. As previously noted, finish ratings listed for panel products used in ASTM E119 tests of assemblies have been used to estimate the delay in the onset of char formation

provided by the panel product. Gardner and Syme¹⁶ found that gypsum board not only delayed the onset of char formation but also reduced the subsequent rate of char formation. In their 2-hour tests, 13-mm- (1/2-in.-) thick gypsum board on wood beams reduced the depth of char by approximately 40 percent. Of the 40 percent, only 17 percent was credited to the initial delay in char formation.

Numerical Heat Transfer Models

The protective membrane contributes to fire resistance by providing thermal protection. Numerical heat transfer methodologies are available to evaluate this thermal protection. Fung¹⁷ developed a one-dimensional finite difference model and computer program for thermal analysis of construction walls. Gammon¹⁸ developed a two-dimensional finite element heat transfer model for wood stud wall assemblies. WALL2D, developed by Forintek Canada,^{19,20} is a two-dimensional finite-difference model for predicting heat transfer through wood-stud walls exposed to fire. Difficulties in modeling the charring of wood and the physical deterioration of the panel products complicate these numerical methodologies. Recent research on such models includes activities in Canada,²⁰ Sweden,²¹ New Zealand,^{22,23} and Australia.²⁴ An important application of such models is the determination of the fire endurance of an assembly when the time-temperature curve is a natural or parametric fire exposure. This application is important for performance-based building codes.

Numerical heat transfer models are used not only to model the performance of the protective membranes but also to model the charring of the structural wood members, the second major factor in the fire endurance of a wood member or assembly.

Charring of Wood

Wood undergoes thermal degradation (pyrolysis) when exposed to fire. (See Figure 4-11.2.) The pyrolysis and combustion of wood have been studied extensively. Literature reviews include publications by Browne,²⁵ Schaffer,^{26,27} Hall et al.,²⁸ and Hadvig.²⁹ By converting the wood to char and gas, pyrolysis results in a reduction in the wood's density. The pyrolysis gas undergoes flaming combustion as it leaves the charred wood surface. Glowing combustion and mechanical disintegration of the char eventually erode or ablate the outer char layer.

The charring rate generally refers to the linear rate at which wood is converted to char. Under standard fire exposure, the charring rates tend to be fairly constant after a higher initial charring rate.

Establishing the charring rate is critical to evaluating fire resistance, because char has virtually no load-bearing capacity. There is a distinct demarcation between char and uncharred wood. The base of the char layers is wood reaching a temperature of approximately 300°C (550°F). SI conversion of inch-pound units has resulted in 288°C, 290°C, and 300°C being used for 550°F. To determine the charring rate, we use both empirical models based on ex-

Figure 4-11.2. Degradation zones in a wood section.

perimental data and theoretical models based on chemical and physical principles.

Standard ASTM E119 Fire Exposure

Expressions for charring rate in the standard ASTM E119 test are the result of many experimental studies. The empirical model that is most generally used assumes a constant transverse-to-grain char rate of 0.6 mm/min. (1½ in./hr) for all woods, when subjected to the standard fire exposure. There are differences among species associated with their density, chemical composition, and permeability. In addition, the moisture content of the wood affects the charring rate. The charring rate parallel to the grain of wood is approximately twice that transverse to the grain.²⁸ As a beam or column chars, the corners become rounded. The rounding is generally considered to have a radius equivalent to the char depth on the sides.

Schaffer³⁰ reported transverse-to-grain charring rates as a function of density and moisture content for Douglas fir, southern pine, and white oak. The regression equations for B (min per mm., the reciprocal of charring rate) were

$$B = (0.002269 + 0.00457u)\rho + 0.331 \text{ for Douglas fir} \quad (2)$$

$$B = (0.000461 + 0.00095u)\rho + 1.016 \text{ for southern pine} \quad (3)$$

$$B = (0.001583 + 0.00318u)\rho + 0.594 \text{ for white oak} \quad (4)$$

where

u = moisture content (fraction of oven-dry mass)

ρ = density (dry mass, volume at moisture content u)

White³¹ developed an empirical model based on eight species. The char rate equation was of the form

$$t = mx_c^{1.23} \quad (5)$$

where

t = time (min)

m = char rate coefficient

x_c = char depth (mm)

The char rate coefficients ranged from 0.48 to 0.72 min/mm^{1.23} for the eight species.^{31,32} The char rate coefficient could be estimated with the equation

$$m = -0.147 + 0.000564\rho + 1.21u + 0.532f_c \quad (6)$$

where

ρ = oven-dry density (kg/m³)

u = moisture content (fraction of oven-dry mass)

f_c = char contraction factor (dimensionless)

The char contraction factor was the thickness of the char layer at the end of the fire exposure divided by the original thickness of the wood layer that was charred (char depth). Average values for the char contraction factor were 0.60 for southern pine, 0.83 for western red cedar, 0.86 for redwood, 0.82 for Engelmann spruce, 0.52 for basswood, 0.59 for hard maple, 0.70 for red oak, and 0.67 for yellow poplar. Recent char rate experiments have been reported in Australia,¹⁶ Europe,³³ and New Zealand.³⁴

In Eurocode 5,⁵ the linear charring rates listed are 0.64 mm/min for glued laminated softwood timber with a characteristic density of 290 kg/m³, 0.67 for solid softwood timber with a characteristic density of 290 kg/m³, and 0.54 mm/min for solid or glued laminated hardwood with a characteristic density of 350 kg/m³. The design values for charring rate depend on the fire endurance methodology being used. The effect of the rounding of the charred member can be taken into account by increasing the values for char rate as is done in Eurocode 5. Eurocode 5 design values for linear charring rate include 0.7 mm/min for glued laminated softwood timber with a characteristic density of 290 kg/m³, 0.8 for solid softwood timber with a characteristic density of 290 kg/m³; 0.5 mm/min for solid or glued laminated hardwood with a characteristic density of 450 kg/m³ and 0.7 mm/min for characteristic density of 290 kg/m³. Additional design values can be found in the Eurocode 5. Some of the charring rate values for density ρ_o are adjusted for other characteristic densities, ρ_k , with a coefficient, k_{ρ} , equal to $\sqrt{\rho_o/\rho_k}$ as a multiplier.⁵

Assumption of a constant charring rate is reasonable when the member or panel product is thick enough to be treated as a semi-infinite slab. For smaller dimensions, the charring rate increases once the temperature has risen above the initial temperature at the center of the member or at the unexposed surface of the panel.

Kanury and Holve³⁵ suggest the model

$$\frac{\ell}{t} \approx \left(\frac{2}{a}\right) \left(1 - \frac{b\ell}{a}\right) \quad (7)$$

where

ℓ = thickness of slab (mm)

t = fire endurance time (min)

a, b = constants

They consider the $2/a$ factor an ideal charring rate and the ratio $b\ell/a$ as a correction factor accounting for thickness and thermal diffusion effects.

Noren and Ostman³⁶ provided the equation

$$b_m = 1.128t + 0.0088t^2 \quad (8)$$

where

b_m = contribution to fire resistance (min)

t = panel thickness (mm)

The equation is based on data for various wood-based panel products. Differences in the fire resistance at equal thickness depended on panel density, moisture content, type of adhesive, and the structural composition of the panel. The effect of fire-retardant treatment and adhesives on fire resistance depends on the type of adhesive or treatment. Lumber bonded with phenolic or resorcinol adhesives has a charring rate consistent with that of solid wood. Fire-retardant treatments are designed to reduce flamespread. The fire retardant's effect on the charring rate may be to only slightly increase the time until ignition of the wood. Some fire retardants reduce flammability by lowering the temperature at which charring occurs. This may increase the charring rate. However, a few fire retardants have been found to improve charring resistance.³⁷

Nonstandard Fire Exposures

The above equations were stated to apply to the standard ASTM E119 fire exposure.¹ Data on charring rates for other fire exposures have been limited. Schaffer²² provided data for constant temperatures of 538°C (1000°F), 815°C (1500°F), and 927°C (1700°F). Lau and White³⁸ presented data for constant 500°C and an empirical model for constant or variable temperatures. The charring rate is a function of the external flux. For a range of 20 to 3300 kW/m², Butler³⁹ calculated the char rate (mm/min) to be 0.022 times the irradiance (kW/m²). Because of increased testing with heat release rate calorimeters, char rate data as a function of external heat flux are becoming more available.⁴⁰⁻⁴⁵ In tests of spruce, charring rates obtained were 0.56, 0.80, and 1.02 mm/min. for external heat fluxes of 25, 50, and 75 kW/m², respectively.⁴² In tests of southern pine, the linear charring rate ranged from 0.44 mm/min at 18 kW/m² to 0.85 mm/min at 55 kW/m².^{40,41} Charring rate has been found to be proportional to the ratio of external heat flux over density.^{42,44}

Hadvig's Equations for Nonstandard Fire Exposure

Hadvig²⁹ has developed equations for nonstandard fire exposure. The charring rate in a real fire depends

upon the severity of the fire to which the wood is exposed. The fire severity depends upon such factors as the available combustible material (fire load) and the available air supply (design opening factor).

The design fire load is

$$q = k \cdot \frac{Q}{A_t} \tag{9}$$

where

- q = design fire load (MJ/m²)
- k = transfer coefficient (dimensionless)
- Q = sum of the products of mass and lower calorific value of materials to be found in the compartment (MJ)
- A_t = total internal area of the compartment, including floor, walls, ceiling, windows, and doors (m²)

The transfer coefficients are given in Table 4-11.3 for different types of compartments and geometrical opening factors. In the case of fire compartments whose bounding structures do not come under any of the types A-H, k is usually determined by a linear interpolation in the table between appropriately chosen types of compartments.

The geometrical opening factor is

$$F' = \frac{A\sqrt{h}}{A_t} \tag{10}$$

where

Table 4-11.3 The Transfer Coefficient, $k^{29,46}$

Type of Fire Compartment ^a	Geometrical Opening Factor, F'					
	0.02	0.04	0.06	0.08	0.10	0.12
A	1.0	1.0	1.0	1.0	1.0	1.0
B	0.85	0.85	0.85	0.85	0.85	0.85
C	3.0	3.0	3.0	3.0	3.0	2.5
D	1.35	1.35	1.35	1.50	1.55	1.65
E	1.65	1.50	1.35	1.50	1.75	2.00
F ^b	1.0-0.5	1.0-0.5	0.8-0.5	0.7-0.5	0.7-0.5	0.7-0.5
G	1.50	1.45	1.35	1.25	1.15	1.05
H	3.0	3.0	3.0	3.0	3.0	2.5

^aA = (Standard fire compartment) The average consisting of brick, concrete, and gas concrete.

B = Concrete, including concrete on the ground

C = Gas concrete (density 500 kg/m³)

D = 50 percent concrete, 50 percent gas concrete (density 500 kg/m³)

E = 50 percent gas concrete (density 500 kg/m³), 33 percent concrete, and 17 percent laminate consisting of (taken from the inside) 13-mm plasterboard (density 500 kg/m³), 10-cm mineral wool (density 50 kg/m³), and brick (density 1800 kg/m³)

F = 80 percent steel plate, 20 percent concrete. The fire compartment is comparable to a storehouse or other building of a similar kind with an uninsulated roof, walls of steel plate, and floor of concrete.

G = 20 percent concrete and 80 percent laminate consisting of a double plasterboard (2 × 13 mm) (density 790 kg/m³), 10-cm air space, and another double plasterboard (2 × 13 mm) (density 790 kg/m³)

H = Steel plate on either side of 100-mm mineral wool (density 50 kg/m³)

^bThe higher values apply to $q < 60$ MJ/m²; the lower values apply to $q > 500$ MJ/m². Intervening values are found by interpolation.

F' = geometrical opening factor (m^{1/2})

A = total area of windows, doors, and other openings in walls (i.e., vertical openings only) (m²)

h = weighted mean value of the height of vertical openings, weighted against the area of the individual openings (m)

The design opening factor is

$$F = F' \cdot k \cdot f \tag{11}$$

where

- F = design opening factor (m^{1/2})
- F' = geometrical opening factor (m^{1/2})
- k = transfer coefficient of bounding structure (dimensionless)
- f = coefficient (dimensionless) to account for horizontal openings

The dimensionless coefficient, f , (Figures 4-11.3 and 4-11.4) increases the opening factors when there are horizontal openings. For only vertical openings, f is equal to 1. Hadvig's²⁹ equations are

$$\theta = 0.0175 \frac{q}{F} \tag{12}$$

$$\beta_0 = 1.25 - \frac{0.035}{F + 0.021} \quad \text{for } 0.02 \leq F \leq 0.30 \tag{13}$$

$$X = \beta_0 \cdot \tau \quad \text{for } 0 \leq \tau \leq \frac{\theta}{3} \tag{14}$$

$$X = \beta_0 \left(-\frac{1}{12} \theta + \frac{3}{2} \tau - \frac{3}{4} \frac{\tau^2}{\theta} \right) \quad \text{for } \frac{\theta}{3} \leq \tau \leq \theta \tag{15}$$

where

- θ = time at which maximum charring is reached for the values used for F and q (min)
- β_0 = initial value of rate of charring (mm/min)
- X = charring depth (mm)
- F = design opening factor (m^{1/2}) (defined in Equation 11)
- q = design fire load (MJ/m²) (defined in Equation 9)
- τ = time (min)

These equations are valid for fire exposures less than 120 min. and for a room where the combustible material is wood. Plastic burns more intensely and for a shorter time than wood. When the combustible materials in the room are plastics, Equations 12 and 13 are therefore modified for faster char rate (β_0 is 50 percent higher), shorter time is allowed for maximum charring (θ is cut in half), and Equation 14 is applicable for $\tau < \theta$.²⁹

Equations 12 through 15 are for glued timber with a density of 470 kg/m³ including a moisture content of 10 percent and minimum width of 80 mm or greater or square members of minimum 50 × 50 mm. Equations 14 and 15 are valid only for $0 < X < b/4$, where b is the dimension of the narrow face of a rectangular member. For

Figure 4-11.3. Diagram for the determination of f for fire temperatures of 500°C and 1000°C.

Figure 4-11.4. Simplified sketch of vertical cross section of ventilated compartment with notation.²⁰

dimensions of nonsquare cross sections between 30 and 80 mm, the ratio of the original dimensions must be equal to or greater than 1.7, the charring depth perpendicular to the wide face is X , and the charring depth perpendicular to the narrow face is determined by multiplying Equation 14 or 15 by the dimensionless quantity

$$1.35 - 0.0044(b) \quad (16)$$

where b equals the dimension of the narrow face (mm).

EXAMPLE 2:

The room is a standard fire compartment consisting of brick, concrete, and gas concrete. The floor area is 5×10 m, and the height is 3 m. The openings are one win-

dow 1.5 m high and 2 m wide, three windows 1.5 m high and 1 m wide, and one skylight 1.5 m \times 3 m. The skylight is 2 m above the midheight of the windows. The fire load is 6 m^3 of wood.

Assuming a fire temperature of 1000°C, a wood density of 500 kg/m^3 , and lower calorific value of 17 MJ/kg , describe the charring of a 38×250 -mm wood beam exposed on three sides after 8 min of the fire.

The geometrical opening factor (Equation 10) is

$$F' = \frac{A\sqrt{h}}{A_t} = \frac{[1(1.5 \times 2) + 3(1.5 \times 1)]\sqrt{1.5}}{[2(5 \times 10) + 2(3 \times 5) + 2(3 \times 10)]}$$

$$= \frac{7.5\sqrt{1.5}}{190} = 0.048 \text{ m}^{1/2}$$

The design opening factor (Equation 11) is

$$F = F' \cdot k \cdot f$$

The k is obtained from Table 4-11.3 ($k = 1.0$ for type A, $F' = 0.048$). The f is obtained from Figures 4-11.3 and 4-11.4.

$$\frac{A_h\sqrt{h_1}}{A\sqrt{h}} = \frac{(1.5 \times 3)\sqrt{2}}{7.5\sqrt{1.5}} = \frac{4.5\sqrt{2}}{7.5\sqrt{1.5}} = 0.69$$

$$\frac{A_h}{A} = \frac{4.5}{7.5} = 0.6$$

For $A_h\sqrt{h_1}/A\sqrt{h}$ of 0.69 and A_h/A of 0.6, the f from Figure 4-11.3 is 2.4.

$$F = (0.048)(1.0)(2.4) = 0.115 \text{ m}^{1/2}$$

The design fire load (Equation 9) is

$$q = k \cdot \frac{Q}{A_t} = (1.0) \frac{(6 \times 500 \times 17)}{190} = \frac{51,000}{190} = 268 \text{ MJ/m}^2$$

Maximum charring rate will be reached at θ min (Equation 12)

$$\theta = 0.0175 \frac{268 \text{ MJ/m}^2}{0.115 \text{ m}^{1/2}} = 41 \text{ min}$$

The initial charring rate (Equation 13) will be

$$\beta_0 = 1.25 - \frac{0.035}{0.115 + 0.021} = 1 \text{ mm/min}$$

At 8 min, the char depth (Equation 14) will be

$$X = 1 \times 8 = 8 \text{ mm} \quad \text{for } 0 \leq 8 \leq \frac{41}{3}$$

The smaller dimension b of the beam is 38 mm. The charring depth criterion $0 < x < b/4$ is $0 < 8 < 9.5$ mm, so Equations 14 and 15 are valid. The ratio of the original dimensions is $25/3.8$ or 6.6. Since 38 mm is less than 80 mm, the multiplying factor (Equation 16) is

$$1.35 - 0.0044(38) = 1.18$$

At 8 min, the uncharred area of the beam will be approximately

$$38 \text{ mm} - 2(8 \text{ mm}) = 22 \text{ mm wide}$$

and

$$250 \text{ mm} - (1.18 \times 8 \text{ mm}) = 240 \text{ mm high}$$

As the charring proceeds after (9.5 mm)/(1 mm/min) or 9.5 min, the $b/4$ criterion of the equations no longer holds. This is because the charring rate increases as the temperature at the center of the beam starts to increase.

Equations for parametric fires are also provided in Eurocode 5. The approach is a simplification of Hadvig's equations. For a period τ_0 , the parametric charring rate is

$$\beta_{\text{par}} = 1.5\beta_0 \frac{5F - 0.04}{4F + 0.08} \quad (17)$$

where

$F = F'$ of Equation 10

$\beta_0 =$ design charring rate of Eurocode 5

The time period τ_0 is

$$\tau_0 = 0.006 \frac{q}{F} \quad (18)$$

where q is the total design load of Equation 9.

At τ_0 , the char rate decreases to zero at $3\tau_0$. The maximum charring depth during the fire exposure and the subsequent cooling period is $2\beta_0\tau_0$. Equations are valid for F between 0.02 and 0.30 $\text{m}^{1/2}$, τ_0 of 40 min or less, and char depths less than one quarter of the dimensions. Oleson and König⁴⁷ tested glued-laminated beams and found agreement with Hadvig's equations for the wide vertical side of a member. Oleson and König⁴⁷ noted that, compared to conditions at standard exposure, the mechanical behavior at natural fire exposure is different due to the changes of temperature in the residual cross section during the cooling period. The influence of elevated temperature is no longer concentrated to the outer layer of the residual cross section.

For situations for which no empirical models exist, solutions may be found by the use of theoretical models. Most theoretical models have the flexibility to be used for any desired fire exposures.

Theoretical Models

Considerable efforts have gone into developing theoretical models for wood charring. Theoretical models allow calculation of the charring rate for geometries other than a semi-infinite slab and for nonstandard fire exposures. Roberts⁴⁸ reviewed the problems associated with the theoretical analysis of the burning of wood, including structural effects and internal heat transfer, kinetics of the pyrolysis reactions, heat of reaction of the pyrolysis reactions, and variations of thermal properties during pyrolysis. He considered the major problems to be in the formulation of a mathematical model for the complex chemical and physical processes occurring and in the acquisition of reliable data for use in the model.

Many models for wood charring are based on the standard conservation of energy equation. The basic differential equation includes a term for each contribution to the internal energy balance. An early model for wood charring was given by Bamford et al.⁴⁹ The basic differential equation used by Bamford was

$$c\rho \frac{\partial T}{\partial t} = K \frac{\partial^2 T}{\partial X^2} - q \frac{\partial w}{\partial t} \quad (19)$$

where

$K =$ thermal conductivity

$T =$ temperature ($^{\circ}\text{C}$)

$X =$ location

$w =$ weight of volatile products per cubic centimeter of wood

$t =$ time

$q =$ heat liberated at constant pressure per gram of volatile material evolved

$c =$ specific heat

$\rho =$ density

In Equation 19, the term on the left side of the equal sign represents the energy stored at a given location as indicated by the increase or decrease of the temperature with time at that location. The first term on the right side of the equal sign represents the thermal conduction of energy away from or into the given location. The second term on the left side represents the energy absorbed (endothermic reaction) or the energy given off (exothermic reaction) as the wood undergoes pyrolysis or thermal degradation. Numerical solutions using computers are normally used to solve these differential equations.

In Bamford's calculations using Equation 19, the rate of decomposition was given by an Arrhenius equation. The heat of decomposition, q , was the difference between the heat of combustion of the wood and that of the products of decomposition. Thermal constants for wood and char were assumed to be the same, and the total thickness of char and wood was assumed to remain constant.

Thomas⁵⁰ added a convection term to Bamford's equation to obtain

$$\rho c \frac{\partial T}{\partial t} = K \frac{\partial^2 T}{\partial X^2} + M c_g \frac{\partial T}{\partial X} - q \frac{\partial w}{\partial t} \quad (20)$$

where

$M =$ local mass flow of pyrolysis gases

$c_g =$ specific heat of the gases

The convection term represents the energy transferred in or out of a location due to convection of the pyrolysis gases through a region with a temperature gradient.

The Factory Mutual Research Corporation model (SPYVAP) includes terms for internal convection of volatiles and thermal properties as functions of temperature and density. It was developed by Kung⁵¹ and later revised by Tamanini.⁵² Atreya⁵³ has further revised this model to include moisture absorption. His energy conservation equation is

$$\begin{aligned}
(\rho_a C_{pa} + \rho_c C_{pc} + \rho_m C_{pm}) \frac{\partial T}{\partial t} &= \frac{\partial}{\partial X} \left(K \frac{\partial T}{\partial X} \right) + i \left(1 - j \frac{\rho_c}{\rho_f} \right) \cdot \\
M_g \frac{\partial H_g}{\partial X} - \frac{\partial \rho_s}{\partial t} \left[-Q + \left(H_a - H_c \frac{\rho_f}{\rho_w} \right) / \left(1 - \frac{\rho_s}{\rho_w} \right) - H_g \right] & \\
- \frac{\partial \rho_m}{\partial t} (-Q_m + H_m - H_g) & \quad (21)
\end{aligned}$$

where

- C_p = specific heat [J/(kgK)]
- K = thermal conductivity [W/(m K)]
- T = temperature (K)
- t = time (s)
- X = distance (m)
- ρ = density (kg/m³)
- M_g = outward mass flux of volatile gases (kg/m²s)
- H = thermal-sensible specific enthalpy (J/kg)
- Q = endothermic heat of decomposition of wood for a unit mass of volatiles generated (J/kg at T_∞)
- i, j = parameters to simulate cracking, between 0 and 1

Subscripts:

- ∞ = ambient
- w = virgin wood
- c = char
- g = volatile gases
- a = unpyrolyzed active material
- m = moisture
- f = final value
- s = solid wood

Equation 21 is similar to the previous equations except the material has been broken up into its components (wood, water, and char). The parameter j eliminates the convection term if the pyrolysis gases are escaping through cracks or fissures in the wood. The last term represents the heat absorbed with vaporization of the water. The conservation of mass equation is

$$\frac{\partial M_g}{\partial X} = \frac{\partial \rho_s}{\partial t} + \frac{\partial \rho_m}{\partial t} \quad (22)$$

and ensures that the mass of the gases equals the mass loss due to thermal degradation of the wood and vaporization of the moisture.

As noted before, the decomposition kinetics equation for wood is the Arrhenius equation

$$\frac{\partial \rho_s}{\partial t} = -A \frac{(\rho_s - \rho_f)}{(1 - \rho_f/\rho_w)} \exp(-E/RT) \quad (23)$$

where

- A = frequency factor (1/s)
- E = activation energy (J/mole)
- R = gas constant

Atreya⁵³ uses a moisture desorption kinetics equation for vaporization of the water in the wood, which is

$$\frac{\partial \rho_m}{\partial t} = -A_m \rho_m \exp(-E_m/RT) \quad (24)$$

The CMA model⁵⁴ developed for NASA provides good results for oven-dry wood because it includes surface recession. Parker⁵⁵ has taken char shrinkage parallel and normal to the surface into account in the model. Parker also includes different Arrhenius equations for each of the three major components of wood: (1) cellulose, (2) hemicelluloses, and (3) lignin. There may be not only moisture desorption but also an increase in moisture content behind the char front caused by moisture movement away from the surface.⁵⁶ A model of Fredlund⁵⁷ includes mass transfer as well as heat transfer and provides for surface recession due to char oxidation. In a model for wood combustion, Bryden⁵⁸ modeled the wood pyrolysis kinetics, including tar decomposition, using three competing primary reactions and two secondary reactions. The surface boundary layer includes both char shrinkage and surface recession due to char combustion.

Kanury and Holve³⁵ have presented dimensional, phenomenological, approximate analytical, and exact numerical solutions for wood charring. Other models include those of Havens,⁵⁹ Knudson and Schniewind,⁶⁰ Kansa et al.,⁶¹ Hadvig and Paulsen,⁶² and Tinney.⁶³

A major issue in the use of the more sophisticated models is the adequacy of the available data to use as input. The thermophysical properties for wood pyrolysis models are discussed by Janssens.⁶⁴ While primarily for zone models, there is an ASTM Standard Guide for Data for Fire Models.⁶⁵ Wood properties are discussed at the conclusion of this chapter.

Most theoretical models for wood charring not only define the charring rate but also provide results for the temperature gradient. This temperature gradient is important in evaluating the load-carrying capacity of the wood remaining uncharred.

Load-Carrying Capacity of Uncharred Wood

In the standard ASTM E119 test of a wood member, structural failure occurs when the member is no longer capable of supporting its design load. The charring of the wood has reduced the cross-sectional area of the member such that the ultimate capacity of the residual member is exceeded. During the charring of the wood member, the temperature gradient is steep in the wood section remaining uncharred. The temperature at the innermost zone of the char layer is assumed to be 300°C. Because of the low thermal conductivity of wood, the temperature 6 mm inward from the base of the char layer is about 180°C once a quasi-steady-state charring rate has been obtained. Some loss of strength undoubtedly results from elevated temperatures. The peak moisture content occurs where the temperature of the wood is about 100°C, which is about 13 mm from the char base. Schaffer et al.⁶⁶ have combined parallel-to-grain strength and stiffness relationships with temperature and moisture content and the gradients of

temperature and moisture content within a fire-exposed slab to obtain graphs of relative modulus of elasticity, compressive strength, and tensile strength as a function of distance below the char layer. (See Figure 4-11.5.) The temperature profile in a semi-infinite wood slab can be expressed as an exponential term or a power term.⁶⁷ An equation based on a power term is

$$T = T_i + (300 - T_i) \left(1 - \frac{x}{d}\right)^2 \quad (25)$$

where

T = temperature (°C)

T_i = initial temperature (°C)

x = distance from the char front (mm)

d = thermal penetration depth (mm)

In the tests of White,³¹ an average value for the thermal penetration depth was 33.⁶⁷ Based on European tests, a more conservative value of 40 was recommended for the thermal penetration depth.⁶⁷ The power term does not provide for the plateau in temperatures that often occurs at 100°C in moist wood. The power term has also been used to estimate the temperature profile in wood exposed to a constant heat flux.⁴¹ The theoretical models discussed previously can be used to determine the temperature gradient within the wood remaining uncharred.

There are two approaches to evaluating the load-carrying capacity: to evaluate the remaining section either as a single homogeneous material or as a composite of layers

Figure 4-11.5. Relative modulus of elasticity and compressive and tensile strength as a function of distance below char layer in softwood section under fire exposures. (Expressed in percent of that at 25°C and initial moisture content of 12 percent). Duration of fire exposure should be equal to or greater than 20 min to apply results of this figure.

or elements with different properties. In the single homogeneous material approach, one uses either reduced material properties or the room temperature material properties. A greater reduction in cross sectional area is calculated if the material properties are not reduced.

Empirical α Models

One common approach in accounting for the loss in strength in the section remaining uncharred is to assume that the strength and stiffness of the entire uncharred region are fractions α of their room temperature values.

For bending rupture of a beam, an equation of this type would be

$$\frac{M}{S(t)} = \alpha \sigma_0 \quad (26)$$

where

M = applied moment (design load)

S = section modulus of charred member

σ_0 = modulus of rupture at room temperature

t = time

Assuming the residual cross-section is rectangular in shape before and during fire exposure, the section modulus of the charred member is⁶⁸

$$S(t) = \frac{1}{6} [(B - 2C_1t)(D - jC_2t)^2] \quad (27)$$

where

B = original breadth of beam

D = original depth of beam

C_1 = charring rate in breadth direction

C_2 = charring rate in depth direction

$j = 1$ for three-sided fire exposure or 2 for four-sided fire exposure (Figure 4-11.6)

Alternative to Equations 22 and 23 are the following, Equations 28 through 30:

$$\frac{k}{\alpha} \frac{B/D}{[d/D - (1 - B/D)]} = \left(\frac{d}{D}\right)^2 \quad (28)$$

for exposure on all four sides,⁶⁹ and

$$\frac{k}{\alpha} \frac{B/D}{[B/D - 2(1 - d/D)]} = \left(\frac{d}{D}\right)^2 \quad (29)$$

for exposure on three sides,^{70,71}

where

k = load, as fraction of room temperature ultimate load of original member

d = critical depth of the uncharred beam

The fire resistance is equal to the time to reach the critical depth, or

$$t = (D - d)/jC \quad (30)$$

Figure 4-11.6. Fire exposure of beams on three or four sides.

Proposed α values ranged from 0.5 in New Zealand to 0.83 in France.⁶⁸ The differences in α values are due to uncertainty, differences in design load, and desired level of safety. The application of the above equations is generally limited to large wood members. In light-frame members, α values would be substantially lower.⁷² In Eurocode 5, this approach is called the “reduced strength and stiffness method.” The reduction factors are a function of the perimeter of the fire-exposed residual cross section divided by the area of the cross section.

In addition to bending rupture, the fire resistance of a beam may depend on lateral buckling of the beam.⁶⁹ Similar expressions can be developed for columns and tension members.^{68,70-71,73} Reviews of fire resistance design methodologies for large wood members include those of Schaffer,⁶⁸ Pettersson,⁷⁴ and Barthelemy and Kruppa.⁷⁵ Kirpichenkov and Romanenkov⁷⁶ discussed the calculation procedures in the Soviet Union. The fire resistance of wood structures is also briefly discussed by Odeen.⁷⁷

In developing a model for fire-exposed unprotected wood joist floor assemblies, Woeste and Schaffer^{78,79} evaluated various time-dependent geometric terms that could be used to modify the strength reduction factor, α . The selected term was

$$\alpha = \frac{1}{1 + (B + 2D/BD)\gamma t_f} \quad (31)$$

where

t_f = failure time

γ = empirical thermal degrade parameter

The model has been experimentally evaluated,^{80,81} extended to floor-truss assemblies,^{79,82} and used as part of a first-order second-moment reliability analysis of floor assemblies.^{78,79} Reliability-based design of the fire endurance of light-frame construction is also discussed by Lau and Barrett.⁷² In a model for metal plate-connected wood trusses,⁸³ the strength degradation factors for the wood

are calculated as a function of the duration of exposure and the temperature profile within the wood component.

Effective Cross-Sectional Area Method

For a second approach, an equivalent zero-strength layer, δ , was calculated and the rest of the member is evaluated using room temperature property values. In the model of Schaffer and others⁶⁶ for beams, the δ was estimated to be 8 mm (0.3 in. thick). This zero-strength layer, δ , was added to the char depth, βt , to obtain the total zero-strength layer. This zero-strength layer model was incorporated within a reliability-based model to predict the strength of glued-laminated beams with individual laminates of various grades of lumber.⁸⁴ This zero-strength layer approach is called the “effective cross-section method” in Eurocode 5. In Eurocode 5, δ is 7 mm after 2 min (linear fraction of 7 mm up to 20 min). In Technical Report 10 of the American Wood Council,⁸⁵ a 20 percent increase in the charring rate is used.

Performance of the structural member in a fire will depend on the ratio of the applied load to the ultimate capacity of the residual member. Calculations of the structural capacity of the remaining cross section are normally made using ultimate strength values. Information on obtaining estimates for average ultimate values from allowable design values can be found in Technical Report 10. Examples of the structural calculations and load ratio tables are also provided. Design or characteristic strength values are used in the Eurocode 5 calculations. Design methods account for the various factors affecting performance in different manners. Care must be taken to ensure that all the design values and the methodologies are compatible.

For fire-damaged members, Williamson⁸⁶ recommended δ of 6 mm (0.25 in.) for designs controlled by compression (16 mm [0.625 in.] if design is controlled by tension) and the use of 100 percent of the original allowable stresses in calculation of load capacity.

Composite Models

The most complex approach to evaluating the fire endurance of a wood member is to assume that the uncharred region consists of layers or elements at different temperatures and moisture contents. The strength and stiffness properties are dependent on the temperature and moisture content profiles. These are referred to as *general calculation methods* in Eurocode 5. In one model with layers, the compressive and tensile strengths and modulus of elasticity of each layer are assumed to be fractions of the room temperature values. Using one 38-mm (1.5-in.) heated layer with reduced properties, Schaffer et al.⁶⁶ analyzed a beam using transformed section analysis. In the similar elastic transformed section model of King and Glowinski,⁸⁷ the heated zone of the remaining wood section is divided into two layers at elevated temperatures. Transformed section analysis is also used by Lee-Gun Kim and Jun-Jae Lee⁸⁸ and by Janssens.⁸⁹ A finite difference model for wood beams and columns was developed by Tavakkol-Khah and Klingsch.⁹⁰

Do and Springer⁹¹⁻⁹³ proposed a fire resistance model for wood beams based on mass loss versus strength data.

The work included a program to predict the temperatures and mass loss within the wood member. The input data came from small-scale tension, compression, and shear tests done on specimens that had previously been heated in a muffle oven.

One-Hour Fire-Resistive Exposed Wood Members

Lie⁷⁰ developed simple formulas for calculating the fire resistance of large wood beams and columns based on theoretical studies involving experimental data and equations similar to Equations 26 through 30. These formulas are recognized by the building codes in the United States and Canada. The methodology is discussed in wood industry publications.^{94,95} These formulas give the fire resistance time, t , in minutes, of a wood beam or column with minimum nominal dimension of 152 mm (6 in.). The net finish width for a nominal 152-mm (6-in.) glued-laminated member is 130 mm (5 1/8 inches).

For beams, the equations are

$$t = 2.54ZB \left[4 - 2\left(\frac{B}{D}\right) \right] \quad \text{for fire exposure on four sides} \quad (32)$$

$$t = 2.54ZB \left[4 - \left(\frac{B}{D}\right) \right] \quad \text{for fire exposure on three sides} \quad (33)$$

where

B = width (breadth) of a beam before exposure to fire (in.)

D = depth of a beam before exposure to fire (in.)

Z = load factor (See Figure 4-11.7.)

For columns, the equations are

$$t = 2.54ZD \left[3 - \left(\frac{D}{B}\right) \right] \quad \text{for fire exposure on four sides} \quad (34)$$

$$t = 2.54ZD \left[3 - \left(\frac{D}{2B}\right) \right] \quad \text{for fire exposure on three sides} \quad (35)$$

where

B = larger side of a column (in.)

D = smaller side of a column (in.)

The $2.54Z$ factor in the above equations is $0.10Z$ for SI units of mm. For columns, the load factor, Z (see Figure 4-11.7) includes the effect of the effective length factor, K_e , (see Figure 4-11.8) and the unsupported length of the column, ℓ . Currently, the codes do not permit the wide side of the column to be the unexposed face (Equation 34). The full dimensions of the column are used even if the column is recessed into a wall.

Connectors and fasteners relating to support of the member must be protected for equivalent fire-resistive construction. Where minimal 1-hr fire endurance is required, connectors and fasteners must be protected from fire exposure by 38 mm (1 1/2 in.) of wood, appropriate

Figure 4-11.7. Load factor versus load on member as percent of allowable. (NBCC uses 12 instead of 11 as criterion for two curves.) Effective column length, ℓ_e , is equal to $K_e \ell$ (Fig. 4-11.8) and d is cross-sectional dimension in plane of lateral support.

thickness of fire rated gypsum board, or any coating approved for a 1-hr rating. The American Forest & Paper Association publication⁹⁴ on the procedure includes diagrams giving typical details of such protection. Carling⁹⁶ summarized work done in Europe on the fire resistance of joint details in load-bearing wood construction. Eurocode 5 also includes information on calculating the fire endurance of connections and protecting connections in fire-rated timber members.

There is often a high-strength tension laminate on the bottom of glued-laminated timber beams. As a result, it is required that a core lamination be removed, the tension zone moved inward, and the equivalent of an extra nominal 51-mm- (2-in.-) thick outer tension lamination be added to ensure that there is still a high-strength laminate left after fire exposure.

EXAMPLE 3:

Determine the fire resistance rating for a 5 1/8-in. × 21-in. (130-mm × 533-mm) beam exposed to fire on three sides and loaded to 75 percent of its allowable load.

$$D = 21 \text{ in.}$$

$$B = 5.125 \text{ in.}$$

From Figure 4-11.7, Z for beam loaded to 75 percent of allowable is 1.1. From Equation 33,

$$t = 2.54(1.1)(5.125)[4 - (5.125/21)]$$

$$t = 53.8 \text{ min}$$

The methodology of this section has building code recognition in the United States and Canada but is only applic-

Figure 4-11.8. *Effective column length.*

able to large wood beams and columns. There is no recognized procedure for solid wood floors or roofs. Possible methodologies for the structural analysis of these timber decks can be found in Technical Report 10,⁸⁵ in an article by Janssens,⁸⁹ and in Eurocode 5. A methodology for estimating the times for thermal failure is in Eurocode 5. The method is based on the design charring rates and a reduction coefficient for the joints in the timber decks.⁸⁹

Property Data

Proper input data are critical to the use of any model. For the models discussed in this section, property data include strength and stiffness properties and thermal properties. Property data for wood can be found in the various chapters of *Wood Handbook: Wood as an Engineering Material*³² (available as pdf files from www.fpl.fs.fed.us). A chapter on fire safety is also in the *Wood Handbook*. Equations and graphs of the strength and stiffness of wood as functions of temperature and moisture content are available.⁹⁷⁻⁹⁹ Recent research in the development of fire endurance models has provided additional data specific for application to such models. An extensive study on fire-exposed wood in tension was done by Lau and Barrett.¹⁰⁰ Thermal properties can also be found in the various references for charring models, Annex E of Eurocode 5, and in other sources.^{64,65,101}

While it is often less complicated to assume constant property values, these properties are very often a function of other properties or factors. Most wood properties are functions of density, moisture content, grain orientation,

and temperature. Chemical composition may also be a factor. Since an understanding of these factors is important to the application of property data, the factors are defined in the rest of this section.

The oven-dry density of wood can range from 160 kg/m³ (10 lb/ft³) to over 1040 kg/m³ (65 lb/ft³), but most species are in the 320 to 720 kg/m³ (20 to 45 lb/ft³) range.³² The density of wood relative to the density of water (i.e., specific gravity) is normally based on the oven-dry weight and the volume at some specified moisture content, but in some cases the oven-dry volume is used. As the empirical equations for charring rate show, the materials with higher density have slower char rate.

Wood is a hygroscopic material, which gains or loses moisture depending upon the temperature and relative humidity of the surrounding air. Moisture content of wood is defined as the weight of water in wood divided by the weight of oven-dry wood. Green wood can have moisture content in excess of 100 percent. However, air-dry wood comes to equilibrium at moisture content less than 30 percent. Thirty percent moisture content is also considered the approximate moisture content at which the cell walls are saturated with water but there is no water in the cell lumens. This condition is known as the *fiber saturation point*. At higher moisture contents, water exists in the cell lumens. Many physical and mechanical properties of wood only change with moisture content at moisture contents below the fiber saturation point. Under the conditions stated in ASTM E119 (23°C, 50 percent relative humidity), the equilibrium moisture content is 9 percent. Moisture generally reduces the strength of wood but also reduces the charring rate.

Both density and moisture content affect the thermal conductivity of wood. The average thermal conductivity perpendicular to the grain is³²

$$k = S(0.0001941 + 0.000004064M) + 0.01864 \quad (36)$$

where

k = thermal conductivity (W/m·K)

S = density based on volume at current moisture content and oven-dry weight (kg/m³)

M = moisture content (percent)

The above equation is valid for moisture contents of 25 percent or less, densities greater than 300 kg/m³, and temperature of 24°C. Conductivity increases about 2 to 3 percent per 10°C.³²

The fiber (grain) orientation is important because wood is an orthotropic material. The longitudinal axis is parallel to the fiber or grain. The two transverse directions (perpendicular to the grain) are the radial and tangential axes. The radial axis is normal to the growth rings, and the tangential axis is tangent to the growth rings. For example, the longitudinal strength properties are usually about 10 times the transverse properties, and the longitudinal thermal conductivity is 1.5 to 2.8 times the transverse property.

In fire-resistance analysis, temperature can have a significant influence on the properties of wood. The preponderance of property data is often limited to temperatures below 100°C. The effect of temperatures on the strength properties of wood is shown in Figures 4-11.9 through 4-11.11. The heat capacity, c_p , (kJ/kg·K) of dry wood is approximately related to temperature, t , in K by³²

$$c_p = 0.1031 + 0.003867t \quad (37)$$

Figure 4-11.9. The immediate effect of temperature on modulus of elasticity parallel to the grain at two moisture contents relative to value at 20°C. The plot is a composite of results from several studies. Variability in reported trends is illustrated by the width of bands.³²

Figure 4-11.10. The immediate effect of temperature on modulus of rupture in bending at three moisture contents relative to value at 20°C.³²

Figure 4-11.11. The immediate effect of temperature on compressive strength parallel to the grain at two moisture contents relative to the value at 20°C.

For moist wood below the fiber saturation point, the heat capacity is the sum of the heat capacity of dry wood and that of water and an additional adjustment factor for the wood–water bond.³²

The major components of wood are cellulose, lignin, hemicelluloses, extractives, and inorganic materials (ash). Softwoods have lignin contents of 23 to 33 percent, while hardwoods have only 16 to 25 percent. The types and amounts of extractives vary. Cellulose content is generally around 50 percent by weight. The component sugars of the hemicelluloses are different for the hardwood and softwood species. Chemical composition can affect the kinetics of pyrolysis (Equation 23) and the percentage weight of the residual char. In the degradation of wood, higher lignin content results in greater char yield.

CHAPTER 12

Smoke Control

John H. Klote

Introduction

In building fires, smoke often flows to locations remote from the fire, threatening life and damaging property. Stairwells and elevators frequently become smoke-logged, thereby blocking and/or inhibiting evacuation. Today smoke is recognized as the major killer in fires.¹

In the late 1960s, the idea of using pressurization to prevent smoke infiltration of stairwells started to attract attention. This was followed by the idea of the “pressure sandwich,” that is, venting or exhausting the fire floor and pressurizing the surrounding floors. Frequently, the building’s ventilation system is used for this purpose. The term *smoke control* was coined as a name for such systems that use pressurization produced by mechanical fans to limit smoke movement in fires.

Research in the field of smoke control has been conducted in Australia, Canada, England, France, Japan, the United States, and West Germany. This research has consisted of field tests, full-scale fire tests, and computer simulations. Many buildings have been built with smoke control systems and numerous others have been retrofitted for smoke control.

In this chapter the term *smoke* is defined in accordance with the American Society for Testing and Materials (ASTM)² and the National Fire Protection Association (NFPA)³ definitions that state that smoke consists of the airborne solid and liquid particulates and gases evolved when a material undergoes pyrolysis of combustion.

Smoke Movement

A smoke control system must be designed so that it is not overpowered by the driving forces that cause smoke movement. For this reason, an understanding of the fundamental concepts of smoke movement and of smoke control is a prerequisite to intelligent smoke control design.

The major driving forces causing smoke movement are stack effect, buoyancy, expansion, wind, and the heating, ventilating, and air conditioning (HVAC) system. Generally, in a fire, smoke movement will be caused by a combination of these driving forces. The following subsections are a discussion of each driving force as it would act independent of the presence of any other driving force.

Stack Effect

When it is cold outside, there is often an upward movement of air within building shafts such as stairwells, elevator shafts, dumbwaiter shafts, mechanical shafts, or mail chutes. This phenomenon is referred to as a *normal stack effect*. The air in the building has a buoyant force because it is warmer and less dense than the outside air. This buoyant force causes air to rise within the shafts of buildings. The significance of normal stack effect is greater for low outside temperatures and for tall shafts. However, normal stack effect can exist in a one-story building.

When the outside air is warmer than the building air, a downward airflow frequently exists in shafts. This downward airflow is called reverse stack effect. At standard atmospheric pressure, the pressure difference due to either normal or reverse stack effect is expressed as

$$\Delta P = K_s \left(\frac{1}{T_0} - \frac{1}{T_1} \right) h \quad (1)$$

where

ΔP = pressure difference (in. H₂O [Pa])

T_0 = absolute temperature of outside air (R [K])*

T_1 = absolute temperature of air inside shaft (R [K])*

*Because the Fahrenheit and Celsius temperature scales are so commonly used by design engineers, these scales are used exclusively in the discussions in the text and in figures. However, the reader is cautioned to use absolute temperatures in calculations where such temperatures are stipulated.

Dr. John H. Klote is a consulting engineer living in McLean, Virginia.

h = distance above neutral plane, ft (m)*
 K_S = coefficient, 7.64 (3460)

For a building 200 ft (60 m) tall, with a neutral plane at the midheight, an outside temperature of 0°F (-18°C) and an inside temperature of 70°F (21°C), the maximum pressure difference due to stack effect would be 0.22 in. H₂O (55 Pa). This means that at the top of the building, a shaft would have a pressure of 0.22 in. H₂O (55 Pa) greater than the outside pressure. At the bottom of the shaft, the shaft would have a pressure of 0.22 in. H₂O (55 Pa) less than the outside pressure. Figure 4-12.1 is a diagram of the pressure difference between a building shaft and the outside. In the diagram, a positive pressure difference indicates that the shaft pressure is higher than the outside pressure, and a negative pressure difference indicates the opposite.

Stack effect is usually thought of as existing between the inside of a building and the outside atmosphere. The air movement in buildings caused by both normal and reverse stack effect is illustrated in Figure 4-12.2. In this case, the pressure difference expressed in Equation 1 would actually refer to the pressure difference between the shaft and the outside of the building.

Figure 4-12.3 can be used to determine the pressure difference due to stack effect. For normal stack effect, the term $\Delta P/h$ is positive, and the pressure difference is positive above the neutral plane and negative below it. For reverse stack effect, the term $\Delta P/h$ is negative, and the pressure difference is negative above the neutral plane and positive below it.

*The neutral plane is the horizontal plane where the hydrostatic pressure inside equals that outside.

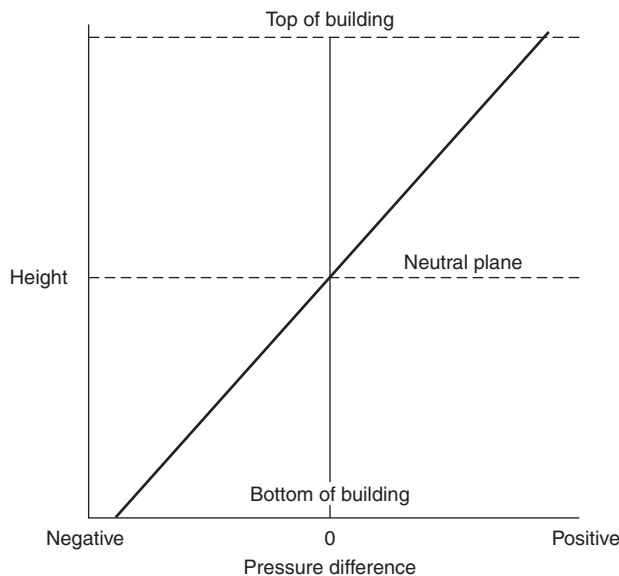

Figure 4-12.1. Pressure difference between an inside shaft and the outside due to normal stack effect.

Figure 4-12.2. Air movement due to normal (left) and reverse stack effect (right). Note: arrows indicate direction of air movement.

Figure 4-12.3. Pressure difference due to stack effect.

In unusually airtight buildings with exterior stairwells, reverse stack effect has been observed even with low outside air temperatures.⁴ In this situation, the exterior stairwell temperature was considerably lower than the building temperature. The stairwell was the cold column of air and other shafts within the building were the warm columns of air.

When considering stack effect, if the air leakage paths between a building and the outside are fairly uniform with height, the neutral plane will be located near the midheight of the building. However, when the leakage paths are not uniform, the location of the neutral plane can vary considerably, as in the case of vented shafts. McGuire

and Tamura⁵ provide methods for calculating the location of the neutral plane for some vented conditions.

Smoke movement from a building fire can be dominated by stack effect. In a building with normal stack effect, the existing air currents (as shown in Figure 4-12.2) can move smoke considerable distances from the fire origin. If the fire is below the neutral plane, smoke moves with the building air into and up the shafts. This upward smoke flow is enhanced by any buoyancy forces on the smoke existing due to its temperature. Once above the neutral plane, the smoke flows out of the shafts into the upper floors of the building. If the leakage between floors is negligible, the floors below the neutral plane, except the fire floor, will be relatively smoke free until the quantity of smoke produced is greater than can be handled by stack effect flows.

Smoke from a fire located above the neutral plane is carried by the building airflow to the outside through openings in the exterior of the building. If the leakage between floors is negligible, all floors other than the fire floor will remain relatively smoke-free, again, until the quantity of smoke produced is greater than can be handled by stack effect flows. When the leakage between floors is considerable, there is an upward smoke movement to the floor above the fire floor.

The air currents caused by reverse stack effect are also shown in Figure 4-12.2. These forces tend to affect the movement of relatively cool smoke in the reverse of normal stack effect. In the case of hot smoke, buoyancy forces can be so great that smoke can flow upward even during reverse stack effect conditions.

Buoyancy

High-temperature smoke from a fire has a buoyancy force due to its reduced density. The pressure difference between a fire compartment and its surroundings can be expressed by an equation of the same form as Equation 1.

$$\Delta P = K_s \left(\frac{1}{T_0} - \frac{1}{T_F} \right) h \tag{2}$$

where

- ΔP = pressure difference (in. H₂O [Pa])
- T_0 = absolute temperature of the surroundings (R [K])
- T_F = absolute temperature of the fire compartment (R [K])
- h = distance above the neutral plane (ft [m])
- K_s = coefficient (7.64 [3460])

The pressure difference due to buoyancy can be obtained from Figure 4-12.4 for the surroundings at 68°F (20°C). The neutral plane is the plane of equal hydrostatic pressure between the fire compartment and its surroundings. For a fire with a fire compartment temperature of 1470°F (800°C), the pressure difference 5 ft (1.52 m) above the neutral plane is 0.052 in. H₂O (13 Pa). Fang⁶ has studied pressures caused by room fires during a series of full-scale fire tests. During these tests, the maximum pressure difference reached was 0.064 in. H₂O (16 Pa) across the burn room wall at the ceiling.

Figure 4-12.4. Pressure difference due to buoyancy.

Much larger pressure differences are possible for tall fire compartments where the distance, h , from the neutral plane can be larger. If the fire compartment temperature is 1290°F (700°C), the pressure difference 35 ft (10.7 m) above the neutral plane is 0.35 in. H₂O (88 Pa). This amounts to an extremely large fire, and the pressures produced by it are beyond the state-of-the-art of smoke control. However, the example is included here to illustrate the extent to which Equation 2 can be applied.

In a building with leakage paths in the ceiling of the fire room, this buoyancy-induced pressure causes smoke movement to the floor above the fire floor. In addition, this pressure causes smoke to move through any leakage paths in the walls or around the doors of the fire compartment. As smoke travels away from the fire, its temperature drops due to heat transfer and dilution. Therefore, the effect of buoyancy generally decreases with distance from the fire.

Expansion

In addition to buoyancy, the energy released by a fire can cause smoke movement due to expansion. In a fire compartment with only one opening to the building, building air will flow into the fire compartment and hot smoke will flow out of the fire compartment. Neglecting the added mass of the fuel (which is small compared to

the airflow), the ratio of volumetric flows can simply be expressed as a ratio of absolute temperatures.

$$\frac{Q_{\text{out}}}{Q_{\text{in}}} = \frac{T_{\text{out}}}{T_{\text{in}}}$$

where

Q_{out} = volumetric flow rate of smoke out of the fire compartment (cfm [m^3/s])

Q_{in} = volumetric flow rate of air into the fire compartment (cfm [m^3/s])

T_{out} = absolute temperature of smoke leaving fire compartment (R [K])

T_{in} = absolute temperature of air into fire compartment (R [K])

For a smoke temperature of 1290°F (700°C) the ratio of volumetric flows would be 3.32. The reader is reminded to use absolute temperatures for calculation. In such a case, if the air flowing into the fire compartment is 3180 cfm (1.5 m^3/s), then the smoke flowing out of the fire compartment would be 10,600 cfm (4.98 m^3/s). In this case, the gas has expanded to more than three times its original volume.

For a fire compartment with open doors or windows, the pressure difference across these openings due to expansion is negligible. For a tightly sealed fire compartment, however, the pressure differences due to expansion may be important.

Wind

In many instances, wind can have a pronounced effect on smoke movement within a building. The pressure, P_w , that the wind exerts on a surface can be expressed as

$$P_w = \frac{1}{2} C_w \rho_o V^2 \quad (3)$$

where

C_w = dimensionless pressure coefficient

ρ_o = outside air density

V = wind velocity

For an air density of 0.075 lb/ft³ (1.20 kg/m³) this relation becomes

$$P_w = C_w K_w V^2 \quad (3a)$$

where

P_w = wind pressure (in. H₂O [Pa])

V = wind velocity (mph [m/s])

K_w = coefficient, 4.82×10^{-4} (0.600)

The pressure coefficients, C_w , are in range of -0.8 to 0.8, with positive values for windward walls and negative values for leeward walls. The pressure coefficient depends on building geometry and varies locally over the wall surface. In general, wind velocity increases with

height in the boundary layer nearest the surface of the earth. Detailed information concerning wind velocity variations and pressure coefficients is available from a number of sources.⁷⁻¹⁰ Specific information about wind data, with respect to air infiltration in buildings, has been generated by Shaw and Tamura.¹¹

A 35 mph (15.6 m/s) wind produces a pressure on a structure of 0.47 in. H₂O (117 Pa) with a pressure coefficient of 0.8. The effect of wind on air movement within tightly constructed buildings with all doors and windows closed is slight. However, the effects of wind can become important for loosely constructed buildings or for buildings with open doors or windows. Usually, the resulting airflows are complicated and, for practical purposes, computer analysis is required.

Frequently in fires, a window breaks in the fire compartment. If the window is on the leeward side of the building, the negative pressure caused by the wind vents the smoke from the fire compartment. This can greatly reduce smoke movement throughout the building. However, if the broken window is on the windward side, the wind forces the smoke throughout the fire floor and even to other floors. This both endangers the lives of building occupants and hampers fire fighting. Pressures induced by the wind in this type of situation can be relatively large and can easily dominate air movement throughout the building.

HVAC Systems

Before the development of the concept of smoke control, HVAC systems were shut down when fires were discovered.

The HVAC system frequently transports smoke during building fires. In the early stages of a fire, the HVAC system can serve as an aid to fire detection. When a fire starts in an unoccupied portion of a building, the HVAC system can transport the smoke to a space where people can smell the smoke and be alerted to the fire. However, as the fire progresses, the HVAC system will transport smoke to every area that it serves, thus endangering life in all those spaces. The HVAC system also supplies air to the fire space, which aids combustion. These are the reasons HVAC systems traditionally have been shut down when fires have been discovered. Although shutting down the HVAC system prevents it from supplying air to the fire, this does not prevent smoke movement through the supply and return air ducts, air shafts, and other building openings due to stack effect, buoyancy, or wind.

Smoke Management

The term *smoke management*, as used in this chapter, includes all methods that can be used independently or in combination to modify smoke movement for the benefit of occupants and fire fighters and for the reduction of property damage. The use of barriers, smoke vents, and smoke shafts are traditional methods of smoke management.

The effectiveness of a barrier in limiting smoke movement depends on the leakage paths in the barrier

and on the pressure difference across the barrier. Holes where pipes penetrate walls or floors, cracks where walls meet floors, and cracks around doors are a few possible leakage paths. The pressure difference across these barriers depends on stack effect, buoyancy, wind, and the HVAC system.

The effectiveness of smoke vents and smoke shafts depends on their proximity to the fire, the buoyancy of the smoke, and the presence of other driving forces. In addition, when smoke is cooled due to sprinklers, the effectiveness of smoke vents and smoke shafts is greatly reduced.

Elevator shafts in buildings have been used as smoke shafts. Unfortunately, this prevents their use for fire evacuation and these shafts frequently distribute smoke to floors far from the fire. Specially designed smoke shafts, which have essentially no leakage on floors other than the fire floor, can be used to prevent the smoke shaft from distributing smoke to nonfire floors.

Principles of Smoke Control

Smoke control uses the barriers (walls, floors, doors, etc.) used in traditional smoke management in conjunction with airflows and pressure differences generated by mechanical fans.

Figure 4-12.5 illustrates a pressure difference across a barrier acting to control smoke movement. Within the barrier is a door, and the high-pressure side of the door can be either a refuge area or an escape route. The low-pressure side is exposed to smoke from a fire. Airflow through the cracks around the door and through other construction cracks prevents smoke infiltration to the high-pressure side.

When the door in the barrier is opened, air flows through the open door. When the air velocity is low, smoke can flow against the airflow into the refuge area or escape route, as shown in Figure 4-12.6. This smoke backflow can be prevented if the air velocity is sufficiently large, as shown in Figure 4-12.7. The magnitude of the ve-

Figure 4-12.5. Pressure difference across a barrier of a smoke control system preventing smoke infiltration to the high-pressure side of the barrier.

Figure 4-12.6. Smoke backflow against low air velocity through an open doorway.

Figure 4-12.7. No smoke backflow with high air velocity through an open doorway.

locity necessary to prevent backflow depends on the energy release rate of the fire, as discussed in the section of this chapter regarding airflow.

The two basic principles of smoke control can be stated as follows:

1. Airflow by itself can control smoke movement if the average air velocity is of sufficient magnitude.
2. Air pressure differences across barriers can act to control smoke movement.

The use of air pressure differences across barriers to control smoke is frequently referred to as *pressurization*. Pressurization results in airflows in the small gaps around closed doors and in construction cracks, thereby preventing smoke backflows through these openings. Therefore, in a strict physical sense, the second principle is a special case of the first principle. However, considering the two principles separately is advantageous for smoke control design. For a barrier with one or more large openings, air velocity is the appropriate physical quantity for both design considerations and for acceptance testing. However, when there are only cracks, such as around

closed doors, determination of the velocity is difficult and including it in the design is impractical. In this case, the appropriate physical quantity is pressure difference. Separate consideration of the two principles has the added advantage of emphasizing the different considerations necessary for open and closed doors.

Because smoke control relies on air velocities and pressure differences produced by fans, it has the following three advantages in comparison to the traditional methods of smoke management:

1. Smoke control is less dependent on tight barriers. Allowance can be made in the design for reasonable leakage through barriers.
2. Stack effect, buoyancy, and wind are less likely to overcome smoke control than passive smoke management. In the absence of smoke control, these driving forces cause smoke movement to the extent that leakage paths allow. However, pressure differences and airflows of a smoke control system act to oppose these driving forces.
3. Smoke control can be designed to prevent smoke flow through an open doorway in a barrier by the use of airflow. Doors in barriers are opened during evacuation and are sometimes accidentally left open or propped open throughout fires. In the absence of smoke control, smoke flow through these doors is common.

Smoke control systems should be designed so that a path exists for smoke movement to the outside; such a path acts to relieve pressure of gas expansion due to the fire heat.

The smoke control designer should be cautioned that dilution of smoke in the fire space is not a means of achieving smoke control, that is, smoke movement cannot be controlled by simply supplying and exhausting large quantities of air from the space or zone in which the fire is located. This supplying and exhausting of air is sometimes referred to as *purging the smoke*. Because of the large quantities of smoke produced in a fire, purging cannot assure breathable air in the fire space. In addition, purging in itself cannot control smoke movement, because it does not provide the needed airflows at open doors and the pressure differences across barriers. However, for spaces separated from the fire space by smoke barriers, purging can significantly limit the level of smoke.

Airflow

Theoretically, airflow can be used to stop smoke movement through any space. However, the two places where air velocity is most commonly used to control smoke movement are open doorways and corridors. Thomas¹² has developed an empirical relation for the critical velocity to prevent smoke from flowing upstream in a corridor.

$$V_k = K \left(\frac{gQ}{W\rho cT} \right)^{1/3} \quad (4)$$

where

V_k = critical air velocity to prevent smoke backflow

Q = heat release rate into corridor

W = corridor width

ρ = density of upstream air

c = specific heat of downstream gases

T = absolute temperature of downstream mixture of air and smoke

K = constant of the order of 1

g = gravitational constant

The downstream properties are considered to be taken at a point sufficiently far downstream of the fire for the properties to be uniform across the cross-section. The critical air velocity can be evaluated at $\rho = 0.081 \text{ lb/ft}^3$ (1.3 kg/m^3), $c = 0.24 \text{ Btu/lb}^\circ\text{F}$ ($1.005 \text{ kJ/kg}^\circ\text{C}$), $T = 81^\circ\text{F}$ (27°C), and $K = 1$.

$$V_k = K_v \left(\frac{Q}{W} \right)^{1/3} \quad (4a)$$

where

V_k = critical air velocity to prevent smoke backflow (fpm [m/s])

Q = heat release rate into corridor (Btu/s [kW])

W = corridor width (ft [m])

K_v = coefficient, 86.9 (0.292)

This relation can be used when the fire is located in the corridor or when the smoke enters the corridor through an open door, air transfer grille, or other opening. The critical velocities calculated from the above relation are approximate because only an approximate value of K was used. However, critical velocities calculated from this relation are indicative of the type of air velocities required to prevent smoke backflow from fires of different sizes.

Equation 4 is not appropriate for sprinklered fires that have small temperature differences between the upstream air and downstream gases. Shaw and Whyte¹³ provide an analysis with experimental verification of a method to determine the velocity needed through an open doorway to prevent backflow of contaminated air. This analysis is specifically for small temperature differences and includes the effects of natural convection. If this method is used for a sprinklered fire where the temperature difference is only 3.6°F (2°C), then an average velocity of 50 fpm (0.25 m/s) would be the minimum velocity needed through a doorway to prevent smoke backflow. This temperature difference is small, and it is possible that larger values may be appropriate in many situations. Further research is needed in this area.

When airflow is used to control smoke, the amount of oxygen supplied to the fire is of concern. Huggett¹⁴ evaluated the oxygen consumed for combustion of numerous natural and synthetic solids. He found that for most materials that are involved in building fires, the energy released per unit of mass of oxygen consumed is approximately 5630 Btu/lb (13.1 MJ/kg). Air is 23.3 percent oxygen by weight. It can be shown that there is sufficient oxygen in 1000 cfm of air at 70°F to support a 1640-Btu/s fire. The equivalent statement in SI units is: There is sufficient oxygen in $1.0 \text{ m}^3/\text{s}$ of air at 21°C to support a 3660-kW fire.

Figure 4-12.8(a). Velocity to prevent smoke backflow (English units).

Figure 4-12.8(b). Velocity to prevent smoke backflow (SI units).

Equation 4a can be evaluated from Figures 4-12.8(a) and (b). For example, for a wastebasket fire of 142 Btu/s (150 kW) and a 4.0-ft- (1.22-m-) wide corridor, Equation 4a yields a critical velocity of 286 fpm (1.45 m/s). For a ceiling height of 8 ft, this amounts to a flow of about 9200 cfm (4.3 m³/s). This is sufficient air to support a 15,000-Btu/s (15,800-kW) fire. Thus the airflow to prevent smoke backflow for this wastebasket fire has sufficient oxygen to support a fire more than 100 times larger than the wastebasket fire. This illustrates the concern of airflow supplying oxygen to the fire, and extreme caution should be exercised when using airflow.

Pressurization

The airflow rate through a construction crack, door gap, or other flow path is proportional to the pressure dif-

ference across that path raised to the power *n*. For a flow path of fixed geometry, *n* is theoretically in the range of 0.5 to 1. However, for all flow paths except extremely narrow cracks, using *n* = 0.5 is reasonable and the flow can be expressed as

$$\dot{V} = CA\sqrt{\frac{2\Delta P}{\rho}} \tag{5}$$

where

\dot{V} = volumetric airflow rate

C = flow coefficient

A = flow area (also called leakage area)

ΔP = pressure difference across the flow path

ρ = density of air entering the flow path

The flow coefficient depends on the geometry of the flow path as well as on turbulence and friction. In the present context, the flow coefficient is generally in the range of 0.6 to 0.7. For $\rho = 0.075 \text{ lb/ft}^3$ (1.2 kg/m³) and *C* = 0.65, the flow equation above can be expressed as

$$\dot{V} = K_f A \sqrt{\Delta P} \tag{5a}$$

where

\dot{V} = volumetric flow rate (cfm [m³/s])

A = flow area (ft² [m²])

ΔP = pressure difference across flow path (in. H₂O [Pa])

K_f = coefficient, 2610 (0.839)

Airflow rate can also be determined from Figure 4-12.9. The flow area is frequently the same as the cross-sectional area of the flow path. A closed door with a crack area of 0.11 ft² (0.01 m²) and a pressure difference of

Figure 4-12.9. Airflow due to pressure difference.

0.01 in. H₂O (2.5 Pa) would have an air leakage rate of approximately 29 cfm (0.013 m³/s). If the pressure difference across the door were increased to 0.30 in. H₂O (75 Pa), then the flow would be 157 cfm (0.073 m³/s).

In field tests of smoke control systems, pressure differences across partitions or closed doors have frequently fluctuated by as much as 0.02 in. H₂O (5 Pa). These fluctuations have generally been attributed to wind, although they could have been due to the HVAC system or some other source. Pressure fluctuations and the resulting smoke movement are a current topic of research. To control smoke movement, the pressure differences produced by a smoke control system must be sufficiently large so that they are not overcome by pressure fluctuations, stack effect, smoke buoyancy, and the forces of the wind. However, the pressure difference produced by a smoke control system should not be so large that door opening problems result.

Purging

In general, the systems discussed in this chapter are based on the two basic principles of smoke control. However, it is not always possible to maintain sufficiently large airflows through open doors to prevent smoke from infiltrating a space that is intended to be protected. Ideally, such occurrences of open doors will only happen for short periods of time during evacuation. Smoke that has entered such a space can be purged, that is, diluted by supplying outside air to the space.

Consider the case where a compartment is isolated from a fire by smoke barriers and self-closing doors, so that no smoke enters the compartment when the doors are closed. However, when one or more of the doors is open, there is insufficient airflow to prevent smoke backflow into the compartment from the fire space. To facilitate analysis, it is assumed that smoke is of uniform concentration throughout the compartment. When all the doors are closed, the concentration of contaminant in the compartment can be expressed as

$$\frac{C}{C_0} = e^{-at} \quad (6)$$

where

C_0 = initial concentration of contaminant

C = concentration of contaminant at time t

a = purging rate in number of air changes per minute

t = time after doors closed (min)

e = constant, approximately 2.718

The concentrations C_0 and C must both be in the same units, and they can be any units appropriate for the particular contaminant being considered. McGuire, Tamura, and Wilson¹⁵ evaluated the maximum levels of smoke obscuration from a number of tests and a number of proposed criteria for tolerable levels of smoke obscuration. Based on this evaluation, they state that the maximum levels of smoke obscuration are greater by a factor of 100 than those relating to the limit of tolerance. Thus, they in-

dicates that an area can be "reasonably safe" with respect to smoke obscuration if its atmosphere will not be contaminated to an extent greater than 1 percent by the atmosphere prevailing in the immediate fire area. It is obvious that such dilution would also reduce the concentrations of toxic smoke components. Toxicity is a more complicated problem, and no parallel statement has been made regarding the dilution needed to obtain a safe atmosphere with respect to toxic gases.

Equation 6 can be solved for the purging rate as

$$a = \frac{1}{t} \log_e \left(\frac{C_0}{C} \right) \quad (7)$$

For example, if doors are open, the contaminant in a compartment is 20 percent of the burn room concentration and at six minutes after the door is closed the contaminant concentration is 1 percent of the burn room, then Equation 7 indicates that the compartment must be purged at a rate of one air change every two minutes.

In reality, it is impossible to ensure that the concentration of the contaminant is uniform throughout the compartment. Because of buoyancy, it is likely that higher concentrations of contaminant would tend to be near the ceiling. Therefore, an exhaust inlet located near the ceiling and a supply outlet located near the floor would probably purge the smoke even faster than the previous calculations indicate. Caution should be exercised in the location of the supply and exhaust points to prevent the supply air from blowing into the exhaust inlet and thus short-circuiting the purging operation.

Door Opening Forces

The door opening forces resulting from the pressure differences produced by a smoke control system must be considered. Unreasonably high door opening forces can result in occupants having difficulty in, or being unable to open doors to refuge areas or escape routes.

The force required to open a door is the sum of the forces (1) to overcome the pressure difference across the door and (2) to overcome the door closer. This can be expressed as

$$F = F_{dc} + \frac{k_d W A \Delta P}{2(W-d)} \quad (8)$$

where

F = the total door opening force (lb [N])

F_{dc} = the force to overcome the door closer (lb [N])

W = door width (ft [m])

A = door area (ft² [m²])

ΔP = pressure difference across the door (in. H₂O [Pa])

d = distance from the doorknob to the edge of the knob side of the door (ft [m])

K_d = coefficient (5.20 [1.00])

This relation assumes that the door opening force is applied at the knob. Door opening forces due to pressure

Figure 4-12.10. Door opening force due to a pressure difference.

difference can be determined from Figure 4-12.10. The force to overcome the door closer is usually greater than 3 lb (13 N) and in some cases, can be as large as 20 lb (90 N). For a door that is 7 ft (2.13 m) high and 36 in. (0.91 m) wide, subject to a pressure difference of 0.30 in. H_2O (75 Pa), the total door opening force is 30 lb (133 N), if the force to overcome the door closer is 12 lb (53 N).

Flow Areas

Airflow paths must be identified and evaluated in the design of smoke control systems. Some leakage paths are obvious, such as cracks around closed doors, open doors, elevator doors, windows, and air transfer grilles. Construction cracks in building walls are less obvious but no less important.

The flow area of most large openings, such as open windows, can be calculated easily. However, flow areas of cracks are more difficult to evaluate. The area of these leakage paths depends on workmanship (i.e., how well a door is fitted or how well weatherstripping is installed). A door that is 36 in. by 7 ft (0.9 × 2.1 m) with an average crack width of 1/8 in. (3.2 mm) has a leakage area of 0.21 ft² (0.020 m²). However, if this door is installed with a 3/4 in. (19 mm) undercut, the leakage area is 0.32 ft² (0.30 m²).

This is a significant difference. The leakage area of elevator doors has been measured in the range of 0.55 to 0.70 ft² (0.051 to 0.065 m²) per door.

For open stairwell doorways, Cresci¹⁶ found that complex flow patterns exist and that the resulting flow through open doorways was considerably below the flow calculated by using the geometric area of the doorway as the flow area in Equation 5a. Based on this research, it is recommended that the flow area of an open stairwell doorway be half that of the geometric area (door height multiplied by width) of the doorway. An alternative approach for open stairwell doorways is to use the geometric area as the flow area and use a reduced flow coefficient. Because it does not allow the direct use of Equation 5a, this alternative approach is not used here.

Typical leakage areas for walls and floors of commercial buildings are tabulated as area ratios in Table 4-12.1. These data are based on a relatively small number of tests performed by the National Research Council of Canada.¹⁷⁻²⁰ The area ratios are evaluated at typical airflows at 0.30 in. H_2O (75 Pa) for walls, and 0.10 in. H_2O (25 Pa) for floors. It is believed that actual leakage areas are primarily dependent on workmanship rather than construction materials, and in some cases, the flow areas in particular buildings may vary from the values listed. Considerable data concerning leakage through building components are also provided in the *ASHRAE Handbook*.²¹

The determination of the flow area of a vent is not always straightforward, because the vent surface is usually covered by a louver and screen. Thus the flow area is less than the vent area (vent height multiplied by width). Because the slats in louvers are frequently slanted, calculation of the flow area is further complicated. Manufacturers' data should be sought for specific information.

Table 4-12.1 Typical Leakage Areas for Walls and Floors of Commercial Buildings

Construction Element	Wall Tightness	Area Ratio A/A_w
Exterior building walls (includes construction cracks, cracks around windows and doors)	Tight	0.50×10^{-4}
	Average	0.17×10^{-3}
	Loose	0.35×10^{-3}
	Very loose	0.12×10^{-2}
Stairwell walls (includes construction cracks but not cracks around windows or doors)	Tight	0.14×10^{-4}
	Average	0.11×10^{-3}
	Loose	0.35×10^{-3}
Elevator shaft walls (includes construction cracks but not cracks around doors)	Tight	0.18×10^{-3}
	Average	0.84×10^{-3}
	Loose	0.18×10^{-2}
		A/A_f
Floors (includes construction cracks and areas around penetrations)	Tight	0.66×10^{-5}
	Average	0.52×10^{-4}
	Loose	0.17×10^{-3}

A = leakage area; A_w = wall area; A_f = floor area

Effective Flow Areas

The concept of effective flow areas is quite useful for analysis of smoke control systems. The various paths of smoke movement in the system can be parallel with one another, in series, or a combination of parallel and series paths. The effective flow area of a given system of flow paths is the area of a single opening that results in the same flow as the given system when subjected to the same pressure difference over the total system of flow paths. This concept is similar to an effective resistance of a system of electrical resistances.

The effective area, A_e , for the three parallel leakage areas of Figure 4-12.11 is

$$A_e = A_1 + A_2 + A_3 \quad (9)$$

If A_1 is 1.08 ft² (0.10 m²) and A_2 and A_3 are 0.54 ft² (0.05 m²) each, then the effective flow area, A_e , is 2.16 ft² (0.20 m²).

Equation 9 can be extended to any number of flow paths in parallel; that is, it can be stated that the effective area is the sum of the individual leakage paths.

$$A_e = \sum_{i=1}^n A_i \quad (10)$$

when n is the number of flow areas, A_i , in parallel.

Three leakage areas in series from a pressurized space are illustrated in Figure 4-12.12. The effective flow area of these paths is

$$A_e = \left(\frac{1}{A_1^2} + \frac{1}{A_2^2} + \frac{1}{A_3^2} \right)^{-1/2} \quad (11)$$

Figure 4-12.11. Leakage paths in parallel.

Figure 4-12.12. Leakage paths in series.

The general rule for any number of leakage areas is

$$A_e = \left(\sum_{i=1}^n \frac{1}{A_i^2} \right)^{-1/2} \quad (12)$$

where n is the number of leakage areas, A_i , in series. In smoke control analysis, there are frequently only two paths in series. For this case, the effective leakage area is

$$A_e = \frac{A_1 A_2}{\sqrt{A_1^2 + A_2^2}} \quad (13)$$

EXAMPLE 1:

Calculate the effective leakage area of two equal flow paths of 0.2 ft² in series. Let $A = A_1 = A_2 = 0.02$ m².

$$A_e = \frac{A^2}{\sqrt{2A^2}} = \frac{A}{\sqrt{2}} = 0.15 \text{ ft}^2 \quad (0.014 \text{ m}^2)$$

EXAMPLE 2:

Calculate the effective area of two flow paths in series, where $A_1 = 0.22$ ft² (0.02 m²) and $A_2 = 2.2$ ft² (0.2 m²).

$$A_e = \frac{A_1 A_2}{\sqrt{A_1^2 + A_2^2}} = 0.219 \text{ ft}^2 \quad (0.0199 \text{ m}^2)$$

Example 2 illustrates that when two areas are in series and one is much larger than the other, the effective area is approximately equal to the smaller area.

The method of developing an effective area for a system of both parallel and series paths is to systematically combine groups of parallel paths and series paths. The system illustrated in Figure 4-12.13 is analyzed as an example.

The figure shows that A_2 and A_3 are in parallel; therefore, their effective area is

$$A_{23_e} = A_2 + A_3$$

Areas A_4 , A_5 , and A_6 are also in parallel, so their effective area is

$$A_{456_e} = A_4 + A_5 + A_6$$

These two effective areas are in series with A_1 . Therefore, the effective flow area of the system is given by

$$A_e = \left(\frac{1}{A_1^2} + \frac{1}{A_{23_e}^2} + \frac{1}{A_{456_e}^2} \right)^{-1/2}$$

EXAMPLE 3:

Calculate the effective area of the system in Figure 4-12.13, if the leakage areas are $A_1 = A_2 = A_3 = 0.22 \text{ ft}^2$ (0.02 m^2) and $A_4 = A_5 = A_6 = 0.11 \text{ ft}^2$ (0.01 m^2).

$$A_{23_e} = 0.44 \text{ ft}^2 \quad (0.04 \text{ m}^2)$$

$$A_{456_e} = 0.33 \text{ ft}^2 \quad (0.03 \text{ m}^2)$$

$$A_e = 0.16 \text{ ft}^2 \quad (0.015 \text{ m}^2)$$

Figure 4-12.13. Combination of leakage paths in parallel and series.

Figure 4-12.14. Building floor plan illustrating symmetry concept.

Symmetry

The concept of symmetry is useful in simplifying problems and thereby easing solutions. Figure 4-12.14 illustrates the floor plan of a multistory building that can be divided in half by a plane of symmetry. Flow areas on one side of the plane of symmetry are equal to corresponding flow areas on the other side. For a building to be so treated, every floor of the building must be such that it can be divided in the same manner by the plane of symmetry. If wind effects are not considered in the analysis or if the wind direction is parallel to the plane of symmetry, then the airflow in only one-half of the building needs be analyzed. It is not necessary that the building be geometrically symmetric, as shown in Figure 4-12.14; it must be symmetric only with respect to flow.

Design Parameters: A General Discussion

Ideally, building and fire codes should contain design parameters leading to the design of functional and economical smoke control systems. Unfortunately, because smoke control is a new field, consensus has not yet been reached as to a definition of reasonable design parameters. Clearly, the designer has an obligation to adhere to any smoke control design criteria existing in appropriate codes or standards, but such criteria should be scrutinized to de-

termine whether they will result in an effective system. If necessary, the designer should seek a waiver of the local codes to ensure an effective smoke control system.

Five areas for which design parameters must be established are (1) leakage areas, (2) weather data, (3) pressure differences, (4) airflow, and (5) number of open doors in the smoke control system.

Leakage areas have already been discussed in this chapter. An additional consideration affecting pressure differences and airflow is whether a window in the fire compartment is broken. This factor is included in the following discussion of these parameters. In the absence of code requirements for specific parameters, the following discussion may be helpful to the designer.

Weather Data

The state-of-the-art of smoke control is such that little consideration has been given to the selection of weather data specifically for the design of smoke control systems. However, design temperatures for heating and cooling during winter and summer are recommended in the *ASHRAE Handbook*.²¹ For example, 99 and 97.5 percent winter design temperatures have been provided. These values represent the temperatures that are equaled or exceeded in these portions of the heating season.*

A designer may wish to consider using these design temperatures of smoke control systems. It should be remembered that in a normal winter, there would be approximately 22 hours at or below the 99 percent design value and approximately 54 hours at or below the 97.5 percent design value. Furthermore, extreme temperatures can be considerably lower than the winter design temperatures. For example, the *ASHRAE* 99 percent design temperature for Tallahassee, Florida, is 27°F (−3°C), but the lowest temperature observed there by the National Climatic Center²² was −2°F (−19°C) on February 13, 1899.

Temperatures are generally below the design values for short periods of time, and because of the thermal lag of building materials, these short intervals of low temperature usually do not result in problems with respect to heating systems. However, the same cannot necessarily be said of a smoke control system. There is no time lag for a smoke control system, that is, a smoke control system is subjected to all the forces of stack effect that exist at the moment the system is being operated. If the outside temperature is below the winter design temperature for which a smoke control system was designed, then problems from stack effect may result. A similar situation can result with respect to summer design temperatures and reverse stack effect.

Wind data are needed for a wind analysis of a smoke control system. *ASHRAE*²¹ provides wind data for smoke control design.

Pressure Differences

It is appropriate to consider both the maximum and minimum allowable pressure differences across the

boundaries of smoke control zones. The maximum allowable pressure difference should be a value that does not result in excessive door opening forces, but it is difficult to determine what constitutes excessive door opening forces. Clearly, a person's physical condition is a major factor in determining a reasonable door opening force for that person. *NFPA 101*[®], *Life Safety Code*[®],²³ states that the force required to open any door in a means of egress shall not exceed 30 lb (133 N). In the section of this chapter on purging, a method of determining the door opening force is provided.

The criterion used in this chapter for selecting a minimum allowable pressure difference across a boundary of a smoke control system is that no smoke leakage should occur during building evaluation.[†] In this case, the smoke control system must produce sufficient pressure differences so that it is not overcome by the forces of wind, stack effect, or buoyancy of hot smoke. The pressure differences due to wind and stack effect can become very large in the event of a broken window in the fire compartment. Evaluation of these pressure differences depends on evacuation time, rate of fire growth, building configuration, and the presence of a fire suppression system. In the absence of a formal method of analysis, such evaluation must of necessity be based on experience and engineering judgment.

A method for determining the pressure difference across a smoke barrier resulting from the buoyancy of hot gases is provided in the section of this chapter regarding buoyancy. For a particular application, it may be considered necessary to design a smoke control system to withstand an intense fire next to a door at the boundary of a smoke control zone. Earlier in this chapter it was stated that in a series of full-scale fire tests, the maximum pressure difference reached was 0.064 in. H₂O (16 Pa) across the burn room wall at the ceiling. To prevent smoke infiltration, the smoke control system should be designed to maintain a pressure slightly higher than that generated in fire conditions. A minimum pressure difference in the range of 0.08 to 0.10 in. H₂O (20 to 25 Pa) is suggested.

If a smoke control boundary is exposed to hot smoke from a remote fire, a lower pressure difference due to buoyancy will result. For a smoke temperature of 750°F (400°C), the pressure difference caused by the smoke 5.0 ft (1.53 m) above the neutral plane would be 0.04 in. H₂O (10 Pa). In this situation, it is suggested that the smoke control system be designed to maintain a minimum pressure in the range of 0.06 to 0.08 in. H₂O (15 to 20 Pa).

Water spray from fire sprinklers cools smoke from a building fire and reduces the pressure differences due to buoyancy. In such a case it is probably wise to allow for pressure fluctuations. Accordingly, a minimum pressure difference in the range of 0.02 to 0.04 in. H₂O (5 to 10 Pa) is suggested.

Windows in the fire compartment can break due to exposure to high temperature gases. In such cases, the pressure due to the wind on the building exterior can be

*The heating season usually consists of three winter months. A more exact definition of these temperatures is available in Chapter 26 of the *ASHRAE Handbook—1997 Fundamentals*.²¹

[†]Other criteria might involve maintaining a number of smoke-free egress routes or preventing smoke infiltration to a refuge area. Discussion of all possible alternatives is beyond the scope of this chapter.

determined from Equation 3. If this window is the only opening to the outside on the fire floor and the window faces into the wind, the boundary of the smoke control system could be subjected to higher pressures. One possible solution is to vent the fire floor on all sides to relieve such pressures. For a building that is much longer than it is wide, it may be necessary to vent only on the two longer sides.

In addition to wind effects, stack effect can be increased in the event of a broken fire compartment window. With a fire on a lower floor during cold weather, stack effect will increase pressures of the fire floor above surrounding spaces. Even though little research has been done on the subject, the chances of a window breaking in the fire compartment are reduced by the operation of fire sprinklers.

Airflow

When the doors in the boundaries of smoke control systems are open, smoke can flow into refuge areas or escape routes unless there is sufficient airflow through the open door to prevent smoke backflow, as discussed in the previous section. One criterion for selecting a design velocity through an open door is that no smoke backflow should occur during building evacuation.* Selection of this velocity depends on evacuation time, rate of fire growth, building configuration, and the presence of a fire suppression system. In the absence of a formal method of analysis, such an evaluation must be based on experience and engineering judgment.

At present, there is still much to be learned about the critical velocity needed to stop smoke backflow through an open door. In the absence of a specific relationship for doorways, the method of analysis presented for corridors in the earlier section regarding airflow can be used to yield approximate results. The width of the doorway may be used in place of the width of the corridor. This technique is based on the assumption that smoke properties are uniform across the cross section. As previously illustrated, for a particular application, it may be considered necessary to design for an intensive fire, such as one with an energy release rate of 8×10^6 Btu/hr (2.4 MW). A critical velocity of approximately 800 fpm (4 m/s) would be required to stop smoke.

In another application, it may be estimated that the building would be subjected to a much less intense fire with an energy release rate of 427,000 Btu/hr (125 kW). To protect against smoke backflow during evacuation, the critical velocity would be 300 fpm (1.5 m/s).

In a sprinklered building, it might be considered that the smoke away from the immediate fire area would be cooled to near ambient temperature by the spray from the sprinklers. In such a case a design velocity in the range of 50 to 250 fpm (0.25 to 1.25 m/s) may be used. Research is

needed to fully evaluate the effect of sprinklers on smoke control design parameters.

Number of Open Doors

The need for air velocity through open doors in the perimeter of a smoke control system has been discussed in this chapter. Another design consideration is the number of doors that could be opened simultaneously when the smoke control system is operational. A design that allows for all doors to be opened simultaneously may ensure that the system will always work, but it will probably add to the cost of the system.

Deciding on the number of doors that will be opened simultaneously depends largely on the building occupancy. For example, in a densely populated building, it is very likely that all the doors will be opened simultaneously during evacuation. However, if a staged evacuation plan or refuge area concept is incorporated in the building fire emergency plan, or if the building is sparsely occupied, only a few of the doors may be opened simultaneously during a fire.

Pressurized Stairwells

Many pressurized stairwells have been designed and built with the goal of providing a smoke-free escape route in the event of a building fire. A secondary objective is to provide a smoke-free staging area for fire fighters. On the fire floor, a pressurized stairwell must maintain a positive pressure difference across a closed stairwell door so that smoke infiltration is prevented.

During building fires, some stairwell doors are opened intermittently during evacuation and fire fighting, and some doors may even be blocked open. Ideally, when the stairwell door is opened on the fire floor, there should be sufficient airflow through the door to prevent smoke backflow. Designing such a system is difficult because of the large number of permutations of open stairwell doors and weather conditions that affect the airflow through open doors.

Stairwell pressurization systems are divided into two categories—single and multiple injection systems. A single injection system is one that has pressurized air supplied to the stairwell at one location; the most common injection point is at the top of the stairwell. Associated with this system is the potential for smoke feedback into the pressurized stairwell (i.e., of smoke entering the stairwell through the pressurization fan intake). Therefore, the capability of automatic shutdown in such an event should be considered.

For tall stairwells, single injection systems can fail when a few doors are open near the air supply injection point. All of the pressurized air can be lost through the few open doors, and the system can then fail to maintain positive pressures across doors farther from the injection point. Such a failure mode is especially likely with bottom injection systems when a ground level stairwell door is open.

*Other criteria might include the allowance of limited smoke leakage into areas to be protected. Under such criteria, the toxicity of the smoke is a factor that must be considered.

For tall stairwells, supply air can be supplied at a number of locations over the height of the stairwell. Figures 4-12.15 and 4-12.16 are two examples of many possible multiple injection systems that can be used to

Figure 4-12.15. Stairwell pressurization by multiple injection with the fan located at ground level.

Figure 4-12.16. Stairwell pressurization by multiple injection with roof-mounted fan.

Figure 4-12.17. Compartmentation of a pressurized stairwell. Note: each four floor compartment has at least one supply air injection point.

overcome the limitations of single injection systems. In these figures the supply duct is shown in a separate shaft, but systems have been built that have eliminated the expense of a separate duct shaft by locating the supply duct in the stairwell itself. Obviously, care must be taken in such a case so that the duct does not become an obstruction to orderly building evacuation.

Stairwell Compartmentation

An alternative to multiple injection is compartmentation of the stairwell into a number of sections, as illustrated in Figure 4-12.17. When the doors between compartments are open, the effect of compartmentation is lost. For this reason, compartmentation is inappropriate for densely populated buildings where total building evacuation by the stairwell is planned in the event of fire. However, when a staged evacuation plan is used and when the system is designed to operate successfully when the maximum number of doors between compartments are open, compartmentation can be an effective means of providing stairwell pressurization for tall stairwells.

Stairwell Analysis

In this section of the chapter, a method of analysis is presented for a pressurized stairwell in a building without vertical leakage. The performance of pressurized stairwells in buildings without elevators may be closely approximated by this method, which is useful for buildings with vertical leakage in that it yields conservative results. Only one stairwell is considered in the building, but the analysis can be extended to any number of stairwells by the concept of symmetry. For evaluation of vertical leakage and open stairwell doors, computer analysis is recommended.

This analysis is for buildings where the leakage areas are the same for each floor of the building and where the only significant driving forces are the stairwell pressurization system and the temperature difference between the indoors and outdoors.

The pressure difference, ΔP_{SB} , between the stairwell and the building can be expressed as

$$\Delta P_{SB} = \Delta P_{SBb} + \frac{by}{1 + (A_{SB}/A_{BO})^2} \quad (14)$$

where

ΔP_{SBb} = the pressure difference, P_{SB} , at the stairwell bottom

y = distance above the stairwell bottom

A_{SB} = flow area between the stairwell and the building (per floor)

A_{BO} = flow area between the building and the outside (per floor)

$$b = \frac{gP}{R} \left(\frac{1}{T_0} - \frac{1}{T_s} \right)$$

T_0 = absolute temperature of outside air

T_s = absolute temperature of stairwell air

For a stairwell with no leakage directly to the outside, the flow rate of pressurization air is

$$Q = \frac{2}{3} NCA_{SB} \sqrt{\frac{2}{\rho} \left(\frac{\Delta P_{SBt}^{3/2} - \Delta P_{SBb}^{3/2}}{\Delta P_{SBt} - \Delta P_{SBb}} \right)} \quad (15)$$

where

N = number of floors

C = flow coefficient (See Equation 5)

ΔP_{SBt} = the pressure difference, ΔP_{SB} , at the stairwell top

EXAMPLE 4:

Each story of a 20-story stairwell is 10.8 ft (3.3 m) in height. The stairwell has a single-leaf door at each floor leading to the occupant space and one ground level door to the outside. The exterior of the building has a wall area of 6030 ft² (560 m²) per floor. The exterior building walls and stairwell walls are of average leakiness. The stairwell wall area is 560 ft² (52 m²) per floor. The area of the gap around each stairwell door to the building is 0.26 ft² (0.024 m²). The exterior door is well gasketed, and its leakage is negligible when it is closed.

For this example, the following design parameters are used: outside design temperatures, $T_0 = 14^\circ\text{F}$ (-10°C); stairwell temperature, $T_s = 70^\circ\text{F}$ (21°C); minimum design pressure differences when all stairwell doors are closed of 0.551 in. H₂O (137 Pa).

SOLUTION:

Using the leakage ratios for an exterior building wall of average tightness from Table 4-12.1, $A_{BO} = 6030 \times (0.21 \times 10^{-3}) = 1.27 \text{ ft}^2$ (0.118 m²). Using leakage ratios for a

stairwell wall of average tightness from Table 4-12.1, the leakage area of the stairwell wall is $560 \times (0.11 \times 10^{-3}) = 0.06 \text{ ft}^2$ (0.006 m²). A_{SB} equals the leakage area of the stairwell wall plus the gaps around the closed doors. $A_{SB} = 0.06 + 0.26 = 0.32 \text{ ft}^2$ (0.030 m²). The temperature factor, 6, is calculated at 0.00170 in. H₂O/ft (1.39 Pa/m). The pressure difference at the stairwell bottom is selected as $\Delta P_{SBb} = 0.080 \text{ in. H}_2\text{O}$ (20 Pa) to provide an extra degree of protection above the minimum allowable value of 0.052 in. H₂O (13 Pa). The pressure difference, ΔP_{SBt} , is calculated from Equation 14 at 0.426 in. H₂O (106 Pa), using $y = 217 \text{ ft}$ (66.1 m). Thus, ΔP_{SBt} does not exceed the maximum allowable pressure. The flow rate of pressurization air is calculated from Equation 15 at 8200 cfm (3.9 m³/s).

The flow rate is highly dependent on the leakage area around the closed doors and upon the leakage area that exists in the stairwell walls. In practice, these areas are difficult to evaluate and even more difficult to control. If the flow area, A_{SB} , were 0.54 ft² (0.050 m²) rather than 0.32 ft² (0.030 m²), then a flow rate of pressurization air of 13,800 cfm (6.5 m³/s) would have been calculated from Equation 15. A fan with a sheave is one approach to allow adjustment of supply air to offset for variations in actual leakage from the values used in design calculations.

Elevator Smoke Control

Elevator shaft smoke control can prevent smoke spread to floors away from the fire by way of the elevator shaft. The problems that can result from smoke migration through elevator shafts are illustrated by the fire at the MGM Grand Hotel.²⁴ The fire occurred on the ground floor, but smoke migrated to the upper floors where the majority of the fatalities occurred. The elevators at this hotel did not have any special smoke protection, and they were one of the major paths of smoke migration to the upper floors. This chapter does not address smoke control of elevator systems intended for fire evacuation; however, the topic is addressed by Klote and Milke.²⁵

Piston Effect

The transient pressures produced when an elevator car moves in a shaft (i.e., piston effect) affect elevator smoke control. Such piston effect can pull smoke into a normally pressurized elevator lobby or elevator shaft. Klote²⁶ analyzed air flows and pressures produced by elevator car motion in a pressurized elevator shaft, based on the continuity equation for the contracting control volume in an elevator shaft above a moving elevator car. Piston effect experiments²⁷ on a hotel elevator in Mississauga, Ontario, Canada, validated the analysis.

From the analysis by Klote, an expression was developed for the critical pressure difference, ΔP_{crit} , at which piston effect cannot overcome the elevator pressurization system.

$$\Delta P_{\text{crit}} = \frac{K_{pe}\rho}{2} \left(\frac{A_s A_e V}{A_n A_{st} C_c} \right)^2 \quad (16)$$

where

- ΔP_{crit} = critical pressure difference (in. H₂O [Pa])
 ρ = air density in elevator shaft (lb/ft³ [kg/m³])
 A_s = cross-sectional area of the elevator shaft (ft² [m²])
 A_{si} = leakage area between the lobby and the building (ft² [m²])
 A_a = free area around the elevator car (ft² [m²])
 A_e = effective area between the elevator shaft and the outside (ft² [m²])
 V = elevator car velocity (ft/min [m/s])
 C_c = flow coefficient for flow around car, dimensionless
 K_{pe} = coefficient, 1.66×10^{-6} (1.00)

The flow coefficient, C_c , was determined experimentally to be about 0.94 for a multiple-car elevator shaft, and about 0.83 for a single-car elevator shaft.²⁸ Equation 16 is for elevators without enclosed elevator lobbies. The effective area from the elevator to the outside is

$$A_e = \left(\frac{1}{A_{si}^2} + \frac{1}{A_{io}^2} \right)^{-1/2} \quad (17)$$

where A_{io} is the leakage area between the outside and the building, in ft² (m²).

EXAMPLE 5:

An elevator shaft with two cars is pressurized to a minimum of 0.05 in. H₂O (12.4 Pa) from the elevator shaft to the building. This system is to prevent smoke movement through the elevator shaft, and there is no enclosed elevator lobby. The parameters are $A_{si} = 1.52$ ft² (0.141 m²), $A_{io} = 2.26$ ft² (0.210 m²), $A_s = 121$ ft² (11.2 m²), $A_a = 80$ ft² (7.43 m²), $\rho = 0.075$ lb/ft³ (1.20 kg/m³), $V = 500$ ft/min (2.54 m/s), and $C_c = 0.94$. Is it possible for the pressure difference due to elevator piston effect to pull smoke into the elevator shaft?

SOLUTION:

From Equation 17, $A_e = 1.26$ ft² (0.117 m²). From Equation 16, $\Delta P_{\text{crit}} = 0.028$ in. H₂O (6.9 Pa). The elevator shaft is pressurized at a level above ΔP_{crit} . Therefore, piston effect will not pull smoke into the elevator shaft.

Elevator Shaft Pressurization

These systems supply air to the elevator shaft and can produce a pressure difference sufficient to prevent smoke flow into the elevator shaft in the event of a fire. Upon fire detection, the general procedure is for elevator cars to be taken out of normal service and automatically recalled to the ground floor. A recent modification of this is the capability for recall to an alternative floor in the event of a fire on the ground floor. Two elevator door scenarios can occur: (1) the elevator doors remain open after the car reaches the ground floor or the alternative floor, or (2) the elevator doors close after sufficient time to allow passengers to leave the car. The fire service has elevator keys that enable them to: (1) operate elevators for rescue

and (2) transport personnel and equipment to fight the fire.

As with pressurized stairwells, factors that must be considered are shaft friction, outside-to-inside temperature difference, and pressure fluctuations due to doors opening and closing. The analysis of pressurized stairwells can be applied to pressurized elevators by redefining the subscript S in the analysis from stairwell to elevator shaft. This analysis is then applicable to buildings without vertical leakage and to shafts with negligible pressure loss due to friction. This analysis can only be used where the elevator pressurization system is the only system using pressurization or operating in the building. Further, the effect of any exhaust system must be negligible. Computer analysis incorporating shaft friction and more complex building flow paths can be done by the programs cited later in this chapter.

Zone Smoke Control

Pressurized stairwells are intended to prevent smoke infiltration into stairwells. However, in a building that has only stairwell pressurization, smoke can flow through cracks in floors and partitions and through shafts to damage property and threaten life at locations remote from the fire. The concept of zone smoke control is intended to limit such smoke movement.

With this smoke control method, a building is divided into a number of smoke control zones, and each zone is separated from the others by partitions, floors, and doors that can be closed to inhibit the smoke movement. In the event of a fire, pressure differences and airflows produced by mechanical fans are used to limit the smoke spread from the zone in which the fire was initiated. The concentration of smoke in the fire zone is unchecked and, accordingly, it is intended that the building occupants evacuate this zone as soon as possible after fire detection.

Frequently, each floor of a building is chosen to be a separate smoke control zone. However, a smoke control zone can consist of more than one floor, or a floor can be divided into more than one smoke control zone. Some arrangements of smoke control zones are illustrated in Figure 4-12.18. All of the nonsmoke zones in the building may be pressurized. The term *pressure sandwich* is used to describe cases where only zones adjacent to the smoke zone are pressurized as in (b) and (d) of Figure 4-12.18.

The intent of zone smoke control is to limit smoke movement to the smoke zone by use of the two principles of smoke control. Pressure differences in the desired direction across the barriers of a smoke zone can be achieved by either supplying outside (fresh) air to nonsmoke zones, by venting the smoke zone, or by both methods.

Venting of smoke from a smoke zone is important because it prevents significant overpressures that are due to thermal expansion of gases as a result of the fire. However, venting only slightly reduces smoke concentration in the smoke zone. Venting in this zone can be accomplished by exterior wall vents, smoke shafts, and mechanical venting (exhausting).

Figure 4-12.18. Some arrangements of smoke control zones. The smoke zone is indicated by a minus (-) sign and pressurized spaces are indicated by a (+) sign. Each floor can be a smoke control zone (a, b) or a smoke zone can consist of more than one floor (c, d). All of the non-smoke zones in a building may be pressurized as in (a) and (c), or only nonsmoke zones adjacent to the smoke zone (b, d). A smoke zone can be limited to a part of a floor (e).

Computer Analysis

Some design calculations associated with smoke control are appropriate for hand calculation. However, other calculations involve time-consuming, trial-and-error solutions that are more appropriately left to a computer. In 1982, the National Bureau of Standards developed a computer program²⁹ specifically for analysis of smoke control systems. A number of other programs applicable to smoke control have been developed. Some calculate steady-state airflow and pressures throughout a building,^{30,31} other programs go beyond this to calculate the smoke concentrations that would be produced throughout a building in the event of a fire.³²⁻³⁵

In 1993, an ASHRAE-sponsored research project evaluated several algorithms for network flow to determine the most appropriate one for smoke control applica-

tions.³⁶ The algorithm selected as the best is the core numerical routine of the public domain computer program CONTAM96.³⁷ While CONTAM96 was primarily developed for indoor air quality applications, it has been extensively used for smoke control. In addition to fast and reliable numerics, CONTAM96 has a graphical user interface that significantly simplifies data input and reduces the probability of input errors.

Each of these programs differs from the others to some extent but all employ similar basic concepts. A building is represented by a network of spaces, or nodes, each at a specific pressure and temperature. The stairwells and other shafts are modeled by a vertical series of spaces, one for each floor. Air flows through leakage paths from regions of high pressure to regions of low pressure. These leakage paths are doors and windows that may be opened or closed. Leakage can also occur through partitions, floors, and exterior walls and roofs. The airflow through a flow path is a function of the pressure difference across the path as presented in Equation 5.

Air from outside the building can be introduced by a pressurization system into any level of a shaft or even into other building compartments, allowing for simulation of stairwell pressurization. In addition, any building space can be exhausted, allowing simulation of zoned smoke control systems. The pressures throughout the building and flow rates through all the flow paths are obtained by solving the airflow network, including the driving forces such as wind, the pressurization system, or a temperature difference between inside and outside air.

Acceptance Testing

Regardless of the care, skill, and attention to detail with which a smoke control system is designed, an acceptance test is needed to ensure that the system, as built, operates as intended.

An acceptance test should be composed of two levels of testing. The first level is functional, to determine if everything in the system works as it is supposed to work (i.e., an initial check of the system components). The importance of the initial check has become apparent because of the many problems that have been encountered during tests of smoke control systems. These problems include fans operating backward, fans to which no electrical power was supplied, and controls that did not work properly.

The second level of testing is performance oriented, to determine if the system, as a system, performs adequately under all required modes of operation. This testing can consist of measuring pressure differences across barriers under various modes of smoke control system operation. In cases where airflows through open doors are important, these should also be measured. Chemical smoke from smoke candles (sometimes called *smoke bombs*) is not recommended for any performance testing because it normally lacks the buoyancy of hot smoke from a real building fire. Smoke near a flaming fire has a temperature in the range of 1000 to 2000°F (540 to 1100°C). Heating chemical smoke to such temperatures to emulate smoke from a real fire is not recommended unless precau-

tions are taken to protect life and property. These same comments about buoyancy apply to tracer gases. Thus, it seems that pressure difference testing is the most practical performance test.

CHAPTER 13

Smoke Management in Covered Malls and Atria

James A. Milke

Introduction

The atrium is an architectural construct originating from the era of the Roman Empire.¹ Initially, the atrium was a courtyard bounded by a building, without a roof. During the latter part of this century, a roof or ceiling has been placed over the courtyard, and occasionally bounding walls around the courtyard are removed to provide openings between the courtyard and adjacent spaces.² Covered malls are also a relatively recent architectural development. Here, the large-volume structure comprises a pedestrian space, often with large openings into the communicating stores.

Smoke management in large-volume spaces, such as atria and covered malls, poses separate and distinct challenges from well-compartmented spaces. In particular, smoke control strategies using pressure differences and physical barriers described by Klote in Section 4, Chapter 12, and NFPA 92A, *Recommended Practice for Smoke-Control Systems*,³ are infeasible. Without physical barriers, smoke propagation is unimpeded, spreading easily throughout the entire space. The tall ceiling heights in many large-volume spaces pose additional challenges in terms of substantial quantities of smoke production and delayed detection times. However, on the positive side, the large-volume space and tall ceiling height permit the smoke to become diluted and cooled as it spreads vertically and horizontally. Dilution acts to reduce the level of hazard posed by the smoke.

In atriums, hazard development is moderated by the large volume typically associated with the space. However, there is still a need to ensure that dangerous concentrations of smoke are prevented.

In addition to atria and covered malls, there are many other examples of large-volume spaces, including con-

vention centers, airport terminals, sports arenas, and warehouses. The engineering principles governing the design of smoke management systems for these various large-volume spaces are the same. However, differences in the smoke management system designs for these large-volume spaces may occur as a result of different fire scenarios and design goals reflecting changes in function, shape, and connection to other spaces, among other factors. Given the similarities in engineering principles affecting smoke management system design, the term *atrium* will be used throughout this chapter to refer to all types of large-volume spaces.

The discussion presented in this chapter is divided into two sections. First, conditions within the atrium prior to actuation of a smoke management system are discussed. As part of this discussion, the smoke filling process is described along with the time required for actuation of a smoke management system. The second part includes a description of conditions within the atrium after actuation of the smoke management system.

As a preface to any discussion on smoke management systems, a definition of smoke must be established (NFPA 92B, *Guide for Smoke Management Systems in Malls, Atria, and Large Areas*,⁴ Section 1-4):

The airborne solid and liquid particulates and gases evolved when a material undergoes pyrolysis or combustion, together with the quantity of air that is entrained or otherwise mixed into the mass.

While only the combustion products are visible and potentially toxic, what is visually observed as smoke is a mixture of the combustion products and the entrained air. Air is entrained along the entire height of the smoke plume below a smoke layer. Proportionally, the smoke is mostly entrained air. In the area between the base and tip of the flames, most of the entrained air is not consumed in the combustion process and only dilutes the combustion products. The entrainment of additional air along the plume acts to further dilute the smoke. The smoke be-

James A. Milke is an associate professor in the Department of Fire Protection Engineering at the University of Maryland. His recent research activities have included assessing the performance of smoke management systems and structural members in fires.

comes increasingly more diluted with the increasing height of the plume. Entraining air into the smoke plume also increases the mass flow in the plume to increase the quantity of smoke produced. However, the entrained air also decreases the concentration of combustion gases and cools the smoke. In some cases, the smoke may be sufficiently diluted to mitigate the associated hazards.

Hazard Parameters

Smoke can adversely affect building occupants, fire brigade members, property (including the building structure and contents), and mission continuity. Typically, the threat to people or objects is posed when they come into contact with smoke for a sufficient period of time.

People who become exposed to smoke are generally harmed as a result of the exposure to toxic gases or elevated temperature. The toxic effects of smoke on people are described in Purser (see Section 2, Chapter 6) and Klote and Milke.⁵ In addition, smoke may reduce visibility. A reduction of visibility may cause people to become disoriented and can in turn increase the amount of time they are exposed to the smoke.⁶ A reduction of visibility may also increase the susceptibility of building occupants to trip over obstructions or even fall over balcony railings.⁷

Building components can be affected by the elevated temperature due to smoke. Building components heated by smoke are considered in fire resistance analyses. In addition, building contents may be affected by exposure to the elevated temperatures, corrosive gases, or particulate matter. Contents exposed to heated smoke may be melted, distorted, or charred, depending on the temperature of the smoke and the degree of exposure. Contents which are submerged in smoke and come into contact with combustion gases and smoke particles may become stained or emit an odor of smoke. Exposure to smoke can damage electronic equipment, especially if restoration activities are not initiated promptly after the fire.⁸

Following a fire, a building or portion thereof may be closed due to restoration, to threaten mission continuity. This results in loss of revenue for the building owner, temporary unemployment of workers in the building, and loss of service of the facility to the community, among other things.

Smoke Layer Interface Position

The smoke layer interface position is located a distance, z , above the top of the fuel, as indicated in Figure 4-13.1. This parameter addresses the danger of people being immersed in a smoke layer. Sole use of this parameter to assess hazard level is conservative by considering any concentration of smoke to be unacceptable. However, even though the physiological effects due to being submerged in "light" smoke levels may be minor, the psychological effects and extended evacuation time may be appreciable. Being surrounded by smoke of any nature may decrease the speed of evacuation, perhaps until the smoke is no longer relatively benign. In terms of property protection issues, any smoke may be unacceptable because of smoke staining or smoke corrosivity.

Figure 4-13.1. Axisymmetric plume.⁴

Light Obscuration

As with the smoke layer depth parameter, light obscuration is not lethal by itself.⁹ Associated with an increase in light obscuration is a reduction in visibility, which is likely to yield a longer evacuation time and extend exposure to the smoke toxins. In some documented fires, evacuation has been terminated due to a lack of sufficient visibility.^{10,11,12} A fire fighter's injury in an atrium fire was attributed to a significant reduction in visibility due to light obscuration.⁷ The fire fighter fell from an upper balcony because he could not see the edge.

Limiting values from 0.23 to 1.2 m^{-1} have been suggested for the extinction coefficient.^{10,11,12} (See Section 2, Chapter 13.) Alternatively, a critical limit may be based on a preferred minimum visibility distance to a particular target. For example, a limit of light obscuration can be suggested such that occupants can see an illuminated exit sign across a room or at the end of a corridor.

Temperature and Gas Specie Concentration

The final two parameters, elevated temperature of the smoke layer and gas specie concentration (such as CO, CO₂, and HCN), can be directly related to the potential for harm. (See Section 2, Chapter 6.) Critical limits for these two parameters can be suggested based on toxicity studies.

Smoke Management Approaches

The design of a smoke management system for an atrium is influenced by the following three characteristics of the atrium:

1. Geometric shape and dimensions
2. Relative location within the building
3. Separation from communicating spaces

Several approaches are available to achieve smoke management goals in an atrium (e.g., limit the fire size,

provide physical barriers, and provide mechanical or natural ventilation). Selection of the best smoke management approach for a particular atrium should consider the use, size, and arrangement of spaces.

Limiting the fire size can be accomplished by controlling the type, quantity, and arrangement of fuel. In addition, the fire size can be controlled through an automatic suppression system.

Physical barriers limit smoke spread to adjacent spaces. The ability of a physical barrier to limit smoke spread is dependent on the leakage of the barrier and pressure difference across the barrier. The barrier needs to withstand the exposure to smoke and an elevated temperature environment. In an atrium with a tall ceiling, the temperature of the smoke layer in the atrium is likely to be only slightly above ambient conditions.

Mechanical or natural ventilation may be provided to remove smoke from the atrium. Removing smoke from the atrium can limit the accumulation of heat and smoke within the atrium or can arrest the descent of the smoke layer. Mechanical ventilation can be provided in a direction opposite the smoke movement to restrict smoke spread to communicating spaces. Gravity vents may be provided to remove smoke, though their performance may be compromised by environmental factors. Discussions of gravity vents are provided elsewhere.¹³ (See Section 3, Chapter 9.)

Analytical Approach

Numerous tools are available to evaluate the adequacy of a smoke management system. The selection of a particular tool is dependent on the accuracy needed for the analysis and the applicability of the analytical tools, given the characteristics of the large space and selected fire scenarios.¹⁴ The principal characteristics that affect applicability are

- Geometry of the large space: variation of horizontal cross-sectional area, sloped versus flat ceiling
- Time period of interest: unsteady versus steady heat release rate, constant operation of smoke management system
- Fire development: heat release rate described by power law
- Environmental effects: stack effect, wind
- Interacting systems: other smoke management systems, HVAC

The range of design tools available to assess the performance of smoke management system designs can be grouped into the following categories:

- Zone model (algebraic equation based)
- Zone model (computer based)
- Field model
- Scale model

The intent of an engineering analysis of smoke conditions in an atrium is to express the level of hazard in terms of physically based parameters, for example, smoke layer interface position, temperature, carbon monoxide concentration, and light obscuration. The magnitude of each of

these parameters can be predicted based on engineering principles. In addition to being predictable, critical threshold values are available for the hazard parameters in order to properly assess the severity of the threat. (See Section 2, Chapter 6.) This chapter will concentrate on the life hazards posed by smoke. The hazards smoke poses to contents, property, and mission continuity are described elsewhere.^{15,5,8}

Scale Models

Scale models provide physical representations of a space, though in a reduced scale. Scale models are especially useful in examining atria with irregular shapes or numerous projections. A review of applying scale models as a design aid for atrium smoke management systems was provided by Milke and Klote.¹⁴

Quintiere provided a review of scaling relationships based on preserving the Froude number.¹⁶ The Froude number, Fr , is defined as v/gl .

The scaling relations are

$$\text{Temperature:} \quad T_m = T_F \quad (1)$$

$$\text{Geometric position:} \quad x_m = x_F \left(\frac{l_m}{l_F} \right) \quad (2)$$

$$\text{Pressure:} \quad \Delta p_m = \Delta p_F \left(\frac{l_m}{l_F} \right) \quad (3)$$

$$\text{Velocity:} \quad v_m = v_F \left(\frac{l_m}{l_F} \right)^{1/2} \quad (4)$$

$$\text{Time:} \quad t_m = t_F \left(\frac{l_m}{l_F} \right)^{1/2} \quad (5)$$

$$\text{Convective heat release:} \quad Q_{c,m} = Q_{c,F} \left(\frac{l_m}{l_F} \right)^{5/2} \quad (6)$$

$$\text{Volumetric flow rate:} \quad V_{fan,m} = V_{fan,F} \left(\frac{l_m}{l_F} \right)^{5/2} \quad (7)$$

Experiments based on Froude modeling may be done with air at atmospheric pressure. Froude modeling does not preserve the Reynolds number. However, appropriate selection of the size of the model can assure that fully developed flow is achieved to minimize this effect. Because the smoke behavior in only certain areas of the scaled atrium may be of interest, fully developed flow only needs to be achieved in these areas. Often, a scale model with a critical dimension of at least 0.3 m in any areas of interest will be sufficient to achieve fully developed, turbulent flow. As an example, in most shopping centers and atria, the critical dimension in question would be the floor-to-ceiling height of one of the balconies.

In addition, Froude modeling does not preserve the dimensionless parameters concerning heat transfer. Generally, this limitation has little effect because the tempera-

ture is the same for the scale model and the full-scale facility. Froude modeling does not apply to high-temperature locations and low Reynolds locations (e.g., near the flame). However, Froude modeling provides useful information about smoke transport away from the fire.

Some surface effects can be preserved by scaling the thermal properties of the construction materials for the model. The thermal properties can be scaled by

$$\text{Thermal properties: } (k\rho c_p)_{w,m} = (k\rho c_p)_{w,F} \left(\frac{1_m}{1_F}\right)^{0.9} \quad (8)$$

Because scaling thermal properties has only a secondary effect on fluid flow, considerations of convenient construction and flow visualization may require that some or all surface materials in the model are different from those selected based on thermal property scaling.

EXAMPLE 1:

A scale model is proposed to determine the equilibrium smoke layer position for the atrium depicted in Figure 4-13.2. Because the horizontal cross-sectional area varies with height, algebraic equation and computer-based zone models are of limited value. Assume that the overall height of the atrium is 30.5 m and the design fire is steady with a heat release rate of 5 MW. An exhaust fan capacity of 142 m³/s is proposed. By applying the scaling relationships to formulate a small-scale model, the basic parameters for the scale model are

- Height: 3.8-m-tall model (1/8 scale)
- Fire size: 28 kW
- Fan capacity: 0.78 m³/s

Analytical Models

Two categories of analytical models are zone and field models. A description of field models is outside the scope of this chapter. Zone models divide each compartment into a limited number of control volumes, typically an upper and a lower zone. Inherent in the zone approach is the as-

sumption of uniform properties throughout each zone. In spaces with a large floor area, this assumption may be tenuous. Nonetheless, calculations associated with the zone model approach are relatively easy to perform and are often accepted for engineering purposes. Calculations following the zone model approach may be in the form of algebraic equations or a computer algorithm.

The zone approach assumes that smoke from a fire is buoyant, rises to the ceiling, and forms a smoke layer. The buoyant nature of smoke is due to the decreased density of the heated smoke. As smoke rises in a plume, air is entrained to increase the mass flow rate in the plume. A decrease in the velocity and temperature of the smoke plume results from the increase in the plume mass flow rate, as dictated by conservation of momentum and energy. In addition, the entrained air dilutes the combustion products in the plume. The entire smoke layer is assumed to have uniform characteristics. As smoke is supplied to the smoke layer from the plume, the interface between the smoke layer and lower clear air zone descends. The additional smoke supplied by the plume also results in an increase in the smoke layer temperature, carbon monoxide concentration, and light obscuration.

Being a simplification, the zone model approach may not be applicable in some situations. One example includes a scenario with operating sprinklers, which may cool the layer and also entrain smoke from the upper layer into the water spray pattern descending into the lower zone. Another example consists of the case where smoke does not reach the ceiling as a result of a loss of relative buoyancy, where the temperature near the ceiling of the atrium is greater than that near the floor. This situation is discussed in more detail later in this chapter. A third situation involves an atrium with a large cross-sectional area where the horizontal variation in conditions from one portion of the atrium to another is important to the analyst. Where local conditions need to be assessed, field models are more appropriate than zone models.

Two categories of fire scenarios for smoke management design in atria include (1) fires located in the atrium, and (2) fires located in a space adjacent and open to the atrium. This chapter concentrates only on fires within the atrium space. Methods to estimate conditions in any of the adjacent spaces, resulting from fires originating in the atrium or from fires in other adjacent spaces, are addressed elsewhere.⁵

Figure 4-13.2. Small-scale model of atrium.

Smoke Filling Period

A smoke layer is formed once the smoke plume reaches the ceiling and the ceiling jet spreads horizontally to reach the bounding walls of the space. Subsequently, the smoke layer starts to descend in the space. In relatively small spaces with low ceilings, the smoke layer forms almost immediately. However, in large spaces with tall ceilings, the time required to form a smoke layer may be appreciable. The delay in forming a layer is attributable to the transport lag of the smoke. The smoke filling period continues until the smoke exhaust fans are actuated.

Transport Lag

The transport lag is composed of the time for a smoke plume to reach the ceiling (plume transport lag) and the time for the ceiling jet to reach the bounding enclosure (ceiling jet transport lag). These two time periods are depicted in Figure 4-13.3.

Correlations for the plume and ceiling jet transport lag are available in the literature for both steady and t^2 fires.^{17,18} Because virtually all fires have a growth period before reaching a steady phase, the transport lag correlations for steady fires have little relevance.

Correlations for the plume transport lag for steady and t^2 -fires are

Steady fires: $t_{pl} = 0.67H^{4/3}/Q^{1/3}$ (9)

t^2 fires: $t_{pl} = 0.1H^{4/5}t_g^{2/5}$ (10)

Estimates of the plume transport lag from equations 9 and 10 are provided in Figure 4-13.4. As indicated in the figure, even the shortest plume transport lag for t^2 fires,

associated with the fast t^2 fire, is greater than that for a modest-size steady fire.

Comparable correlations for the ceiling jet transport lag for steady and t^2 fires are

Steady fires: $t_{cj} = \frac{r^{11/6}}{1.2\dot{Q}^{1/3}H^{1/2}}$ (11)

t^2 fires: $t_{cj} = \frac{0.72rt_g^{2/5}}{H^{1/5}}$ (12)

A comparison of the ceiling jet transport lag for a modest-size steady fire and t^2 fires is presented in Figure 4-13.5. Again, the transport lag associated with the steady fire is much less than that associated with any of the t^2 fires.

Smoke Layer Interface Position

Once the smoke layer has formed, the initial rate of descent of the layer is very rapid, slowing as the layer descends. This is attributable to the dependence of the rate of smoke production on the distance from the top of the fuel to the smoke layer.

Both empirical correlations and theoretically based methods are available to address conditions during the smoke filling period using a zone model approach. Theoretically based methods use statements of conservation of mass and energy to determine the volume of the upper layer.¹⁹ Conservation of mass accounts for the smoke mass supplied from the plume to the smoke layer along with any smoke leaving the zone through ventilation openings. Conservation of energy is applied to address the energy being supplied by the plume along with heat losses from the layer.

Generally, predictions of the smoke layer interface position by the two analytical methods differ. The principal reason for the discrepancy is the difference in definitions of the smoke layer interface used by the two

Figure 4-13.3. Plume and ceiling jet transport lag.

Figure 4-13.4. Plume transport lag.

Figure 4-13.5. Ceiling jet transport lag.

methods. The empirical correlations are based on first indications of smoke, either using temperature rise or visual measurements. The theoretically based approach defines the smoke layer position as the demarcation between the upper and lower zones.

Empirical Correlations

Empirical correlations have been developed by Heskestad to determine the smoke layer interface position as a function of time for steady and t^2 fires. These correlations, included in NFPA 92B, *Guide for Smoke Management Systems in Malls, Atria, and Large Areas*,⁴ are based on experimental data in large spaces. In the experimental efforts, the smoke layer interface position was established by a variety of means, including visual observations and first change temperature, carbon dioxide concentration, or optical density measurements.

The correlations are simple expressions with easily acquired input and minimal computations. The correlations provide conservative estimates of the smoke layer interface position (i.e., predicting the smoke layer interface to be lower than may be typically expected.)²⁰ The correlations are applicable to simplified cases related to the fire and geometry of the space. Fire scenarios are either steady or growing and follow a t^2 profile. The assumed geometrical configuration is a space of uniform cross-sectional area (i.e., rectangular or right cylindrical solids). In addition to the noted simplifications, second-order parameters such as environmental factors (e.g., stack effect, wind) and the effect of HVAC systems are neglected.

Steady fires: The position of the smoke layer interface for steady fires can be estimated using Equation 13.^{21,22} Equation 13 is based on experimental data from fires in large-volume spaces with A/H^2 of 0.9 to 14.²³⁻²⁵

$$\frac{z}{H} = 1.11 - 0.28 \ln \left(\frac{t\dot{Q}^{1/3}H^{-4/3}}{A/H^2} \right) \quad (13)$$

where $z/H \geq 0.2$.

Equation 13 is presented in nondimensional form. The quantity $t\dot{Q}^{1/3}H^{-4/3}$ represents the normalized time from ignition. The significance of the normalized time parameter is to indicate that the same relative smoke layer position occurs for a long duration, low heat release rate fire in a tall ceiling height atrium, as for a short duration, large fire in an atrium with a short ceiling height. Different atrium geometries are accounted for by the nondimensional shape factor, (A/H^2) .^{23,24}

The limits noted for A/H^2 reflect the range of shape factors for the facilities in which the experiments were performed.^{23,24} Examples of atria within the noted range include atria with a cross-sectional area of 10,000 m² and a height of 105 m ($A/H^2 = 0.9$) or a height of 27 m ($A/H^2 = 14$). Comparisons of the predictions from Equation 13 to experimental data from fires in tall spaces are provided in Figure 4-13.6.²⁵⁻²⁷

The initial time period to form a smoke layer is implicitly included in Equation 13. Evidence of this charac-

Figure 4-13.6. Comparisons of smoke layer position—experimental data versus predictions.

teristic is obtained for short time durations where the resulting z/H is greater than 1.0 (otherwise $z/H > 1$ would literally mean that the smoke layer interface is above the ceiling). The lower limit for z/H of 0.2 relates to the lowest level where data were taken in any of the referenced experiments.

t^2 fires: Equation 14 provides a correlation of the time-dependent smoke layer interface position for fires following a t^2 -type profile.^{21,22} Equation 14 is also based on experimental data in spaces with shape factors ranging from 0.9 to 14.^{25,28}

$$\frac{z}{H} = 0.91 [t t_g^{-2/5} H^{-4/5} (A/H^2)^{-3/5}]^{-1.45} \quad (14)$$

Equations 13 and 14 both assume that the fire is located near the center of the atrium floor, remote from any walls. Smoke production is greatest for the centered configuration and thereby represents the worst-case condition.

EXAMPLE 2:

For a fast, t^2 fire in an atrium with a cross-sectional area of 800 m² and height of 20 m, determine the position of the smoke layer interface after 120 s if the atrium cross-sectional area is 800 m².

SOLUTION:

Applying Equation 14 with $A/H = 2.0$ and $t_g = 150$ s, z/H is 0.95 or $z = 19$ m.

EXAMPLE 3:

For a fast, t^2 fire in an atrium with a cross-sectional area of 800 m² and height of 20 m, determine the time for the smoke layer interface to reach 15 m above floor level.

SOLUTION:

Re-expressing Equation 14 to solve for t ,

$$t = 0.94t_g^{2/5}H^{4/5}(A/H^2)^{3/5}(z/H)^{-0.69} \quad (15)$$

Applying Equation 15 with $A/H^2 = 2.0$ and $t_g = 150$ s, t is 140 s.

Reviewing the results from Examples 2 and 3, the smoke layer barely descends below the ceiling in the first 120 s. This is indicative of the lag time required for the plume to reach the ceiling and to form a layer. Then, after only another 20 s, the smoke layer descends 4 m, demonstrating the rapid initial descent rate of the smoke layer interface. The rapid descent is attributable to the significant quantity of smoke produced during the early stage of a fire in a tall ceiling space. The trend of rapid filling during the early stage of a fire has been reported by eyewitness accounts from four fires in atria.^{7,29-31}

Theoretically Based Approach

Conservation of mass and energy can be applied to provide an estimate for the position of the theoretical smoke layer interface.¹⁹ Equation 16 expresses the conservation of mass, m_u , for the upper smoke layer, assuming no exhaust from the layer

$$\frac{dm_u}{dt} = \dot{m} \quad (16)$$

Approximating the smoke as an ideal gas with properties of heated air, and assuming that the ambient pressure and specific heat are constant, the expression for conservation of energy for the smoke layer is

$$(\rho h)_u \frac{dV_u}{dt} = \dot{Q}_c + \dot{m}h_1 \quad (17)$$

Given the previously assumed conditions, ρh is a constant. Substituting the volumetric flow rate for the mass flow rate and simplifying,

$$\frac{dV_u}{dt} = \frac{\dot{Q}_c}{\rho h} + \dot{V} \quad (18)$$

The growth rate of the upper layer indicated in Equation 18 is dependent on two terms: (1) the volume supplied by the plume and (2) the expansion of the volume due to heating. For the case of an atrium with a constant cross-sectional area, A ,

$$\frac{dV_u}{dt} = A \frac{dz_u}{dt} \quad (19)$$

As long as the smoke layer interface is well above the flaming region (see discussion later in this chapter), the plume mass entrainment rate can be estimated from³²

$$\dot{m} = 0.071\dot{Q}_c^{1/3}(z - z_o)^{5/3} + 0.002\dot{Q}_c \quad (20)$$

For large clear heights (i.e., clear heights in excess of 10 m), several simplifications can be made. The clear height is the distance from the top of the fuel to the bottom of the smoke layer. The magnitude of the second

term is much less than the first. Generally, z is much greater than z_o . In addition, the volume increase of the upper layer supplied by the plume is appreciably greater than that due to expansion. With these simplifications and by substituting Equations 19 and 20 into Equation 18, an expression for dz_u/dt can be formulated

$$\frac{dz_u}{dt} = \frac{k_v\dot{Q}_c^{1/3}z^{5/3}}{A} \quad (21)$$

In Equation 21, k_v is the volumetric entrainment constant, defined as

$$k_v = 0.071 \frac{\dot{Q}_c}{\rho\dot{Q}}$$

The convective heat release fraction is the ratio of the convective heat release rate to the total heat release rate and is typically assumed to be on the order of 0.7 to 0.8. Throughout this chapter, a value of 0.7 is selected for the convective heat release fraction.⁴ Assuming a plume entrainment constant of $0.071 \text{ kg kW}^{-1/3}\cdot\text{m}^{-5/3}\cdot\text{s}^{-1}$ and the density of ambient air as 1.2 kg/m^3 , the volumetric entrainment constant is $0.053 \text{ m}^4/3\text{kW}^{-1/3}\text{s}^{-1}$. One difference between Equations 20 and 21 is that the convective portion of the heat release rate is included in Equation 20, whereas the total heat release rate is included in Equation 21.

An expression for the smoke layer position resulting from a steady fire as a function of time can be obtained by integrating Equation 9:

$$\frac{z}{H} = \left[1 + \frac{2k_v t \dot{Q}_c^{1/3}}{3(A/H^2)H^{4/3}} \right]^{-3/2} \quad (22)$$

Alternatively, for a t^2 fire

$$\frac{z}{H} = \left[1 + \frac{4k_v t (t/t_g)^{2/3}}{(A/H^2)H^{4/3}} \right]^{-3/2} \quad (23)$$

A comparison of the predictions from Equations 13 and 22 is provided in Figure 4-13.6. One principal difference relates to the time delay for the smoke layer to form, i.e., transport lag. Transport lag is included implicitly in Equation 13. Equation 22 assumes that a smoke layer forms immediately. The transport lag can be accounted for separately.¹⁷

EXAMPLE 4:

For a fast, t^2 fire in an atrium with a cross-sectional area of 800 m^2 and height of 20 m , determine the position of the smoke layer interface after 120 s .

SOLUTION:

Applying Equation 23 with $A/H^2 = 2.0$ and $t_g = 150$ s, z/H is 0.72 or $z = 14.4 \text{ m}$.

Vented Period

If a smoke management system includes the capability to exhaust smoke, the descent of the smoke layer can

be arrested if the volumetric rate of smoke exhaust from the smoke layer equals the volumetric rate of smoke supplied to the layer. Neglecting the effect of expansion, the layer descent is stopped when the mass exhaust rate is equal to the mass entrainment rate by the plume. Algebraic equations are available to estimate the properties of the smoke layer, including

1. Position of smoke layer interface
2. Temperature of smoke layer
3. Light obscuration in smoke layer and
4. Gas concentration in smoke layer

Equilibrium Smoke Layer Interface Position

The exhaust rate necessary to arrest the descent of the smoke layer can be estimated based on a knowledge of the mass entrainment rate into the plume. The mass entrainment rate depends on the configuration of the plume. Plume configurations reviewed in this chapter are

1. Axisymmetric plume
2. Wall plume
3. Corner plume
4. Balcony spill plume

Axisymmetric plume: Axisymmetric plumes are formed from fires involving fuel packages remote from any walls (i.e., near the center of the atrium floor). Being remote from any walls, air is entrained around all of the plume perimeter along the entire clear height of the plume. The functional relationship of the mass entrainment rate to the heat release rate and clear height is³³

$$\dot{m} = f(\dot{Q}_c^{1/3} z^{5/3}) \quad (24)$$

The equations for the mass entrainment rate included within NFPA 92B, *Guide for Smoke Management Systems in Malls, Atria, and Large Areas*,⁴ were originally derived by Heskestad.³² One of the equations, previously presented as Equation 20 with z_0 set equal to zero, is applicable when the clear height, z , is greater than the limiting height, z_f . The limiting height is defined as the height of the continuous flaming region, (i.e., where flames are present 50 percent of the time). The limiting height may be estimated as³²

$$z_f = 0.166 \dot{Q}_c^{2/5} \quad (25)$$

The validity of neglecting z_0 in Equation 20 is based on the observation that z_0 is typically small, compared to z .⁴ The location of the virtual origin of an assumed point source can be estimated as³²

$$z_0 = 0.083 \dot{Q}_c^{2/5} - 1.02 d_0 \quad (26)$$

For noncircular fuels, an equivalent diameter needs to be defined. The definition of an equivalent diameter is based on a circle that has an area equal to the floor area covered by the fuel. Considering a wide range of diameters and heat release rates associated with a variety of typical fuel packages, the virtual origin ranges from 0.5 to -5 m. Negative values are obtained when the second

term is greater than the first (i.e., for fuel commodities with modest heat release rates spread over a large area).

For clear heights less than the limiting height, the entrainment rate is estimated using Equation 27

$$\dot{m} = 0.032 \dot{Q}_c^{3/5} z \quad (27)$$

Originally, Equations 20 and 27 were developed to describe plumes from horizontal, circular flammable liquid pool fires. However, these equations have been shown to be applicable to more complex fuels, as long as the limiting height is greater than the diameter of the fuel, and the fire only involves the surface of the material (i.e., is not deep-seated).³²

The mass rate of smoke production estimated by Equations 20 and 27 is independent of the type of materials involved in the fire, other than indirectly in terms of the heat release rate. This is due to the mass rate of entrained air being much greater than the mass rate of combustion products generated, which is true as long as sufficient air is available for combustion. As a result of the fire being approximated as a point source in the entrainment equations, even the shape or form of the fuel is not of primary importance. Thus, the material-related parameters are relegated to a level of secondary importance.

In both Equations 20 and 27, the mass entrainment rate is dependent on the clear height, where the mass entrainment rate increases with increasing values of the clear height. During the early stages of the fire, the clear height has its maximum value to provide the maximum smoke production rate, thereby supporting the eyewitness accounts of the smoke filling process in atria. This is especially true if the flame height is well below the smoke layer, where the smoke production rate is proportional to $z^{5/3}$.

In most engineering applications, the smoke production (or exhaust) rate is expressed in terms of a volumetric rate rather than a mass rate. In order to accommodate this preference, the relationship between the volumetric rate and mass rate is expressed as Equation 28.

$$\dot{V} = \frac{\dot{m}}{\rho} \quad (28)$$

Assuming smoke to have the same properties as air, the density of smoke may be evaluated as the density of air at the temperature of the smoke layer.⁵ Graphs relating the volumetric smoke production rate to the clear height for selected total heat release rates ranging from 1000 to 10,000 kW are provided in Figure 4-13.7.

EXAMPLE 5:

A fire has a total heat release rate of 5000 kW and is located at the center of the atrium floor. The smoke layer interface is 35 m above the floor. Determine the mass and volumetric rates of smoke being supplied by the plume to the smoke layer (i.e., at the location of the smoke layer interface).

SOLUTION:

First, the limiting height is evaluated using Equation 25 to determine the applicable equation for the mass rate of entrainment, assuming the convective heat release fraction is 0.7, $z_f = 4.3$ m. Because $z_f < z$, Equation 20 is the

Figure 4-13.7. Smoke production rate for axisymmetric plumes.

applicable equation for determining the mass rate of smoke production. Neglecting z_o , the mass smoke production rate is 410 kg/s. The associated volumetric rate (from Equation 28, assuming standard conditions) is 340 m³/s.

Wall and corner plumes: Fires located near walls and corners principally entrain air only along the surface of the plume away from the walls or corner. Consequently, the amount of smoke production is reduced for these locations, compared to the axisymmetric plume remotely located from the walls. Using the concept of reflection, the smoke production rate from wall and corner plumes can be estimated.^{34,35}

A plume generated by a fire located against a wall only entrains air from approximately half of its perimeter, as indicated in Figure 4-13.8. According to the concept of reflection, the smoke production rate is estimated as half of that from a fire that is twice as large (in terms of heat release rate).

Similarly, a plume generated by a fire located near a corner of a room is referred to as a corner plume. (See Figure 4-13.8.) Using the concept of a reflection, the smoke production rate from corner plumes, where the intersecting walls form a 90-degree angle, is estimated as one-quarter of that from a fire that is four times as large.

EXAMPLE 6:

A fire located on the floor of an atrium has a total heat release rate of 5000 kW. The smoke layer interface is 35 m above the floor. Compare the mass rates of smoke being supplied by the plume to the smoke layer, given an axisymmetric, wall, or corner plume configuration.

SOLUTION:

In Example 5, $z_f = 4.3$ m and the smoke production rate for the axisymmetric plume using Equation 20 is

Figure 4-13.8. Wall and corner plume diagrams.

410 kg/s. Applying the same equation for the wall plume, the smoke production rate for a fire size of 10,000 kW is estimated as 520 kg/s. Dividing that rate by two provides the smoke production rate for the wall plume (260 kg/s). Similarly, for the case of the corner plume, the smoke production rate is 170 kg/s (considering one-quarter of the smoke production rate from a 20,000 kW fire).

Comparing the smoke production rates for the three plumes (axisymmetric, wall, and corner plumes), the smoke production rate is greatest for the axisymmetric plume (410 kg/s) compared to 260 and 170 kg/s for the wall and corner plumes, respectively. Thus, conservative hazard assessments should assume an axisymmetric plume is developed from a fire that is located away from the walls, near the center of the space.

Balcony spill plume: A balcony spill plume is generated in cases where smoke reaches an intermediate obstruction, such as a balcony, travels horizontally under the obstruction and then turns and moves vertically. Scenarios with balcony spill plumes involve smoke rising above a fire, reaching a ceiling, balcony, or other significant horizontal projection, then traveling horizontally toward the edge of the balcony. Characteristics of the resulting balcony spill plume depend on characteristics of the fire, width of the spill plume, and height of the ceiling above the fire. In addition, the path of horizontal travel from the plume centerline to the balcony edge is significant.

For situations involving a fire in a communicating space, which is immediately adjacent to the atrium, air entrainment into balcony spill plumes can be estimated using Equation 29. Equation 29 is based on Law's³⁶ interpretation of small-scale experimental data obtained by Morgan and Marshall.³⁷ Equation 29 provides an approximation of the mass flow in the plume for a complex situation.

$$\dot{m} = 0.36(QL^2)^{1/3}(z + 0.25H_b) \quad (29)$$

The small-scale experiments simulated the situation of smoke being generated from a fire in a store, discharging out of the store through a single opening, traveling under a walkway serving the level above, then turning and rising once, reaching the edge of the walkway. The applicability of Equation 29 is questionable as a result of appreciable heat losses from the smoke for situations involving smoke discharging from a space connected to the atrium through a long corridor.

Predictions of the smoke production rate using Equation 29 for the balcony spill plume are included in Figure 4-13.9. The calculations represented in the figure consider a 3-m height to the underside of the balcony.

A comparison of the smoke production rate for axisymmetric and balcony spill plumes is provided in Figure 4-13.10. The heat release rate for both fires is 5000 kW, z_0 30 for the axisymmetric plume, and H_b 33 m for the balcony spill plume. For short heights, the smoke production rate for the balcony spill plume is appreciably greater than that for the axisymmetric plume. However, with increasing height, the smoke production rates from the two plumes become comparable. Eventually, the two curves intersect, suggesting that, at some height, the balcony spill plume behaves the same (i.e., produces the same amount of smoke) as an axisymmetric plume. The point of intersection can be determined by setting Equation 20 equal to Equation 29. For large z and z much greater than H_b , the mass flow rates are equal when z is 12.5 times the width. Consequently, for greater heights the smoke production rate from a balcony spill plume should be estimated using Equation 20 with z evaluated from the balcony to the smoke layer.

The width of the plume, W , can be estimated by considering the presence of any physical vertical barriers attached to the balcony. The barriers act to restrict dispersion of the horizontal flow of smoke under the balcony. However, in the absence of any barriers, an equivalent width can be defined, based on results from visual observations of the width of the balcony spill plume at

Figure 4-13.9. Smoke production rate predictions for balcony spill plumes ($H=3\text{m}$).

Figure 4-13.10. Comparison of smoke production rate for axisymmetric and balcony spill plumes.

the balcony edge from the set of small-scale experiments by Morgan and Marshall.³⁷ The definition of an *equivalent confined plume width* is the width that entrains the same amount of air as an unconfined balcony spill

plume. The equivalent width is evaluated using the following expression

$$L = w + b \tag{30}$$

Properties of Smoke Layer

Properties of the smoke layer are of interest both during the filling period of the fire and during the vented period. During the filling period, determination of the smoke layer properties is important to assess the level of hazard prior to actuation of a mechanical smoke management system. During the vented period, smoke layer properties are of interest to assess the level of hazard associated with those cases where occupants are exposed to smoke (i.e., the highest walking level is submerged in the smoke layer). The smoke layer properties of interest include temperature, light obscuration, and gas species concentration.

Temperature rise in smoke layer: The temperature of the smoke layer can be determined based on an energy balance for the volume of the smoke layer. Energy is supplied to the layer by the fire. Energy may be lost from the layer to the enclosure (walls, ceiling) of the space. During the filling period, the resulting expression is¹⁹

$$T = T_o \exp\left(\frac{(1 - \chi_l)Q}{Q_o}\right) \tag{31}$$

Estimates for χ_l vary appreciably. Most of the design guides suggest assuming that the smoke layer is adiabatic (i.e., setting $\chi_l = 0$), in order to be conservative.^{4,38} Walton suggested values for χ_l between 0.6 and 0.9 for relatively small spaces of near cubic shape.³⁹ In many of the large spaces with tall ceiling heights, the temperature rise anticipated for the smoke layer is relatively modest such that convection and radiation heat transfer to an enclosure will also be modest. Consequently, in such applications, the adiabatic assumption will provide reasonable predictions of the temperature rise. However, in low ceiling spaces (under approximately 10 m), the temperature may be significantly overestimated by applying the adiabatic assumption.

Similarly, the equilibrium smoke layer temperature during venting can be approximated by applying an energy balance to the smoke layer. In this case, energy is also lost from the layer due to smoke being exhausted from the atrium.

$$\Delta T = \frac{(1 - \chi_l)\dot{Q}_c}{c_p \dot{m}} \tag{32}$$

If the adiabatic assumption is applied, the smoke layer temperature will be overestimated, providing a conservative estimate of the hazard. In reality, some heat is lost from the upper smoke layer to the surrounding walls and ceiling. However, no elementary method is available to estimate the overall proportion of heat that is lost to the surroundings.^{40,41} Some zone and field computer fire models account for heat losses to the boundary.^{24,42} The adiabatic smoke layer temperature for a range of fire sizes is presented in Figure 4-13.11.

Figure 4-13.11. Temperature rise of smoke layer for axisymmetric plumes.

The degree of overestimation can be assessed by comparing the estimated smoke layer temperature with the plume centerline temperature. For thermodynamic reasons, the smoke layer temperature cannot exceed the plume centerline temperature. The plume centerline temperature, T_c , can be evaluated using Equation 33⁴³

$$T_c = 0.08T_o\dot{Q}_c^{2/3}z^{-5/3} + T_o \tag{33}$$

The volumetric venting rate for other heat release rates or temperature rises may be determined considering that the specific heat is virtually constant for the expected temperature range of interest

$$\frac{\dot{Q}_{c1}}{\dot{Q}_{c2}} = \frac{V_1}{V_2} \frac{\Delta T_{ad1}}{\Delta T_{ad2}} \frac{T_2}{T_1} \tag{34}$$

As can be observed from Equation 34, doubling the volumetric venting rate for the same size fire reduces the temperature rise by approximately 50 percent (the temperature rise is not precisely halved, since the absolute temperature of the smoke layer in both instances is not exactly the same).

Light obscuration: The visibility distance through smoke can be related to the optical density per unit path-length via empirical correlations.^{44,45} (See Section 2, Chapter 13.) The experimental basis for the correlations consists of tests with humans viewing objects through smoke. However, the participants were not directly exposed to the irritating effects of smoke. Consequently, the reported correlations are likely to overestimate the visibility distance.

In addition to the light obscuration quality of the smoke, the visibility of an object is dependent on the light source for the object being viewed as well as ambient lighting conditions.^{45,46}

Mulholland provides the following expression to relate visibility to the optical density (see Section 2, Chapter 13):

$$\text{Visibility} = \frac{0.43K}{D} \quad (35)$$

The optical density of the smoke layer can be determined considering that all of the particulates generated by the fire are transported to the layer via the plume and accumulate in the layer. Any deposition on enclosure surfaces is neglected. The resulting expression for the smoke filling and vented periods are provided as Equations 36 and 37.¹⁹

$$\text{Smoke filling:} \quad D = \frac{D_m \dot{Q}}{\chi_a H_c A (H - z)} \quad (36)$$

$$\text{Vented:} \quad D = \frac{D_m \dot{Q}}{\chi_a \Delta H_c \dot{m} / \rho} \quad (37)$$

The mass optical density is dependent on the fuel, burning mode, ventilation conditions, and operation of sprinklers. The mass optical density can vary by orders of magnitude for different ventilation conditions.

While a reduction in visibility is not directly life-threatening, it does reduce the walking speed of individuals, thereby increasing the exposure time to toxic gases and elevated temperature. In addition, the reduction in visibility may lead to an increased susceptibility to occupants tripping or falling. The relationship between visibility and movement speed is indicated in Figure 4-13.12.

Carbon monoxide concentration: The concentration of gas species contained in the smoke layer can be determined considering that all of the mass that is supplied to the layer via the plume accumulates in the layer. No absorption by the enclosure is assumed. The resulting expressions for the smoke filling and vented periods are¹⁹

$$\text{Smoke filling:} \quad Y_i = \frac{f_i \dot{Q}}{\rho_o \chi_a H_c A (H - z)} \quad (38)$$

$$\text{Vented:} \quad Y_i = \frac{f_i \dot{Q}}{\dot{m} \chi_a H_c} \quad (39)$$

Figure 4-13.12. Relationship between visibility through smoke and walking speed.

In order to express the gas species concentration in units of ppm, Equation 40 needs to be applied

$$\text{ppm}_i = \frac{MW_{\text{air}}}{MW_i} Y_i \times 10^6 \quad (40)$$

Input for evaluating the gas species concentration includes the yield fraction and heat of combustion, both of which are fuel dependent parameters. The yield fraction is dependent on the burning mode and oxygen concentration. Most of the information tabulated on the yield fraction, such as that by Tewarson (see Section 3, Chapter 4), assumes well-ventilated, flaming combustion. Most of the fires of interest in large spaces will involve flaming combustion and are likely to be well-ventilated. However, fires in small, connected spaces may become under-ventilated. Caution needs to be exercised in properly identifying ventilation conditions when predicting these parameters because the yield fraction can vary by orders of magnitude for different ventilation conditions. Also, the yield fractions noted by Tewarson are relevant only to cases where sprinklers are not operating.⁴⁷

EXAMPLE 7:

Estimate the steady-state smoke layer properties (temperature, visibility to an internally illuminated exit sign, and CO concentration) during the vented period, given the following situation:

1. The smoke layer interface is maintained 35 m above floor level.
2. The rate of heat release of the flaming fire is 5000 kW.
3. The fuel is comprised principally of polyurethane foam.

SOLUTION:

Smoke Layer Temperature

Equation 32 can be applied to determine the adiabatic smoke layer temperature rise. In Example 5, a mass rate of smoke production of 410 kg/s was determined. Thus, assuming an adiabatic smoke layer, a convective heat release rate fraction of 0.7 and specific heat of air of 1.0 kJ/kg·K, the temperature rise is 8.5°C.

Visibility

Visibility during the vented period is estimated using Equation 37. Fuel-related parameters are obtained in Section 3, Chapter 4 and Section 2, Chapter 13.

$$D_m = 260 \text{ m}^2/\text{kg}$$

$$H_c = 12,400 \text{ kJ/kg}$$

Evaluating ρ at the temperature of the smoke layer to be 1.17 kg/m³, the optical density is 0.32 m⁻¹ and the associated visibility is 8.5 m.

CO Concentration

CO concentration for the vented period is estimated using Equations 39 and 40, with the fuel-related properties again evaluated from Section 3, Chapter 4.

$$f_{\text{CO}} \text{ for polyurethane is } \sim 0.030 \text{ kg}_{\text{co}}/\text{kg}_{\text{fuel}}$$

The resulting CO concentration in the smoke layer is 31 ppm.

Special Conditions

There are some aspects of smoke management system design which involve special attention. These aspects, which affect actuation of active smoke management systems and the efficiency of exhaust fans, are

- Intermediate stratification
- Confined flow
- Plugholing
- Make-up air supply

Intermediate Stratification

The upward movement of smoke in the plume is dependent upon the smoke being buoyant relative to the surroundings. Delays in activation may be experienced where ceiling-mounted initiating devices are present if the air near the ceiling is warmer than the rising smoke.^{4,48} Dillon⁴⁹ reported measurements of the difference in ambient temperature from floor to ceiling to be on the order of 50°C in some atria with glazed ceilings. A prefire, warm air layer may be created due to a solar load where the ceiling contains glazing materials. In such cases, the smoke will stratify below this warm air layer and not reach the ceiling. Early after ignition, the maximum height to which the smoke plume will rise depends on the convective heat release rate and the ambient temperature variation in the open space.

Algebraic correlations may be applied to address two situations (see Figure 4-13.13):

1. The temperature of the ambient air is relatively constant up to a height above which there is a layer of warm air at uniform temperature. This situation may occur if the upper portion of a mall, atrium, or other large space is unoccupied so that the air in that portion is left unconditioned.
2. The ambient interior air within the large space has a constant temperature gradient (temperature change per unit height) from floor level to the ceiling. This case is less likely than the first.

In the first case, where the interior air has a discrete temperature change at some elevation above floor level, then the potential for stratification can be assessed by de-

Figure 4-13.13. Prefire temperature profiles.

termining the temperature of the plume at the height associated with the lower edge of the warm air layer. Where the plume centerline temperature is equal to the ambient temperature, the plume is no longer buoyant, loses its ability to rise, and stratifies at that height. One correlation for the plume centerline temperature was presented previously as Equation 23.

In the particular case where the ambient, prefire temperature increases uniformly along the entire height, the maximum plume rise can be determined from²²

$$z_m = 3.79F^{1/4}G^{-3/8} \tag{41}$$

where

$$F = g\dot{Q}_c / (T_o\rho_o c_p)$$

$$G = -(g/\rho_o)d\rho_o/dz$$

Assuming standard conditions and that air is a perfect gas, the expressions for F and G are

$$F = 0.0279\dot{Q}_c$$

$$G = 0.0335 dT_o/dz$$

Because dT_o/dz is a constant, $\Delta T_o/H$ may be substituted for the derivative. Substituting the simplified expressions for F and G into Equation 41 yields⁴⁸

$$z_m = 5.54\dot{Q}_c^{1/4}(\Delta T_o/H)^{-3.8} \tag{42}$$

By reformulating Equation 42 to solve for \dot{Q}_c , a minimum fire size can be determined that is just large enough to force the smoke to the ceiling of an atrium without prematurely stratifying due to the increasing ambient temperature.

$$\dot{Q}_c = 0.00118H^{5/2}\Delta T_o^{3/2} \tag{43}$$

The results of an analysis of intermediate stratification are presented in Figure 4-13.14. In one case, a step function is assumed to provide a 30°C change in temperature 15 m above the floor due to the upper portion of the atrium being unconditioned. For the other case, a tem-

Figure 4-13.14. Indoor air and plume temperature profiles with the potential for intermediate stratification.

perature gradient of 1.5°C/m is arbitrarily assumed in an atrium with a ceiling height of 20 m. Plume centerline temperatures from two size fires are graphed based on Equation 23. As indicated in the figure, for the case with the uniform gradient, smoke is expected to stratify approximately 13 or 15 m above the floor, depending on the fire size. For the case involving the step function change in temperature, the smoke stratifies from both fire sizes at the height of the step change in temperature.

If the smoke is expected to stratify at an intermediate height below the ceiling, then something other than ceiling-mounted detectors (such as projected beam detectors) needs to be considered to initiate the smoke management system. The beam detectors should be placed below the height of stratification to intercept the rising plume. In general, once the smoke management system operates, the warm air layer should be exhausted to permit the smoke to reach the ceiling.

Confined Flow

As a plume rises it also widens, as a result of the entrainment of additional mass into the plume. For tall, narrow spaces, the plume may fill the entire cross section of the atrium prior to reaching the ceiling. Above this position, air entrainment into the plume is greatly reduced due to the limited amount of air available. In such situations, initially the bottom of the smoke layer may be assumed to be located at this point of contact. Following a delay to fill the entire volume above the point of contact, the descent of the smoke layer can be estimated by analogy with the ceiling being moved down to the point of contact. The delay to fill the upper volume can be estimated by assuming duct flow, with the velocity estimated as the plume velocity at the height of contact.

In order to determine the point of contact of the plume with the walls, the plume width must be expressed as a function of height. The width of the plume has been addressed theoretically and also experimentally.

Based on theory (see Section 2, Chapter 1), the plume width is expected to be

$$d = 2.4\alpha z \quad (44)$$

where $\alpha \cong 0.15$

$$\text{Thus,} \quad d = 0.36z \quad (45)$$

Experimentally, the plume width is estimated by examining photographs⁵⁰ or the difference between the plume temperature and ambient temperature (i.e., temperature excess at various horizontal distances from the plume centerline).³³ Using temperature measurements, the plume width is defined as the position where the temperature excess is one-half of the value at the centerline.

Handa and Sugawa⁵⁰ developed an empirical correlation of the width of the plume determined from photographs of the visual plume from wood crib fires

$$d = d_o z^{1/2} \quad (46)$$

Heskestad⁵¹ noted that the visible plume diameter was greater than that determined from the temperature excess. Consequently, Heskestad estimated the visible plume di-

ameter to be twice that determined by the excess temperature approach. Thus, the plume diameter is estimated as

$$d = 0.48 \left(\frac{T_c}{T_o} \right)^{1/2} z \quad (47)$$

The plume centerline temperature, T_c , can be evaluated using Equation 23. As indicated in Equation 23, the plume centerline temperature decreases appreciably with increasing height. Thus, for tall spaces, the plume centerline temperature may be close to ambient. For example, at a height of 30 m with a fire size of 5000 kW and T_o of 293 K, T_c is 312 K. In this case $(T_c/T_o)^{1/2}$ in Equation 47 is only 1.03. Because of the rapid decline in T_c with increasing height, for engineering purposes $(T_c/T_o)^{1/2}$ can be approximated as being 1.0. Consequently, in many cases the total plume diameter may be approximated by considering the plume diameter to be approximately one-half of the height.

Considering the variety of analyses for plume width, the plume width is estimated to be 25 to 50 percent of the height above the top of the fuel package, with the 36 percent proportion from theory being near the middle of the range.

Plugholing

Plugholing occurs when the exhaust capacity at a single point is sufficiently large to draw air from the lower layer in addition to smoke. As such, less smoke is removed by the exhaust fans and a deeper layer results. Because a simple method to estimate the proportion of air drawn in from below the smoke layer by the fans is unavailable, an elementary method of estimating the smoke layer depth during plugholing is not available. As such, simple calculations can only be performed to assess the occurrence of plugholing, not the effect.

The original research on plugholing was done for natural vents (see Section 3, Chapter 9). Recently, Loughheed and Hadjisophocleous demonstrated that the plugholing analysis for natural vents was also applicable to mechanical venting.⁵² In order to avoid plugholing, the maximum exhaust capacity at an extract point is

$$\dot{m} = 1.5 \left[g(H-z)^5 \left(\frac{T_s - T_o}{T_s} \right) \left(\frac{T_o}{T_s} \right) \right]^{1/2} \quad (48)$$

Results of applying Equation 48 are provided in Figure 4-13.15 for a range of temperature rise values of the smoke. Where venting capacities greater than the maximum limit are needed to achieve smoke management objectives, multiple extract points need to be provided to avoid plugholing.

Assuming an axisymmetric plume, \dot{m} can be replaced using Equation 20, and the smoke layer temperature can be replaced using Equation 32 (assuming adiabatic conditions) to express the minimum smoke layer depth in terms of the heat release rate and clear height as indicated in Figure 4-13.16.

For a single extract point, the minimum smoke layer depth is slightly less than 40 percent of the clear height. If numerous extract points are provided, each extracting the same exhaust capacity, the d/z ratio without plugholing can be reduced, as presented in Figure 4-13.17. However,

Figure 4-13.15. Effect of smoke layer depth and temperature rise on maximum exhaust capacity.

Figure 4-13.17. Ratio of smoke layer depth to clear height for multiple exhaust points.

Figure 4-13.16. Ratio of smoke layer depth to clear height for single exhaust point.

the d/z ratio is relatively insensitive to the exhaust rate per fan once if more than 5 exhaust points exist. The d/z ratio approaches an asymptotic value of approximately 0.1. While the legend in the figure indicates that only a heat release rate of 5 MW is considered, the same d/z ratio is obtained for a 5 MW fire with an exhaust per fan of 20 m³/s as for a 2.5 MW fire with an exhaust rate per fan of 10 m³/s and a 10 MW fire with an exhaust rate per fan of 40 m³/s. This trend can be generalized by indicating that the same d/z value is obtained as long as the ratio of the exhaust rate per fan to fire size is maintained constant (in this case 4 m³/s-MW).

Makeup Air Supply

The makeup air supplied to the atrium should be

- Uncontaminated
- Introduced below the smoke layer
- Introduced at a slow velocity
- Supplied at a rate less than the required exhaust rate

Air that is not contaminated by smoke can be provided by locating intakes for the makeup air remote from

the smoke exhaust discharge, preventing smoke feedback. In the event that smoke is introduced into the makeup air supply, a smoke detector should be provided to shut down the makeup air supply system. Selection of a smoke detector for this application should consider the operating conditions, range of temperatures, and installation within a duct.

All makeup air should be provided below the smoke layer interface. Any makeup air provided above the smoke layer interface merely adds mass to the smoke layer, which must be added to the required capacity of the smoke exhaust to prevent an increase in the smoke layer depth. If introduced near the smoke layer interface, the makeup air may increase the amount of mixing of clean air with the smoke to further add to the smoke layer.

Makeup air should be provided at a slow velocity so that the plume, fire, and smoke layer are not adversely affected. Makeup air supplied at a rapid velocity near the plume may deflect the plume to enhance the entrainment rate, thereby increasing the rate of smoke production. In addition, the burning rate of the fire may be increased by makeup air provided at an excessive velocity. Because the entrainment process induces an air velocity of approximately 1 m/s, the maximum makeup air velocity in the vicinity of the plume is often recommended to be 1 m/s. Because of the diffusion of air once past the diffuser, the makeup air velocity at the diffuser may be greater than 1 m/s. The relationship of air velocity with distance from the diffuser is outlined elsewhere.⁵³

Finally, the mass rate of makeup air supplied must be less than that being exhausted. Failure to follow this guideline may lead to the atrium being pressurized relative to the communicating spaces. Being at a positive pressure, smoke movement will be forced through any unprotected openings in physical barriers into the communicating spaces.

Limited Fuel

In some cases smoke management objectives may be fulfilled without a dedicated smoke management system due to the intrinsic qualities of the atrium. The intrinsic

qualities of the atrium include parameters, such as the composition and quantity of fuel and geometry of the atrium. As an example, a limited amount of fuel may be present that is unable to sustain a fire for a sufficient period of time to create conditions beyond the allowable limits. The amount of fuel consumed during the time period of interest depends on whether the fire is steady or unsteady. In the case of a steady fire, the fuel mass consumed in a given period of time is determined as

$$\dot{m}_f = \frac{\dot{Q}t}{H_c} \quad (49)$$

Alternatively, for an unsteady, t^2 profile fire, the fuel mass consumed during a given period of time is given as

$$\dot{m}_f = 333 \frac{t^3}{H_c t_g^2} \quad (50)$$

When analyzing the inherent ability of the atrium to fulfill the smoke management design goals, the time period should relate either to the performance of a fire protection system or to the development of smoke layer conditions in excess of acceptable levels. For example, in life safety-oriented designs, the time period may be either that required for evacuation, or for untenable conditions to be generated, whichever is less.

Opposed Airflow

Opposed airflow refers to systems where airflow is provided in a direction opposite to smoke movement. Opposed airflow may be used in lieu of physical barriers to prevent smoke spread from one space to another (i.e., between the communicating space and the atrium). Opposed airflow limits smoke flow by countering the momentum of the smoke attempting to enter the communicating space. A minimum airflow velocity at all points of the opening must be provided in order to prevent smoke migration through the opening. Two empirical correlations to estimate the minimum average velocity for the entire opening are available, based on limited experimental data.⁵⁴ The calculated average velocity is greater than the actual minimum velocity required at a point to oppose smoke propagation. The excess velocity is required so that the minimum critical velocity is achieved at all points, considering the effects of turbulence caused by the edges and corners of the opening.

The minimum average velocity to oppose smoke originating in the communicating space is evaluated using Equation 51.

$$v_e = 0.64 \sqrt{\frac{gH(T_s - T_o)}{T_s}} \quad (51)$$

Alternatively, if the smoke at the opening is part of a rising plume that is rising along the side of the atrium wall, then Equation 52 is applicable.

$$v_e = 0.057 \left(\frac{\dot{Q}}{z} \right)^{1/3} \quad (52)$$

The opposed airflow velocity should not exceed 1 m/s. Above that limit, the airflow velocity may deflect the

plume away from the wall, making more plume surface area available for entrainment. The increased area for entrainment will enhance the smoke generation rate. Consequently, the problem of propagation to the communicating space may be solved by an excessive average velocity; however, other problems may be created by the increased smoke production rate and a possible increase in the depth of the smoke layer in the atrium. The volumetric capacity of the mechanical equipment required to deliver the necessary velocity for opposed airflow can be approximated as

$$V_{oa} = A_o v_e \quad (53)$$

If several openings are protected with the opposed airflow approach using the same mechanical equipment, the cross-sectional area should be the sum of the areas for all of the openings. The opposed airflow technique may be infeasible due to the substantial amount of airflow capacity required to protect numerous openings having a large total area.

Where opposed airflow is incorporated to prevent smoke migration into a communicating space from the atrium, the impact of the volume of air being introduced into the atrium must be assessed. Specifically, if smoke exhaust equipment is also provided to maintain a constant position of the smoke layer interface in the atrium, then all of the additional air used for opposed airflow must also be exhausted. The additional air can be accounted for by increasing the required mass rate of exhaust in the atrium by the amount used for the opposed airflow. The additional air being exhausted will also affect the qualities of the smoke layer within the atrium. (See Equations 32, 37, and 39.) The smoke layer temperature, T_s (K), can be determined using Equation 54, based on an analysis included elsewhere.⁵

$$T = 293 + \left[0.0018 + 0.072 \dot{Q}_c^{-2/3} z^{5/3} + \frac{712 A_o \sqrt{H(T - 293)}}{\dot{Q}_c T^{3/2}} \right]^{-1} \quad (54)$$

Equation 54 must be applied iteratively to determine the resulting smoke layer temperature. In cases with large clear heights, the temperature of the air used for the opposed airflow strategy will be virtually equal to the temperature of the smoke layer to permit the addition of volumetric rates of air rather than mass rates.

EXAMPLE 8:

Considering the atrium from Example 5. There are five 5-m-wide \times 2.5-m-high openings to the communicating space. The bottoms of the openings are 30 m above the floor of the atrium. Considering a 5000-kW fire in the center of the floor of the atrium, determine the following:

1. Minimum airflow velocity required for opposed airflow
2. Volumetric rate of air supply for opposed airflow
3. Capacity of the exhaust fans in the atrium to maintain the smoke layer interface at an elevation 25 m above floor level and also to accommodate the additional air from the opposed airflow approach

CHAPTER 14

Water Mist Fire Suppression Systems

Jack R. Mawhinney and Gerard G. Back, III

Introduction

This chapter is about the engineering of fixed fire suppression systems that discharge water mist. The term *water mist* as currently understood in the fire protection field relates to fine water sprays with no drops larger than 1.0 mm, or 1000 μm (microns).^{1,2} Such sprays are not true mists, however. A *mist* in the scientific sense consists of drops somewhere on a continuum between *aerosol* (particles with diameter $\sim 5 \mu\text{m}$) and *fog* (droplet diameters ranging between 10 and 100 μm). Particles less than 20 μm in diameter take a long time to settle out, and hence create what is recognized in both literature and science as a “mist.” A water mist as intended for fire protection purposes is a fine water spray consisting of a range of droplet sizes, many of which are in the range of true mist particles and some of which are considerably larger. Water mist nozzles produce sprays that have a higher fraction of very fine droplets, in the range of mist, than is typical of standard sprinklers or water spray nozzles.

Fire suppression research performed in the past 50 years typically referred to “fine water sprays” or “finely divided water sprays” as their subject of study. Remarkable success at cooling and extinguishing diffusion flames was documented using fine water sprays with mean di-

ameters less than 0.3 mm (300 μm).^{3,4} The 1950s researchers confirmed the expected improvement in the efficiency of heat absorption due to the increase in surface area available for heat transfer as a spray is divided into smaller and smaller particle sizes. Also, as particles become smaller they settle out less quickly, providing more time for heat absorption and evaporation to take place. More heat is absorbed per unit of mass as the particle size decreases. Thus it was understood that increasing the fraction of very fine water droplets contained in a water spray could reduce the amount of water needed for fire suppression, or in other words, improve the efficiency of application.

The term *water mist* was adopted by the National Fire Protection Association Committee, NFPA 750, *Standard for Water Mist Fire Protection Systems* 2000 edition (current), in the early 1990s as part of the renewed interest in efficient use of water in fire suppression systems. This term distinguishes the technology of NFPA 750 from that of NFPA 15, *Standard for Fixed Water Spray Systems*, 1996 edition⁵ and NFPA 13, *Standard for Installation of Sprinkler Systems*, 1999 edition.⁶ A more thorough discussion of drop size distribution as a significant spray characteristic is presented later in this chapter.

For technical and economic reasons, the knowledge about the advantages of using fine water sprays for fire suppression did not result in an immediate movement to finer sprays for fire protection. Technical concerns included the negative effects of increasing operating pressures to improve atomization, the potential plugging of small orifices with corrosion products, and doubts about the long-term maintainability of equipment. Economic concerns related to the fact that there were less expensive alternatives: either standard sprinklers or the halogenated hydrocarbons—gaseous agents (halons) such as Halon 1301—could be used. So long as water was cheap and halons were available to handle the special hazards, finer water sprays did not offer enough of a suppression advantage to justify their widespread use.

Jack R. Mawhinney is a senior engineer with Hughes Associates, Inc., in Baltimore. He holds a masters degree (1979) in civil engineering from the University of Alberta. He has 35 years experience in fire protection construction and research, including 11 years with the National Research Council, Canada, Institute for Research in Construction. Mr. Mawhinney is chair of the NFPA 750, Water Mist Systems Committee.

Gerard G. Back, III, is a senior engineer with Hughes Associates, Inc., in Baltimore. He has a bachelor degree (1983) in mechanical engineering and masters in fire protection engineering (1996), both from the University of Maryland. In fifteen years with HAI, Mr. Back has conducted extensive fire testing and analysis of the performance of water mist systems for the U.S. Army, Navy, and Coast Guard research and development programs, and for other international clients.

Three events happened in the 1980s that changed the economic background and revitalized interest in using fine water sprays for fixed fire suppression systems. These were

1. The aviation industry response to the Manchester air crash in 1984
2. The 1987 signing of the Montreal Protocol, an agreement to phase out the use and manufacture of ozone depleting substances (halons)
3. An International Maritime Organization (IMO) ruling that required the installation of marine sprinklers on all existing and new passenger ships capable of carrying more than 35 passengers

The Manchester, England, plane crash in 1984⁷ initiated an international effort to develop a fixed water spray system for passenger compartments on aircraft. The SAVE program, as it was called, was funded by the Civil Aviation Authority in England, the Federal Aviation Administration (FAA) in the United States, Transport Canada, and by the major builders of aircraft, such as Boeing and Airbus. The objective of the program was to increase the time available for evacuation of an aircraft passenger compartment exposed to a ground pool fire after a crash landing. Tests were conducted utilizing water spray to prolong the tenability of the space to allow more time for safe evacuation. The SAVE program set well-defined performance objectives relating to tenability.⁸ The design was constrained by the need to minimize the weight of the system. The choice of a fine water spray to maximize the effectiveness of a small quantity of water was a natural outcome of the work. A water mist system that exceeded all of the performance objectives was accomplished. The system extended tenability for 7 min, within the weight and volume constraints, using approximately 10 l of water. The SAVE study demonstrated that a fine water mist system using a limited supply of water could be custom designed to meet very specific objectives, within the constraints of the industry. The aviation industry regulatory authorities, however, did not make such systems mandatory on aircraft, on the basis that the cost-per-life-saved was unacceptably high.⁷

The second key event that spurred interest in fine water spray fire suppression systems was the 1987 signing of the Montreal Protocol, an international agreement to reduce the manufacture and use of ozone depleting substances.⁹ Widely used halogenated fire suppression gases were discovered to be ozone depleting substances. The threat of a phase-out of halon fire extinguishing agents motivated the release of funds for research into alternative fire suppression agents, water among them. Water at least was not likely to be phased out in the future as an environmentally harmful substance. The high-level research into halon alternatives provided a windfall of improved scientific understanding of the physical and chemical nature of combustion and extinguishment processes. Advances in measurement of suppression phenomena, understanding of fire dynamics, and computer modeling of complex fire scenarios were applicable to the engineering design of innovative fire suppression systems. The loss of halons forced the reexamination of old assumptions about the unsuitability of water for certain types of

fires, such as Class B fires in machinery compartments. With improved atomization and reduced flow rates, water could be used where the traditional default had been to use halons. Fine water spray fire suppression systems began to look viable from both performance and economic perspectives as an alternative to gaseous fire suppressants for some applications.

A third congruent event that propelled the use of fine water sprays into the realm of practical fire suppression systems was a move by the International Maritime Organization (IMO) to mandate the installation of sprinkler systems on passenger ships. This very influential rule-making body involves the interests of marine shipping societies, marine regulatory authorities (coast guards), and shipping companies, worldwide. This regulatory action came about as a result of several large life-loss fires on board Scandinavian passenger ferries that occurred in the 1980s.¹⁰ In response, the International Maritime Organization mandated the installation of marine sprinklers on all ships capable of carrying 35 or more passengers, to come into effect in 1995. Marine architects view marine sprinklers as a negative feature in terms of weight, space, and effects on stability. Adding weight to the upper levels of a ship creates potential stability problems, particularly when sprinklers are retrofitted to an existing ship that was not designed to support the additional weight. There were strong economic and technical incentives to develop a system equivalent to sprinklers that would satisfy the intent of the IMO ruling but use less water and weigh less than traditional marine sprinklers. Fine water spray fire suppression systems promised to deliver just that.

Research was conducted to develop performance criteria for fine water spray systems that could be impartially evaluated as equivalent to sprinklers installed on Solas II-2/12.^{11,12,13} The Scandinavian countries Sweden, Norway, and Finland performed development testing that laid the foundation for fire test protocols for marine machinery rooms and for accommodations and public spaces on passenger ships. The Swedish National Testing and Research Institute (SP) in Borås, Sweden; SINTEF, the Norwegian fire research institute in Trondheim, Norway; and VTT Building Technology research facility in Espoo, Finland, were the key centers of development for water mist fire testing. Manufacturers who were interested in developing water mist nozzles participated in the development of the tests. The test results were discussed, modified, and eventually accepted as consensus test protocols at meetings of the IMO fire protection subcommittees.

The availability of substantial funding to support research for Halon alternatives, and the creation of a worldwide market for alternatives to marine sprinklers, were the two most important factors that changed the economic viability of using fine water sprays for fire suppression systems. Now there was financial incentive to support the cost of overcoming the engineering challenges involved.

As a result of the two distinct origins of renewed interest, there are two basic domains of application for water mist systems. One area of application is as a replacement for gaseous fire suppressants such as Halon 1301. Thus, in applications involving Class B flammable liquid fuels—or where clean agents were used because of

concern about water damage—water mist is viewed as a halon alternative. For applications where the water mist systems are installed for Class A fuels (ordinary cellulosic combustibles), a water mist system is viewed as a sprinkler equivalent.

Fundamentals of Water Mist Systems

The following review of the fundamentals of water mist system design covers mechanisms of extinguishment and suppression, and spray characteristics.

Mechanisms of Extinguishment and Suppression

Excellent discussions of the extinguishing mechanisms of water mist from an engineering perspective can be found in References 3, 4, and 14. An understanding of the mechanisms of extinguishment associated with water mist (then called “finely divided water spray”) was articulated approximately 50 years ago.^{3,4} Braidech and Rasbash both concluded that fires were extinguished by dilution of the air (oxygen) with water vapor (steam), resulting from evaporation of water droplets in the area local to the flame. They also concluded that the cooling effects of the water may contribute to the extinguishment of flames.

Mawhinney et al.,¹³ describe three primary and two secondary mechanisms associated with extinguishment of hydrocarbon fires. The primary mechanisms are

- Gas phase cooling
- Oxygen depletion and flammable vapor dilution
- Wetting and cooling of the fuel surface

The secondary mechanisms are

- Radiation attenuation
- Kinetic effects

The extinguishing mechanisms apply to extinguishment of Class B liquid fuel fires as well as Class A solid fuels, although with different importance of one mechanism over another. Typically, all mechanisms are involved to some degree in the extinguishment process.

Gas phase cooling: Gas phase cooling refers to the removal of heat from the flame and hot gases, due to evaporation of water. The cooling efficacy of water mist is due to the fact that the water is broken up into many fine droplets, which enhances the evaporation rate. The more water that evaporates, the greater the amount of heat that is extracted from the flame, and the more the temperature of the flame is reduced. If the flame temperature is reduced below the critical value necessary to sustain combustion (limiting adiabatic flame temperature), the flame will be extinguished. The limiting adiabatic flame temperature for diffusion flames is approximately 1600 K (1326°C).¹⁵ The cooling of the flame also reduces the radiation (thermal feedback) to the fuel surface, thus reducing the pyrolysis rate of the fuel. Scientific work involving the extinguishment of methane/air counterflow flames has been conducted that has shown that water mist/vapor is more effective on a mass basis than Halon 1301, if it can be

delivered at near 100 percent efficiency.^{16,17} The reality is that in full-scale compartment fire suppression, the efficiency of application of water is very much less than 100 percent.

Various attempts have been made to establish a design relationship between the fire size and amount of water needed to extinguish it by gas phase cooling. Wighus¹⁸ defined the term *spray heat absorption ratio* (SHAR), which relates the rate at which heat is absorbed by evaporation of a given mass of water (Q_w), to the rate at which heat is given off by the fire (Q_f).

$$\text{SHAR} = \frac{Q_w}{Q_f}$$

Wighus's experiments showed that, for optimized application of mist to an unconfined propane flame, the heat absorption rate in the water needs to be only a fraction of the heat release rate of the fire, as low as 0.3 under optimum conditions. SHAR values in the range of 0.6 were noted for more realistic machinery space conditions, where small flames can persist in shielded areas to cause re-ignition. (Only enough heat has to be absorbed from the flame to drop the temperature to the limiting adiabatic flame temperature: it is not necessary to drop the temperature to ambient.)

On the surface, it seems promising to use a calculation of the amount of water that must be evaporated to extinguish a fire of a certain heat release rate as a design parameter. In real systems, however, the efficiency of delivery of water mist into flame, hence the rate of evaporation of the droplets in the flame zone, is almost unpredictable, and certainly uncontrollable over the range of conditions encountered in machinery space fires. The SHAR relationship nonetheless holds interesting possibilities for a hydrocarbon extinguishment submodel for use in a computational fluid dynamics (CFD) approach to mist system design.^{19,20,21}

Andersson et al.,²¹ present the concept of the required extinguishing medium portion (REMP). This is the ratio of the mass application rate of extinguishing agent required (m'_e) to the mass rate of fuel consumed (m'_g). The REMP parameter is similar to the SHAR in that a certain mass of water must be evaporated to extract enough heat to extinguish the flame.

$$\text{REMP} = \frac{m'_e}{m'_g}$$

For propane flames, Andersson et al.²¹ measured that the mass application rate of water needed to extinguish a propane flame under laboratory mixing conditions was between 1.2 and 2.2 times the mass burning rate of propane gas. They indicate that this range of REMP values corresponds to a water content volume concentration of 100 to 200 g/m³—that is, the mass of water mist suspended in a unit volume of air. Note that both the SHAR and REMP values were measured under conditions of ideal interaction of flame and mist: the mist was discharged downward into the upward rising plume. The velocity vectors of mist and flame were opposite, resulting in the maximum degree of turbulent mixing in the collision zone. The mass flow rate of mist estimated from the

REMP values should represent the minimum mass application rate. The mist mass flow rate values for real systems could be expected to be higher, to account for inefficiency in delivery of mist to the flame, and variability in the directional aspects of interaction.

The REMP parameter suggests that the mass application rate of extinguishing agent would have to be set for the largest expected mass burning rate of fuel. This assumption does not take into account the simultaneous action of other extinguishing mechanisms, however. As will be discussed shortly, for fires in enclosures, larger fires can be extinguished using less water than smaller fires, due to the increased efficiency of evaporation attributed to the heat confinement and other phenomena. Thus, one would expect the REMP values to go in opposite directions for enclosed fires versus unenclosed fires.

As was suggested for the SHAR parameter, the REMP parameter is potentially useful in a computer sub-model of extinguishment of spray or pool hydrocarbon flames.²⁰

A number of researchers have sought to estimate a critical extinguishing concentration (in g/m^3) of water mist surrounding a diffusion flame. Experimental values range from 100 to 200 g/m^3 ^{21,22,23,24} although values as low as 50 g/m^3 have successfully extinguished heptane flames.²⁵ Although this appears to be a promising possibility for a universal design parameter, it is difficult to make practical use of this value for selecting spray characteristics or nozzle spacing. It is possible to calculate *nominal* total mass discharge per unit volume values for nozzles discharging into a compartment. It is even possible to measure volume concentrations in g/m^3 of mist at various points in a spray, using a particle size anemometer. On the macroscale of a machinery space, however, it is extremely difficult to predict or control volume concentrations at the point of interaction with flame. There are many randomizing events affecting local concentrations of water mist.

Oxygen depletion and flammable vapor dilution: These mechanisms can occur on either a localized or compartmental scale. On the localized scale, as the water droplets are converted to the vapor phase, the volume occupied by the water increases over three orders of magnitude. If the vaporization of the water occurs in the flame, the volumetric expansion can disrupt the entrainment of air (oxygen) into the flame. On a compartmental scale, the production of steam resulting from mist interactions with the flame, hot gases, and/or hot surfaces can significantly reduce the oxygen concentration in the space.²⁶ The oxygen available for combustion is a function of the size of the fire, the compartment volume, and the ventilation conditions in the compartment. As the size of the fire increases, the average temperature in the space increases, and the oxygen concentration decreases due to consumption of the oxygen by the fire and dilution of the oxygen by water vapor. If the combined effects of oxygen depletion due to the fire and dilution by water vapor can reduce the oxygen concentration below the critical value necessary to sustain combustion [limiting oxygen concentration (LOC)], the fire will be extinguished.²⁶ The LOC for most hydrocarbon fuels is approximately 13 percent.¹⁵

Wetting and cooling of the fuel surface: Wetting/cooling of the fuel surface will be in many cases the dominant extinguishment mechanism for fuels that do not produce combustible mixtures of vapor above the fuel surface at ambient temperatures (i.e., solid fuels, and liquid fuels with flashpoints above normal ambient temperatures). Wetting/cooling of the fuel surface reduces the pyrolysis rate of the fuel. If the vapor/air mixture above the fuel surface is reduced below the lower flammability limit (LFL) of the fuel, the flame will be extinguished.

Radiation attenuation and kinetic effects: Water mist and water vapor measurably reduce radiant heat flux to objects near the fire, which assists in preventing fire spread to unburned fuel. Within the combustion zone, *radiation attenuation* is the result of gas phase cooling and the increase in water vapor concentration between the fuel and the flame. Lowering the flame temperature reduces the radiation feedback to the fuel surface. Also, water vapor in the air above the fuel surfaces acts as a graybody radiator that absorbs radiant energy and reradiates it to the fuel surface at a reduced intensity.¹⁹

Kinetic effects may contribute either to flame intensification or to extinction. Flame intensification has been measured¹⁴ as a flare-up of a flame upon first contact with mist. Possibly the turbulence and entrainment associated with the rapid evaporation at the flame surface accelerates the burning rate. Kinetic effects may also be involved in flame suppression, the result of both gas phase cooling and oxygen depletion/dilution. When a diluent (in this case water vapor and recycled, vitiated combustion gases) is added in to the combustion reaction, combined with flame cooling, it is expected that reaction rates at the molecular level are changed. The flame speed may be reduced, rendering the combustion reaction susceptible to being blown out by higher-velocity gas streams.

Enclosure effects, turbulent mixing, and cycling: The importance of enclosure effects is described by Mawhinney, Dlugogorski, and Kim¹⁴ and by Liu, Kim, and Su.²⁷ Enclosure effects maximize the benefits of oxygen depletion and dilution. The hot, vitiated gases collecting in the upper layer of an enclosure are cooled rapidly by the first contact with mist. Vitiated gases plus water vapor are forced down by the spray to the seat of the fire and contribute to extinguishment through oxygen depletion. Depending on the temperature and depth of the hot layer, the rapid cooling results in an instantaneous volume reduction, creating a negative pressure that can suck in the windows or walls of a tight enclosure. If the enclosure had reached flashover temperatures before mist activation, assuming that water could flow through the pipes and mist could be introduced, it is hard to say which phenomenon would dominate, the expansion due to steam generation or contraction due to cooling. At least one manufacturer has investigated a means of allowing an initially small injection of spray to initiate cooling, followed by a gradual increase in flow. Such an approach took the "shock" out of the system. Generally, an automatically activated system will release in the first few minutes of a fire in an enclosure before the upper layer has become too hot and deep. With systems that are man-

ually activated, some thought should be given to the expected effect on introduction of the water mist into a very hot compartment.

Some manufacturers have noticed that turning the spray off momentarily, then on again, can speed up extinguishment in enclosures. The benefits of pulsing, that is, the on/off action of water sprays, also described as cycling, are well described in References 27 and 28. Liu et al.²⁷ showed that pulsing the injection of water mist into an enclosure resulted in more rapid extinguishment, with less total water usage, than continuous application of mist. It was noted that the compartment temperature rose as the fire regrew during the first off stage, allowing for more evaporation of lingering fine mist. The resurgent fire further reduced the oxygen concentration in the enclosure. The next injection of spray further cooled and mixed the oxygen depleted gases. In this manner, cycling appeared to lead to greater net evaporation and oxygen reduction than with steady injection. Liu et al. attributed the improvement of the efficacy of water mist in fire suppression using cycling discharges to the faster depletion rate of oxygen in the compartment and the recurrent turbulent mixing created by cycling discharge.

In some systems cycling was used to avoid too-rapid cooling of the simulated turbine casing in the FMRC test protocol.²⁹ That protocol includes a test to ensure that cooling of the turbine casing will not result in damage to the turbine blades. By having spray on for only 50 percent of the time, not only was the cooling test passed, but also the volume of stored water needed for 10 min of protection was significantly reduced. The manufacturer's design criteria therefore incorporated the cycling as an essential element of system performance. Although the repeated off stages in the cycle had been acceptable for purposes of passing the FMRC test protocol, the author notes that cycling may not always be acceptable in installations where the equipment cannot tolerate re-exposure to flame during an extended off cycle. Furthermore, the apparent benefit is likely to be very dependent on the volume of the compartment.

Explosion hazard mitigation with water mist: This section examines a number of practical questions about the possibility of using water mist to mitigate explosion hazards. Water mist systems have been installed to replace Halon 1301 in gas compressor modules on Alaska's North Slope oil fields. The water mist systems were developed and tested for control of liquid fuel or lubricating oil spray or pool fires associated with the turbines that drive the gas compressors. The hazard also involves the potential for a methane gas leak, ignition, and explosion, however. Because the water mist systems are installed for the fire hazard, the question has been raised as to whether water mist could also provide benefits to mitigate the explosion hazard.

A review of experimental work performed over the last 3 decades reveals that there is mixed opinion about "whether application of water spray will quell or invigorate an explosion."³⁰ It is evident that there were major differences in spray characteristics involved in the various experimental programs, so the data are inconclusive. In general, the literature tends to support the idea that

benefits of using water mist to mitigate explosions are substantial, provided attention is paid to the details of application.³¹

Butz et al.³² investigated the use of water sprays to reduce explosion overpressures from a stoichiometric mixture of hydrogen gas and air released in a test chamber. The test scenario involved creating a mixture of hydrogen and air in a closed chamber, injecting a water spray, and then igniting the mixture. The tests demonstrated that the mist did not stop ignition from occurring, but it required a higher ignition energy than without the mist. The study also indicated that the overpressure generated by the deflagration was reduced by about 15 percent (see Figure 4-14.1). Figure 4-14.1 shows a pressure reduction from 35 to 30 psia "with mist." Butz also measured a significant temperature reduction of the passing flame front, which could reduce the risk of burn injury to personnel who might be exposed to the flash inside a compartment.

Butz concluded that although water mist could not inert the compartment, its use as an explosion hazard mitigant could be justified. The mist concentration required for successful quench (no discernible pressure rise) was found to be 0.7 l/m³. Cooling in the compartment reduced the likelihood of an ignition source persisting, and the water mist appeared to increase the energy required for ignition.

Much research on explosion hazards on offshore platforms has been conducted at British Gas's (BG) Spadeadam facility in northern United Kingdom as part of a multiyear, multi-industry study aimed at improving the oil industry's confidence in its safety systems with respect to hydrocarbon fires and explosions. The results of almost a decade of testing are reported in the project final report.³³

In contrast to Butz's results, work done by British Gas of the United Kingdom and by the Christian Mikkelsen Institute in Norway has shown that water spray augmented the overpressure caused by ignition of a methane-air mixture in a fully enclosed compartment

Figure 4-14.1. Reduction in explosion chamber overpressure due to presence of water mist.³²

Figure 4-14.2. Blast overpressures measured in an enclosure with no open side, with and without water mist, from Selby and Burgan.³³

(Figure 4-14.2). However, in an open compartment (one wall removed) from the test compartment, a reduction in the overpressure was recorded (Figure 4-14.3), but it was a much greater reduction than the 15 percent measured by Butz. This study also pointed out the role that turbulence plays in accelerating the flame front. Both clutter and the injection of large drop water sprays increase turbulence in the gas/air mixture, and thereby contribute to worsen the deflagration. There were significant differences in the spray characteristics of the nozzles used in Butz's and in British Gas's work. British Gas studies were conducted using a water deluge nozzle typically used on offshore platforms, which probably produces spray much coarser than what we now define as water mist. The editors of the industry report conclude that more work is needed, with focus on working with sprays with finer drop size distributions.

During preparation of the first edition of NFPA 750 (1996), a task group of the committee prepared a review of the literature on fine water spray suppression systems. The literature review was longer than could be accommodated in the space available, so it was not published. The collected material is still on file with the NFPA, however. As part of that work, Robert Zalosh of Worcester Polytechnic Institute (WPI) prepared a review of studies on the use of fine water sprays to mitigate explosion hazards.³⁴ Several relevant conclusions based on his review are summarized below:

- In an unconfined environment, high-momentum water spray can entrain air into a gas cloud and dilute it below the lower flammable limit.
- Water vapor can slightly narrow the flammability limits for a gas, and it can dilute the gas/air mixture below the flammability limit. At higher temperatures,

Figure 4-14.3. Blast overpressure reduction due to the application of water mist in an enclosure with one open side, from Selby and Burgan.³³

higher concentrations of water vapor are possible than at lower temperatures, so warm mist is likely to be more effective than cool mist.

- In near-limit gas/air mixtures, the spray/mist can have either a mitigating effect or an exacerbating effect on flame speeds and pressures depending on the turbulence produced by the spray and the characteristic drop size. The mitigating effect has occurred only with gas concentrations only slightly above the lower flammable limit.
- In the case of a very high flame speed with an accompanying shock wave, the spray/mist can reduce deflagration pressures and possibly extinguish the flame because the shock wave breaks up the drops into a micromist with a characteristic drop size on the order of $\sim 1 \mu\text{m}$. These tiny drops can evaporate in a sufficiently short time interval to absorb a significant fraction of the combustion energy released during the deflagration.
- The exacerbating effect that occurs in some situations is due to the turbulence produced by the water spray causing the flame speed to increase and/or causing a larger fraction of the flammable gas to burn.
- Generally, drops do not vaporize rapidly enough to absorb the combustion energy before the deflagration is complete, unless they are very small (i.e., on the order of $1 \mu\text{m}$).
- More widespread use of water spray systems for deflagration control will depend on the viability of generating a micromist with sufficiently small drop sizes. This will require water mist systems that are different from those being developed commercially for fire suppression applications.

Spray Characteristics

Measuring and understanding the characteristics of sprays produced by different nozzles are prerequisites for understanding differences in performance. To fully characterize a spray requires information about the following elements:

- Drop size distribution (DSD)
- Cone angle
- Velocity of the discharge jet(s)
- Mass flow rate
- Spray momentum (product of velocity and mass)

These spray characteristics potentially determine the nozzle spacing as well as ceiling height limitations.

Drop size distribution: It is difficult to discuss water mist without remarking on its most notable feature, the fact that it is made up of finely divided water drops. Except for computer modeling, the drop size distribution of the spray cannot be used explicitly as a variable in the design of a water mist system. That stage awaits the results of further research work. The value in knowing the drop size distribution (and other characteristics) of a water spray lies in the fact that it relates to system performance, such as the rate of evaporation, how spray is affected by obstructions, and the dynamics of the spray interaction with the fire. If we do not measure the differences in drop size distributions of water sprays, we may never be able to explain the differences in performance between different manufacturers' nozzles. For computer modeling of the dynamics of suppression with water mist, a quantitative measure of the drop size characteristics of the spray is essential.

The term *drop size distribution* refers to the range of drop sizes contained in a representative sample of a spray or mist. There is a distribution of small and large drops, which varies with location in the spray as well as with time. For a continuous discharge, the distribution of drop sizes changes with distance from the source as drops collide, evaporate, or hit surfaces and fall out. For a short burst of spray, the distribution measured at a point in space changes with time as the larger droplets pass through quickly, leaving increasingly finer drops, which take more time to settle.

There are a number of ways to present data about drop size distributions of sprays.^{27,28} It is customary in some fields to refer to the size of particles in a spray by a single drop size parameter, such as a Sauter mean diameter (SMD), or volumetric median diameter (VMD). Such single point parameters reveal little about the range of drop sizes in a spray, however. It is important to know about the fraction contained in larger drop sizes and the fraction contained in much smaller drop sizes in a spray, to understand its performance as a fire suppressant.

NFPA 750 has adopted the curve of cumulative percent volume versus diameter to represent the distribution of drop sizes in a water mist. Reasons for this choice are that the cumulative percent volume plot visually reveals the range of sizes, and the volume distribution converts readily to mass distribution, which is the most relevant term for analyzing heat transfer and evaporation rates us-

ing computer modeling. The range of drop sizes can be fully described by characteristic parameters such as $D_{v,0.90}$ and $D_{v,0.50}$. The $D_{v,0.90}$ is the drop diameter at which 90 percent of the volume of a sample of the spray is contained in drops of that diameter or smaller. Similarly $D_{v,0.50}$ is the volumetric mean drop diameter, that is, 50 percent of the volume of the spray is contained in drops less than that diameter.

Spray cone angle: Commercially available nozzles typically produce either 90° or 120° spray cones. Other cone angles are possible but not available as listed nozzles. Typically the sprays are solid cones, not hollow cone sprays.

Spray velocity: There are several aspects of spray velocity to consider. First, velocity is a vector quantity—it has both direction and magnitude. The directions of individual jets define the shape of the spray cone. The magnitude of the jet velocity is the velocity at which water emerges from a small orifice and begins to atomize. Second, there is a transfer of the velocity of the individual jets to the surrounding air (through drag effects). It is the overall velocity of the spray from all the jets, combined with the air entrained in the flow, that contributes to the spray momentum, which dictates the overall impact of the spray on a fire plume.

Discharge rate: The mass discharge rate of a nozzle is a function of water pressure and the total area of the orifice(s). Ideally the discharge rate per nozzle could be designed around the SHAR or REMP values—theoretical minimum application rates relative to the amount of heat to be absorbed. In reality, discharge rates vary for different manufacturers for the same fire test scenario.

Spray momentum: Momentum is calculated as mass times velocity. The combination of the mass of water droplets plus the mass of entrained air, multiplied by the velocity of mist particles plus entrained air, constitutes the momentum of a water spray. In general, for a constant mass discharge rate, increasing spray velocity increases the air entrainment rate, which contributes to the spray momentum. Like velocity, momentum is a vector quantity—it has both magnitude and direction—and its direction relative to the fire plume or fuel source has a bearing on its effectiveness. Where the spray direction is opposed to the fire plume direction, there is penetration of the flame by the water mist, and any water vapor created in the flame may be carried to the seat of the fire. In contrast, codirectional flows may not create the turbulent flame/mist mixing needed to enhance evaporation and cooling, and the water vapor formed will be carried away from the fuel surface rather than pushed down to it. Studies to evaluate the relative benefits of using high velocity or low velocity water mist nozzles must include this directional component of the momentum factor, not only the magnitude of jet velocities. Also, since the entrained air forms a significant proportion of the mass flow rate, it contributes to the momentum of the overall spray cone. Two nozzles with similar jet velocities could have very different degrees of air entrainment—hence the spray momentum for each could differ significantly.

As control over the directional aspects of spray application can be a design choice, spray velocity and spray momentum represent potential first-principles design parameters.

Measurement of drop size distributions: Appendix D of NFPA 750 describes a methodology for obtaining a statistically meaningful measurement of the drop size distribution of a water spray. The drop size distribution in a spray is not the same at all locations in the spray cone. A single reading taken at one location may not be representative of the average condition in the spray. It is standard practice in other engineering disciplines in which drop size distribution is of interest (environmental scrubbers for stack emissions, for example) to take a set of readings and combine them into a statistically representative value.^{35,36}

Figure 4-14.4 illustrates a setup in which spot readings were taken at 24 different positions in the spray, measured on a plane 1 m below the nozzles. The positions for taking a measurement represent the midpoint of sectors of equal area in the circular cross section of a spray cone. A grid of collector pans is used to collect the flux density

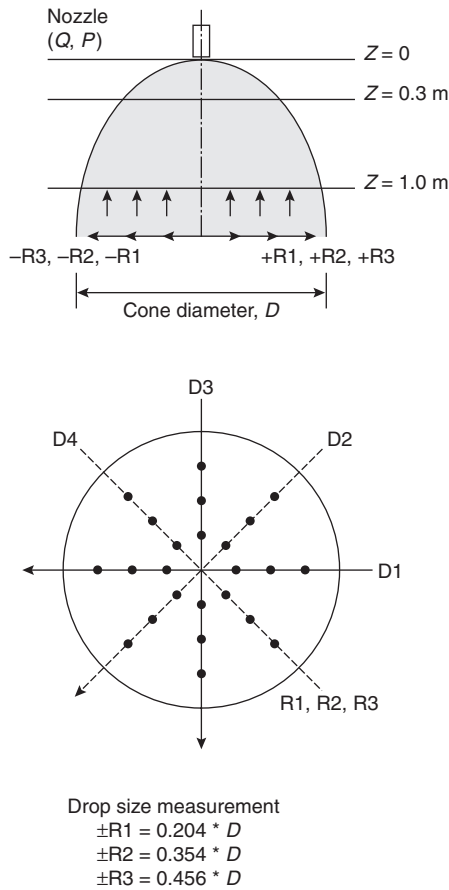

Figure 4-14.4. Locations within spray cones for measurement of flux density distribution and drop size distribution. The positions shown are the centroids of segments of equal area.³⁶

at each of the measurement locations. It is assumed that the drop size distributions measured in areas of high flux density are more representative of the overall distribution than measurements taken in areas of low flux density. Thus, Equation 1 is used to calculate a weighted average drop size distribution curve, weighted according to the flux density measurements at each location.

$$R_k = \frac{\sum_i (R_{j,i} \times A_i \times V_i)}{\sum_i (A_i \times V_i)} \quad (1)$$

where

R_k = weighted cumulative volume percent readings for sizes equal to and less than d_{upper}

$R_{j,i}$ = cumulative volume percent readings for sizes equal to and less than d_{upper} at location i

A_i = area centered at location i in which the size distribution is represented by R_k

V_i = water flux density measured at location i

The NFPA 750 appendix method was used to obtain weighted average cumulative percent volume DSD curves for four commercially available water mist nozzles. Figure 4-14.5 compares the weighted cumulative percent volume drop size distribution curves for the four nozzles investigated.^{37,38} Nozzles A and B were low-pressure single-fluid nozzles; nozzles C and D were high-pressure single-fluid nozzles. It is interesting to note that even the coarsest spray measured (A) had at least 50 percent of its volume (which equates to its mass) contained in drop sizes smaller than 300 μm . Spray B shows approximately 80 percent of its volume (mass) in drop sizes smaller than 300 μm . However, nozzle B discharged at a

Figure 4-14.5. Comparison of statistically weighted cumulative percent volume versus drop size distribution plots for two low-pressure (A and B) and two high-pressure (C and D) water mist nozzles.

rate of 5 l/min (= kg/min) whereas nozzle A discharged at a rate of 12 kg/min. Therefore nozzle A generated about 6 kg/min of drop sizes below 300 μm , while nozzle B produced only 4 kg/min of sub-300 μm droplets. In terms of potential for heat extraction, one cannot conclude that one spray is "better" than another on the basis of drop-size distribution alone. Factors such as discharge rate, cone angle, and velocity also influence the mixing of mist with fire gases in the compartment.

Spray Velocity

As part of the same study referred to for the drop size distributions shown in Figure 4-14.5, measurements of vertical-downward velocity profiles were taken for two of the nozzles.^{37,38} The velocity was measured by placing a vane-type anemometer horizontally in the spray cone at different locations and at two different distances below the nozzle. The anemometer is not measuring the velocity of the spray jets or individual water particles. It measures the vertical component of the velocity of the entrained air plus water drops. Individual drops hitting the rotating vane may either accelerate or decelerate the vane. It was estimated that the effects of individual water drops on the vane speed approximately cancel out, so that the velocity of the entrained air dominates. The measured velocity is then probably less than the velocity of the fastest moving drops, but close to the average velocity of the entrained air.

Figure 4-14.6 compares the downward velocity profiles measured 0.3 m and 1.0 m below a high-pressure (C) and a low-pressure (A) nozzle. These data provide a qualitative means of understanding the difference between how a high-pressure and low-pressure water mist nozzle might interact with the fire plume.

At this time it is not possible to make invariable links between spray drop size distributions, spray velocity, and the suppression efficiencies of different water mist nozzles.

However, without a measure by which different nozzles can be compared, we will not be able to analyze the relative importance of different spray characteristics.

Additives and Health Concerns

Low concentrations of additives, such as alkali salts and the surfactants in AFFF solution, improve the extinguishment capabilities of water mist.^{39,40} In Class B fires, the surfactant spreads over the liquid pool surface, blocks the generation of fuel vapors, and helps extinguish small flames in hidden corners. Extinguishing the small flames helps break the extinction-reignition cycles that prolong the extinguishment of obstructed pool fires. For enclosed systems, the addition of gaseous additives, such as an inert gas (nitrogen or carbon dioxide) to the mist has been demonstrated to enhance extinguishment by aiding in oxygen depletion.⁴¹ Antifreeze and biocides to prevent algae growth are also potential water mist additives.

The use of additives introduces concern about possible negative effects on human health. The U.S. Environmental Protection Agency (EPA) permits the use of water mist as a halon alternative in occupied spaces only when potable water or normal seawater is used.⁴² This permission was based on the response of a panel of toxicity experts convened under the Halon Alternatives Research Corporation (HARC) to questions about the possible adverse health effects of water mist. The report concluded that even the smallest drop sizes in water mist are not present in sufficient quantities to harm humans if breathed into the lungs. However, additives pose a potential threat—if additives are used, the onus is on the proponent of the additive to prove to EPA that it does not pose a health risk.

The report *Water Mist Fire Suppression Systems Health Hazard Evaluation* (1995) was generated by the Halon Alternatives Research Corporation (HARC).⁴³ Members of the NFPA 750 committee provided technical input to the

Figure 4-14.6. Downward spray velocity profiles, measured 0.3 m and 1.0 m below a high-pressure (C) and a low-pressure (A) water mist nozzle.

panel of health experts. The report provides a good background for discussion of concerns over water mist and additives to the water. This report includes a section entitled "Toxicity Profile—Water Mist Spray with Additives" that was prepared for the Army Program Executive Office, Armored Systems Modernization group, by the Toxicology Division, U.S. Army Environmental Hygiene Agency. Some highlights from this document are provided below.

There are concerns with storage of water in cylinders for water mist systems for crew compartments in military vehicles. The major concerns range from toxicology of additives used as antifreeze agents or fire retardants, to bacteriological growth in stored water—that is, untreated stored water in which bacteria are present may pose a toxicological hazard as well as water with chemical additives.

The army report summarizes the available toxicity data on water mist and six potential additives. It recommends additives that are the least toxic, and it identifies additional information required for further evaluation of candidate chemicals:

- Propylene and ethylene glycol (antifreeze)—acceptable
- Potassium acetate and calcium chloride (antifreeze plus fire retardant)—acceptable with reservation
- Potassium iodide and lithium chloride—potentially hazardous to humans

The army toxicity profile report notes that its conclusions do not address the matter of how much additive may be present. Is a product safe at 1 percent but unsafe at 5 percent? Some antifreeze solutions may be as high as 30 to 50% by weight. The concentrations needed for bacteria control may be below harmful threshold. One must distinguish between chronic, or long-term exposure, and short-term, low-probability exposure. These matters need to be addressed before the constraints against use of additives in water mist can be relaxed.

In summary, the U.S. Environmental Protection Agency (EPA) states that only "pure" (i.e., potable) water or natural seawater can be used without question for water mist systems in occupied spaces. If additives are considered, the onus is on the proponent to prove that there is no toxicological risk. This ruling raises a difficulty for anyone (within the jurisdiction of the EPA) who proposes to use an additive in a water mist system intended for an occupied space. The only way to prove an additive harmless is to conduct an expensive medical study.

Fire Suppression Modeling

The major difficulties with water mist systems are those associated with design and engineering. These problems arise from the need to generate, distribute, and maintain an adequate concentration of the proper size drops throughout the compartment while gravity and agent deposition losses on surfaces deplete the concentration. There is currently no theoretical basis for designing these parameters. System design parameters are being extrapolated from large-scale test data on a case-by-case basis. This is expensive to the water mist system manufacturers

and poses special problems for standards-making and regulating authorities.

An empirical understanding of how water mist systems extinguish a fire is now emerging. This degree of understanding is not yet at the stage where water mist systems can be designed from first principles, though significant progress has been made over the past few years.

A basic understanding of the mechanisms of extinguishment associated with water mist was developed approximately 40 years ago.^{3,4} Braidech and Rasbash both concluded that fires were extinguished by dilution of the air (oxygen) with water vapor (steam), resulting from evaporation of water droplets in the area local to the flame. They also concluded that the cooling effects of the water might contribute to the extinguishment process. Research conducted to date has not altered this description. Recent research has, however, identified the primary mechanism(s) associated with extinguishment for a given set of conditions as well as some additional less predominant extinguishment mechanisms.¹⁴

The mechanisms of extinguishment can be broken down into two basic groups—direct and indirect flame interaction. Direct flame interaction includes gas phase cooling and localized oxygen depletion, and indirect effects include global oxygen depletion and surface wetting/cooling effects.

Direct flame interaction encompasses a broad range of both chemical and thermodynamic relations associated with the release and distribution of energy in the combustion process. Extinguishment by direct flame interaction (primarily gas phase cooling) is basically the removal of energy from the flame and hot gases. As the energy is removed from the flame, the temperature of the flame is reduced. If the flame temperature is reduced below the critical value necessary to sustain combustion (limiting adiabatic flame temperature), the flame will be extinguished. The limiting adiabatic flame temperature for a number of hydrocarbon fuels is approximately 1600 K (1326°C).¹⁵

Recent investigations have bounded some of the parameters associated with direct flame interaction.^{20,22} Numerous research programs have focused on identifying the critical mist concentrations needed to extinguish diffusion flames^{17,44,45,46} and to extinguish hydrocarbon pool fires.^{22,47} Other research agencies have studied the effects of water vapor as an inerting gas,^{48,49} as well as the attenuation of radiation to the fuel surface provided by the mist.^{50,51}

The difficulty in predicting extinguishment by direct effects is associated with being able to predict and/or measure the amount of mist reaching the fire. The ability of mist to diffuse into all areas in the space in the same manner as the gaseous agents is significantly limited in the range of drop sizes produced by current commercially available hardware.^{47,52} Recent studies have shown that the concentration of mist decreases by more than a factor of two after traveling less than a meter horizontally away from the spray pattern of a nozzle. To compensate for this limitation, the higher performance water mist systems rely on high-velocity sprays to mix the mist throughout the compartment. The fire size (heat release rate) and fire location are also variables that need to be considered. The

fire tends to alter the mist conditions in the compartment by changing the drop size distribution (vaporization and condensation) and affecting the flow patterns throughout the space due to the plume and ceiling jets.

Additional research has bounded the effects of oxygen depletion and dilution (indirect effects) on extinguishment.^{18,53,54,55} The production of steam resulting from mist interactions with the flame, hot gases, and/or hot surfaces can significantly reduce the oxygen concentration in the space. The oxygen available for combustion on a compartmental scale is a function of the size of the fire, the compartment volume, and the ventilation conditions in the compartment. As the size of the fire increases, the average temperature in the space increases, and the oxygen concentration decreases due to both the consumption of the oxygen by the fire and dilution of the oxygen by water vapor (steam). If the combined effects of oxygen depletion and dilution can reduce the oxygen concentration below the critical value necessary to sustain combustion [limiting oxygen concentration (LOC)], the fire will be extinguished. The LOC for most hydrocarbon fuels is approximately 13 percent.⁵⁶

Fuel surface effects can be the predominant extinguishment mechanism for fuels that do not produce combustible mixtures of vapor above the fuel surface at ambient temperatures, that is, solid fuels and liquid fuels with high flashpoints (i.e., diesel $\approx 60^\circ\text{C}$). Wetting/cooling of the fuel surface reduces the pyrolysis rate of the fuel. If the vapor/air mixture above the fuel surface is reduced below the lower flammability limit (LFL), the flame is extinguished. The ability to predict extinguishment based on surface cooling has also been investigated in numerous experimental programs.^{57,58,59,60} This information includes both Class A materials as well as high-flashpoint hydrocarbon pool fires.

Typically a combination of mechanisms are involved to some degree in the extinguishment process. In order to accurately predict the conditions required for extinguishment, the combustion chemistry, combined with thermodynamics and fluid dynamics, needs to be covered in detail. These complex relations are best analyzed using computational models that are based on first principles. The current mathematical models used to predict suppression of fires by water mist systems cover the range of approaches from zone fire modeling to computation fluid dynamics (CFD), which are often referred to as field models.

A zone model calculates the fire environment by dividing each compartment into one or two homogeneous zones. The energy balance and conservation of mass equations are solved based on a control volume dictated by the boundaries of the compartment for a single-zone model, or by the zonal boundaries for a two-zone model.

The input requirements for zone models vary depending on the model and the desired output. The compartment geometry and opening dimensions are needed to define the space and the surroundings. The thermal properties of the compartment boundaries are needed to estimate the heat loss through the walls, ceiling, and floor. The fire size must be entered, though the model may modify the heat release rate as the oxygen concentration in the compartment is reduced by the fire. Some zone

models account for effects of mechanical ventilation, which means that the fan flow rate and the location of the vent inlets and outlets are required.

CFD models divide the space into a large number of elements and estimate the fire environment in a space by numerically solving the conservation equations (mass, energy, momentum, diffusion, species, etc.) within each element. This is accomplished by using finite difference, finite element, or boundary element methods. The results are three-dimensional in nature and are very refined when compared to a zone-type model. The enormous number of computations performed during these modeling exercises are very time consuming and require powerful computational equipment.

Like zone models, CFD models require a description of the compartment geometry and the openings within the compartment as input. Depending on the sophistication of the extinguishment/fire model, the fire heat release rate may also need to be specified. Heat losses to the compartment boundaries are calculated using the thermal properties of the bounding materials. CFD models may be used to simulate such phenomena as open plumes (bonfires) and shafts since they are not strictly limited to compartment fire scenarios.

Quasi Steady-State Zone Model

Zone fire suppression models for water mist have been developed by Back et al.,⁶⁰ Forssell et al.,⁶² and Vaari.⁶³ All three models assume a single zone and vary in sophistication from steady-state predictions to transient computations.

The quasi steady-state model was developed to predict the effectiveness of water mist systems for extinguishing fuel spray and pool fires in machinery space applications.⁶⁴ The model was developed for obstructed fires where extinguishment primarily occurs as a result of a reduction in oxygen concentration (consumption and dilution) and neglects the effects of the interaction of mist with the flame. Consequently, the predictions made by the model serve as the limiting case where obstructions prevent direct spray interactions with the fire. The model is based on conservation of energy and requires the following input parameters: fire size, compartment geometry, vent area, and water flow rate. The steady-state compartment temperatures and oxygen concentrations predicted by the model can be used to determine the smallest fire (critical fire size) that will sufficiently reduce the oxygen concentration to below the LOC of the fuel.

The energy balance used in the model can be expressed by the following equation:

$$\dot{Q}_{\text{Fire}} = \dot{Q}_{\text{Boundary}} + \dot{Q}_{\text{Vent}} + \dot{Q}_{\text{Vapor}} + \dot{Q}_{\text{Water}} \quad (2)$$

where

\dot{Q}_{Fire} = heat release rate of the fire

$\dot{Q}_{\text{Boundary}}$ = energy lost through the walls, ceiling, and floor

\dot{Q}_{Vent} = energy lost out of the vent opening

\dot{Q}_{Vapor} = heat absorbed by evaporation

\dot{Q}_{Water} = energy absorbed by the mist

The following assumptions were made to simplify the calculation:

- Combustion is complete and takes place entirely within the confines of the compartment (the heat release rate of the fire is a constant).
- The temperature is uniform within the compartment at all times (after discharge), and the gases exhausted are assumed to be at the compartment temperature.
- The exhaust gases and the gases contained in the compartment are assumed to be saturated with water vapor.
- A single surface heat transfer coefficient is used for the entire inner surface of the compartment.
- The heat transfer through the compartment boundaries is unidimensional, that is, corners and edges are ignored and the boundaries are assumed to be infinite slabs.
- Mist droplets are assumed to be heated to the compartment gas temperature.

The individual components of Equation (2) are calculated as follows: The heat release rate of the fire is an input parameter and is calculated based on the known fuel spray or mass burning rate of the fire and the heat of combustion of the fuel. The heat lost through the boundaries of the compartment is determined using an overall heat transfer coefficient developed for preflashover fires. The energy losses by vent gas flow are based on the temperature of the exhaust gases and the exhaust rate determined from a vent flow correlation applicable to well-stirred compartment environments. The heat lost by evaporation is based on achieving the equilibrium vapor pressure (assuming saturation), the vent flow rate, and the heat of vaporation. The heat absorbed by the water is determined from the water mist application rate, assuming all the mist is heated to the compartment temperature.

The computational exercise begins by solving the energy balance to predict the steady-state compartment temperatures in the space and the mass flow rate of air/gases through the vent opening. Once the steady-state temperatures and the mass flow rates are known, the steady-state oxygen concentration is then calculated by first determining the amount of oxygen consumed by the fire and then diluting the remaining oxygen with water vapor until the gases are saturated.

The steady-state oxygen concentrations are then used to predict the critical fire size for the selected compartment configuration and water mist system flow rate. In this context, the critical fire size is defined as the smallest fire that will reduce the oxygen concentration below the LOC of the fuel.

The extinguishment times are predicted using a coupled energy and mass-transfer correlation. The mass transfer is implicit in the following equation, while the energy/temperature dependence is embedded in the volumetric flow rate and predicted steady-state oxygen concentration terms. Assuming that steady-state conditions occur quickly and that the extinguishment of these fires becomes related to the time required to dilute the gases in the compartment, the extinguishment times can be approximated using the following equation:

$$\Delta C_{O_2(t)} = \Delta C_{O_2(ss)}(1 - e^{-\dot{v}t/v}) \quad (3)$$

where

$C_{O_2(t)}$ = oxygen concentration (percent by volume) in the compartment at time t

$C_{O_2(ss)}$ = predicted steady-state oxygen concentration

v = volume of the compartment

\dot{v} = volumetric flow rate of air/gas through the compartment

The extinguishment times are determined by setting $C_{O_2(t)}$ equal to the LOC of the fuel (14% is typically used during this calculation) and solving Equation (3) for t . This approach is a first-order approximation and is best suited to predict the extinguishment times of large fires. This method loses accuracy as the fire size approaches the critical value. The primary outputs of the model are the extinguishment times for a range of fire sizes for a specific compartment configuration and water mist discharge rate.

The model was developed and validated for hydrocarbon fuel fires (both spray and pan fires). The predictions made by the model compared favorably to the results of four full-scale machinery space investigations conducted for the U.S. Coast Guard. For the range of compartment sizes (100–3000 m³) and ventilation conditions [closed compartment, naturally ventilated (1.25–5.7 m^{5/2} ventilation factors), and forced ventilation (25 m³/min)] included in these investigations, the model was able to accurately predict the steady-state compartment temperatures and oxygen concentrations that occurred during the test. In many cases, the larger fires were extinguished before steady-state conditions were reached. This was also predicted by the model. The results of the model were also used to accurately predict the smallest fire (critical fire size) that could be extinguished due to a reduction in oxygen concentration in the space. The model was able to accurately predict the extinguishment times for a wide range of fire sizes, but lost accuracy as the fire approached the critical value.

Although the model shows promise for predicting the steady-state temperatures and oxygen concentrations in an enclosure for a given set of parameters, the limits of the model need to be explored further. The primary assumptions used in the model are that the gases in the compartment are well mixed and saturated with water vapor. The assumption of saturated vapor is a significant limitation, since the model cannot distinguish between water mist systems with similar discharge rates but different spray characteristics. The model also assumes that steady-state conditions are achieved quickly, which may or may not be a good assumption. In order to validate these assumptions, the transient conditions in the space would need to be analyzed. The analysis of these transient conditions significantly increases the complexity of the model.

Transient Zone Models

Two transient zone models that predict the effectiveness of water mist systems to extinguish hydrocarbon fires have also been developed.^{62,63} The two models are similar in some respects but different in others.

With respect to similarities, both models solve the conservation of mass and energy equations as a function of time for a given set of conditions. The conservation of mass equations used in the quasi steady-state model have been replaced by conservation of species. The mass/volumetric flow rate of air through the vent is determined using an orifice flow correlation and the pressure in the compartment similar to the quasi steady-state model. The compartment pressure is calculated from the density and gas temperature in the compartment using the equation of state for an ideal gas. The assumption of saturated vapor used in the quasi steady-state model has been replaced by a droplet evaporation algorithm. The method for predicting extinguishment has also been revisited.

The models are different with respect to how they handle boundary losses, handle drop evaporation, and predict extinguishment. The model developed by Vaari neglects all energy losses to the boundaries, whereas the model developed by Forssell includes a lumped mass boundary heat loss algorithm similar to the quasi steady-state model.

The evaporation algorithms differ significantly between the two models. The algorithm developed by Vaari is fairly detailed, as compared to the simplified version developed by Forssell. In the algorithm developed by Vaari, it is assumed that the heat transfer between the gas and liquid phase is infinitely fast, making the two phases identical temperatures. As a result, all of the heat absorbed by the drop is utilized in the evaporation process. The algorithm includes drop concentration and drop size subroutines that include drop agglomeration and terminal velocity predictions. Using the Clausius-Clapeyron equation to calculate the vapor pressure near the drop surface, the mass transfer number (B) for a single drop is determined. This mass transfer number is then used to determine evaporation rate for a single drop, which in turn is applied to the entire spray.

In the algorithm developed by Forssell, the evaporation model has been simplified and incorporates a correlation constant that represents the combination of the mass transfer number (B) and the surface area-to-volume ratio of the droplet. Rather than including a set of subroutines based on a large number of assumptions that need validation, Forssell chose a single empirically fitted correlation constant.

The extinguishment algorithms are also somewhat different in the two models. In the algorithm developed by Vaari, extinguishment is predicted based on a calculated flame temperature determined based on an energy balance conducted in the flame. For this calculation, a limiting flame temperature of 1550 K was selected. This energy balance calculates the temperature of the gases in the flame region by taking into account the species concentrations in the combustion process as well as the mist entrained into the flame. In order to estimate the amount of water droplets entrained into the flame, a simple mist concentration algorithm was developed based on mist discharge rate, terminal drop velocity, and compartment height.

Forssell selects a critical oxygen concentration (14%) to predict extinguishment, similar to the quasi steady-state model. This is basically equivalent to the previous

approach with the exception that the entrainment of mist into the flame is not included in the computation.

Both transient models provide as output the gas (species) concentrations and temperature histories in a compartment for a given compartment configuration, ventilation condition, and fire scenario. The advantage of the transient models over a steady-state computation is that they provide the capability to study scenarios that never achieve steady-state conditions. Two examples of these are growing fires (fires with varying heat release rates) and variable flow rate water mist systems. Both transient models include evaporation algorithms, which, in theory, should allow the distinction between two mist systems with similar discharge rates but different spray characteristics. The transient models should also predict extinguishment more accurately than a steady-state model. The limitations are associated with the single zone approximation and the need for experimental data to define the unknown parameters used in the model. The single zone approximation may cause the model to fail if the space is not well mixed or the fire is allowed to burn for a significant duration prior to mist system activation. Neither of the two transient zone models have been thoroughly validated. However, the limited validation data show promise with respect to the accuracy of these models.

CFD Models (Field Models)

CFD models are a level of sophistication above typical zone models and show promise for handling the complex physical and chemical relations required of this application. As stated previously, CFD models divide the computational domain into a large number of small control volumes and solve the conservation equations (Navier-Stokes) in each one simultaneously. CFD models can provide detailed information on the mass/energy transfer between the fire and the water mist, and on the distribution of water spray droplets in the compartment.

Like zone models, CFD models require a description of the compartment geometry and the openings within the compartment as input. Compartment contents and boundary materials must also be specified. The model is run for a specific set of conditions (compartment configuration, fire scenario, and water mist system). The outputs are very detailed in nature and consist of data files containing information pertaining to the conditions (temperature, velocity, mist concentration, gas/species concentrations, etc.) for each element and time step in the computation. This detailed information allows a graphical/visual representation of the conditions in the compartment during selected time intervals. For example, color contour temperature images and velocity fields represented by small arrows, with the magnitude of the velocity indicated by the length of the arrow, are typical outputs for CFD modeling runs. These outputs allow the visualization of the conditions that occur in the compartment during a specific scenario.

Some of the CFD models currently in use include JASMINE, FLOW3D, PHOENICS, SOFIE, TASCFLOW, VULCAN, STAR-CD, and the Fire Dynamics Simulator (FDS), but only a limited number of them have been used to model water mist applications. Many of these models contain variants of the K-Epsilon submodel required to

handle the turbulent conditions produced in this application. K-Epsilon submodels are two additional differential or algebraic equations (where K is turbulence energy and Epsilon is its dissipation rate) that relate turbulent stresses and fluxes to the flow field.

The primary limitations for applying CFD modeling to water mist applications are associated with the lack of knowledge/algorithms to determine fire extinguishment and accurately predict drop transport. Detailed extinguishment algorithms must include an energy balance conducted in the flame and at the fuel surface while completing the combustion process. This combustion process must take into account the following species concentrations: fuel vapor, water vapor, oxygen, nitrogen, combustion gases, and water mist concentration. In most cases, the fuel vapor concentration is driven by the radiation from the flame back to the fuel surface and must be solved simultaneously. The difficulty with drop transport is associated with linking the liquid water droplets to the gas phase domain and showing the influence of one on the other. Recent research has focused on the development of some extinguishment algorithms, but only limited attention has been given to drop transport.

With respect to extinguishment algorithms, the physics and computational issues associated with numerical modeling of fire suppression have been identified.^{64,65} Additional studies have focused on specific fire types and scenarios. The National Institute of Standards and Technology (NIST) and the Naval Research Laboratory (NRL) have both recently developed algorithms to predict suppression of opposed flow diffusion flames.^{66,67} Limited research has also been conducted on premixed flames as well.⁶⁸ On a larger scale, extinguishment algorithms have also been developed for pool fires.^{69,70} While these advances are promising, there is still the need to develop an all-encompassing extinguishment algorithm capable of handling a variety of fuel types and configurations to be used with CFD modeling.

The manner in which the spray characteristics of the nozzle affect drop transport and the transport phenomenon in general also needs additional research. Although the effects of fire plumes and ceiling jets on water droplets have been investigated in numerous research efforts,^{71,72} the problem lies more on a fundamental level. Drop transport and tracking is currently being performed using either Eulerian or Lagrangian formulations.^{73,74} An Eulerian formulation uses a fixed grid and assumes the drops pass through (drops and gases travel at different velocities), whereas the Lagrangian formulation considers the droplets and gases to be a single homogenous mixture. A majority of the water mist modeling has been conducted using the Lagrangian formulation, but the information found throughout the literature is very inconclusive regarding the choice of the appropriate method.⁷⁵ The appropriate formulation may depend on the spray characteristics of the nozzle as well as on the application.

A limited number of studies using CFD models for full-scale fire suppression research have been carried out by Hadjisophocleous.^{71,76} The research includes the extinguishment of liquid pool fires in both open and closed compartments, and fire suppression in an aircraft cabin. The modeling was performed using the CFD model

TASCFLOW with the water spray transport handled using a Lagrangian tracking model. During the initial study,⁷¹ water mist system parameters (the number of nozzles, nozzle locations, spray characteristics, and discharge rate) were systematically varied to determine their effect on the extinguishment process. The predicted results showed reasonably good agreement with corresponding experimental data.

The strengths of CFD modeling are associated with its capabilities to analyze the detailed chemical and thermodynamics processes required of this application. The graphical/visual nature of the output can illustrate the physical phenomena occurring during the event. The limitations are associated with the need to develop and validate algorithms to predict both drop transport and extinguishment. The ability to apply CFD modeling to a specific application (grid selection) is time consuming and requires a certain level of expertise. The licensing of the CFD code and the computing power required to run the model also significantly increases the cost of the effort.

The results obtained using CFD modeling demonstrate that it is a promising tool for analyzing the complex physical and chemical phenomena of fire suppression by water mist. CFD modeling has demonstrated the potential to extend the understanding of the relationships between the water mist systems design parameters and fire suppression. CFD modeling not only has the potential to augment the test and evaluation process, but also shows promise for approving specific designs for actual installations. The potential for CFD modeling as a research and design tool is now being recognized. CFD modeling is already being used as a research tool at NRC Canada, NRL, NIST, SP, SINTEF, and at numerous universities.

Summary

An empirical understanding of how water mist systems extinguish a fire is beginning to emerge. Although progress has been made over the past few years, this degree of understanding is not yet at the stage where water mist systems can be designed from first principles, though significant progress has been made over the past few years. In order to accurately predict the conditions required for extinguishment, the combustion chemistry, combined with thermodynamics and fluid dynamics, needs to be covered in detail. These complex relations are best analyzed using computational models. The current mathematical models used to predict suppression of fires by water mist systems cover the range of approaches from zone fire modeling to computation fluid dynamics (CFD), which are often referred to as field models.

Three zone models (one steady-state and two transient) have been developed to predict the effectiveness of water mist systems against hydrocarbon fuel fires (both spray and pan fires). The models appear to make reasonably accurate first-order approximations of the extinguishment of a range of fire sizes for a given compartment configuration and set of mist system characteristics. The strengths of the zone models are their ability to bound the capabilities of a water mist system for a given application. The limitations of these zone models are associated with a general lack of detail incorporated in the computation,

and as a result, these models may lose accuracy when applied to complex configurations (geometries).

CFD modeling has been demonstrated to be a promising tool for analyzing the complex physical and chemical phenomena of fire suppression by water mist. Additional research is required to further develop and validate both the drop transport and extinguishment algorithms used in the CFD codes. The strengths of the CFD models are their ability to expand the understanding of how the water mist system design parameters effect the extinguishment process. The limitations are associated with the high labor and equipment (computer and software) costs required to model a specific application.

In any case, modeling has the potential not only to augment the test and evaluation process, but also to aid in approving specific designs for actual installations.

The Importance of Fire Testing

In the absence of a large empirical database of design criteria and a set of general principles that applies to all water mist hardware, NFPA 750 requires that all water mist system designs be linked to formal fire tests. Testing has shown that the performance of water mist systems is dependent on the specific manufacturer's equipment, particularly the nozzle design. One manufacturer might pass a fire test program at a particular flow rate and nozzle spacing. Another might operate at a lower pressure but have a higher flow rate and closer nozzle spacing to pass the same test. The average flux density for the two systems may differ by a factor of 3! Consequently, it is not yet possible to set generic design criteria (such as nominal flux density for a particular fire scenario) that are independent of the manufacturer's equipment. It appears that barely perceived differences in atomization, spray cone angle, and velocity influence the ability of the spray to mix and cool hot gases and extinguish a fire. The only way to be sure that a particular manufacturer's water mist system will work in a given application is to conduct fire tests.

If a water mist system is "listed" for an application, the system design criteria and performance objectives have been validated through fire tests conducted by a recognized testing laboratory. Table 4-14.1 shows a list of fire test protocols recognized in North America and Europe. Test protocols are intended to test the limits of performance of systems against a realistic range of conditions, including worst-case scenarios, and to establish agreed-upon and measurable performance objectives. Considerable thought and experience go into achieving consensus on the test scenarios. In North America, end users of water mist technology tend to rely on third-party listings by Factory Mutual Research Corporation (FMRC) or Underwriters Laboratories (UL) to confirm suitability. In Europe and Asia, end users are more likely to accept the results of ad hoc testing. Probably the major differences between an ad hoc tests program and a formalized test protocol are the degree of effort put into looking for failure conditions, range of applicability, and breadth of criteria for judging acceptability. Ad hoc tests will be very specific to an application. Ad hoc testing is easier to carry out and less costly than developing a consensus test protocol. World-

wide, many ad hoc water mist test efforts have taken place and continue to take place. Examples include local application systems;²⁵ high-voltage cable tunnels;⁸¹ railway tunnels;^{82,83} heritage properties, libraries, and archival storage on fixed shelving;^{84,85} electronic equipment rooms;⁸⁶ computer room underfloor areas;⁴¹ aircraft cargo bays;⁸⁷ and outdoor transformers.⁸⁸ Some of those ad hoc test programs will eventually become formal test protocols. Manufacturers for the most part bear the cost of conducting these tests.

For marine applications, consensus test protocols have been developed through the International Maritime Organization. For land-based industrial applications, formal test protocols have been developed by FMRC for turbine enclosures, machinery spaces, and pump rooms where liquid fuel fire hazards exist (see Table 4-14.1). FMRC has also developed a test protocol for wet benches in clean room environments. Both FMRC and UL have test protocols for light and ordinary hazard applications that are based on the IMO test protocols for crews' quarters and public spaces on ships.

The existence of a listing simplifies the problem of matching a water mist system to a particular hazard. At the same time, complete reliance on a generalized listing, without checking that the performance promised by the listing meets the end-user's actual needs, can be a mistake. The fire protection engineer responsible for the design of a water mist system must confirm that the application is close to the conditions of the listing. He or she must also check that the performance criteria used to judge pass or fail in the test protocol are compatible with the end-user's needs in the actual installation. In some cases the performance requirements of the listing may be lower than what the end-user really needs, so measures to upgrade performance will be required.

Appendix C of NFPA 750² describes a number of fire test protocols in detail. Note that the criteria by which systems are deemed acceptable are decided by consensus of a committee. Successful performance does not necessarily mean extinguishment of the fire. For example, the IMO tests for accommodation spaces and public spaces on ships require only that the fire be controlled for a period of ten minutes. At the end of ten minutes, the fire is manually extinguished, and a damage assessment is made. Fire extent and damage to the test materials must be within certain limits. During that ten minutes, the fire continues to burn, and if the water mist system is shut off, the fire will regrow. The IMO machinery space protocol, on the other hand, does require extinguishment of all fires, including small, hidden bilge fires. To achieve extinguishment, the system designers are permitted to utilize combinations of total flooding ceiling nozzles and screening nozzles over the ventilation opening, as well as the addition of surfactants to the water supply. In some cases, separate bilge protection systems are incorporated.

Development of Fire Test Protocols

In the absence of a generalized design method based on engineering first principles, water mist systems must be "listed for specific hazards and protection objectives." It is the intent of NFPA 750 that such listings be obtained

TABLE 4-14.1 *Fire Test Protocols for Water Mist Fire Protection Systems as of September 1998*

through full-scale fire tests and system component evaluations conducted by internationally recognized laboratories to demonstrate that reasonable performance objectives can be met. New potential applications of water mist arise continuously, for which ad hoc test procedures must be developed. With respect to fire test protocols, the intent of NFPA 750² is as follows:

- The test protocols shall be based on a fire protection engineering evaluation of the fire hazard, the compartment conditions, and the performance objectives for the system.
- The test protocols shall be developed, carried out, and interpreted by recognized fire testing laboratories.

The design of a meaningful fire test scenario includes the following steps:

1. Simulate the compartment conditions and fuel geometry (volume, height, width, and elevation of ventilation and exhaust openings).

2. Be able to vary the ventilation conditions to determine sensitivity of the performance to ventilation factors.
3. Select the fuel arrangement that simulates the expected combustibility and fire growth rate. This may require conducting a review of the end-users' facilities to establish a realistic fuel geometry. Obtain enough fuel packages to do repeatable tests.
4. Establish meaningful and measurable performance objectives, neither too high nor too low.
5. Develop an experiment plan to test the range of parameters for the water mist system design: nozzle selection, cone angle, K-factor, operating pressure (hence, flow rate), nozzle locations, spacing, and orientation.

Test protocols developed in the above manner may eventually be recognized as the basis of a listing. The full listing process culminates in the following outputs:

- A report showing the results of the fire tests
- A report summarizing the results of the component evaluations. This is intended to verify the functional-

ity, durability, corrosion, and environmental resistance of the key components

- A design and installation manual explaining the correct application, installation, and maintenance of the specific equipment. The nozzle characteristics; spacing between nozzles, and maximum distances from walls, ceilings, or obstructions; minimum operating pressures; and water supply requirements are all documented in the manual.

Engineering Details of Water Mist Systems

Design of water mist systems at this stage requires validation through full-scale fire testing. This may be viewed as a negative factor, in that it increases the cost of development of new markets. On the other hand, it creates an opportunity to depart from the constraints of traditional fire protection system design, given that system performance can be validated through testing. If you have to test, why not experiment a little? New ideas have emerged in setting performance objectives for a wide range of fire suppression challenges. There has been much innovation in equipment design. We now have cycled discharge, compressed gas storage, positive displacement high-pressure pumps, and the use of new materials approaches to fire detection and release. New types of nozzles require new types of distribution systems, and new approaches to commissioning and acceptance testing. This section describes a few of the engineering concepts that have been introduced as a result of water mist system research and development.

Types of Water Mist Systems

There are several engineering criteria by which to distinguish one type of a water mist system from another. NFPA 750 refers to three types by *application*: total compartment application, local application, and zoned application systems. Whether a system is a pre-engineered or an engineered system is also discussed under this heading. System types can also be distinguished based on the *method of spray generation*: single-fluid or twin-fluid nozzles. A third division into type is based on the *pressure regime*: low-, intermediate-, or high-pressure systems. This latter division also covers both constant-pressure systems supplied by a pumped source, and declining-pressure systems driven by compressed gas. The following discusses the important engineering features associated with each type of system.

Application systems: As has been noted, water mist systems are most efficient in enclosed compartments where the confinement of water vapor and the normal oxygen depletion caused by the fire can contribute to the extinguishment of even-shielded fires. If the compartment is very large relative to the size of the fire, these enclosure effects are diminished, and more attention must be paid to projecting water mist to the seat of the fire. Thus the approach to setting design criteria will differ depending on the nature of the compartment.

Total compartment application (TCA) systems consist of open nozzles distributed throughout the compartment according to the manufacturer's spacing rules. Open nozzles are used so that water is discharged from all nozzles upon opening of a control valve. TCA systems benefit from enclosure effects (capture of heat, confinement of water vapor, and recirculation of oxygen-depleted gases). TCA systems should not be referred to as "total flooding" systems, because water mist does not extinguish fire in the same manner as a gaseous total flooding agent.⁵² Unlike a total flooding gaseous system, it is not enough to inject a fixed quantity of mist into a compartment, close the door, and expect the fire to go out. The amount of time needed to extinguish a fire varies according to the compartment size and size of fire. Therefore, water mist must be injected continuously for a sufficient length of time to bring about control. Gaseous agents require 100 percent integrity of the compartment boundaries to contain the suppression agent, whereas total compartment water mist systems may be effective with fairly large openings in the compartment.⁶¹

When activated, water is discharged from all nozzles in the manner of a deluge system. It is intended that TCA water mist systems be activated automatically by a separate fire detection and release system. The detection of fire is relatively straightforward since any fire signature picked up anywhere in the compartment initiates release of a single valve. In that case, the fire may be relatively small at the time of activation but may continue to grow for a short period before enclosure effects begin to come into play. In some marine or military applications, however, manual activation of the system is permitted. Some caution should be observed in the design of a system intended to be manually released. If there is a long delay in activation, the combustion gas layer in the compartment may become quite hot and deep. The empty piping and nozzles may become so hot that water will boil explosively, rupturing the piping system. If water reaches the nozzles, the sudden introduction of water mist into the hot gas layer may result in a very rapid cooling, which creates a strong negative pressure in the compartment. During experimental work at the National Fire Laboratories at National Research Council Canada, one wall of a 60-m³ test enclosure deflected inward and ripped open along the ceiling line when water mist was injected after a 90-s preburn of a 750-kW pan fire. Similar negative pressure spikes were described in Reference 39. The potential for doing damage to the structure upon activation of the mist system in a tight enclosure is not generally noted as a concern in most test protocols, but perhaps it ought to be.

One major drawback to TCA systems is that they demand a lot of water. Many nozzles discharging a small amount of water still adds up to a lot of water! As compartment size increases, there will be a point at which it is unreasonable or unaffordable to discharge water throughout the entire compartment for a fire in a limited area of the compartment. The removal of runoff from a total compartment application system should also be considered as part of the design of the system.

Total compartment systems may be designed for a range of objectives. The IMO machinery space systems

are intended to completely extinguish the fire in a specified period of time. The nozzle spacing and flow rates are designed to meet that challenging objective. On the other extreme, TCA systems have been installed in Norwegian historic wood stave churches to achieve flashover suppression^{37,83,84} at much lower flow rates. For flashover suppression a fine mist is injected into the upper portion of the compartment to cool the fire gases and reduce thermal feedback to the objects in the compartment, which prevents flashover from occurring. The amount of water that strikes the painted icons on the walls is minimized. Extinguishment of the source fire is achieved by installing nozzles at floor level that discharge water spray at a much higher rate than the ceiling nozzles, without damaging the treasured wall paintings. The lower nozzles are local application nozzles that work in concert with the total compartment system.

Local application (LA) systems are arranged to discharge directly on an object or hazard in an enclosed, partially enclosed, or open outdoor area. Since there may be little confinement of heat, water vapor, or vitiated gases, extinguishment will depend almost entirely on gas phase cooling or wetting of the fuel. To achieve extinguishment will require direct projection of mist to all areas in which fire can persist. Local application systems do not necessarily have to achieve extinguishment. As with the TCA system, it may be sufficient to use the local application system as a screen to block radiant heat from igniting or damaging equipment. Local application systems are considered as necessary subparts of some machinery room systems on ships and in industrial process buildings. Although there must be a TCA system of nozzles installed, the compartment ceiling may be so high that specific equipment must be surrounded with local application mist nozzles to ensure control. Thus a local application system may be installed around specific hazards such as diesel engines, flammable liquid or vapor compressors, or large turbines in an open floor area.

Local application water mist systems may be considered for industrial food processing burners, deep-fat fryers, outdoor transformers, flammable liquid storage racks, and a host of special equipment. As with all water mist systems, NFPA 750 intends that engineering design of local application systems be based on fire testing. There is an FMRC test protocol for a water mist local application system designed for wet benches in clean rooms. VDS in Germany has test protocols for local application systems for engine test cells and electric cable tunnels (see Table 4-14.1). The IMO committees have proposed test protocols for local application system nozzles for marine machinery spaces. One proposed protocol is to mount a single nozzle above a small liquid fuel pan fire, and measure how far to one side it can be moved before it fails to extinguish the fire. This distance is taken to represent one-half the required nozzle spacing. Another proposed test protocol calls for constructing a machinery room mockup with a three-dimensional grid of nozzles surrounding the object. The petroleum industry has examined the use of water mist nozzles around outdoor pumping equipment. The distance of nozzles from the object, spacing between nozzles, height of nozzles above the object, flow rates, and cone angles all must be selected on the basis of ability

to meet the test performance criteria. Criteria for judging the performance of the systems must be based on analysis of the specific needs of the application.

As discussed for the total compartment applications, choice of fire detection and release strategy for local application systems is an important part of the design of the system. Some are intended to be manually released, whereas others incorporate special detection systems customized to the application. The detection system, release, and delivery equipment must be carefully matched to the conditions dictated by the hazard.

Zoned application (ZA) systems are designed to protect hazards in a portion of an enclosure, negating the need to fully deluge the entire compartment. The usual incentive for zoning a system is to reduce the overall water flow requirement to a quarter or third of that required by a total compartment application system. The method of extinguishment may be as per a local application system, although enclosure effects may also be contributors. Design of the detection and release system is of critical importance in developing a ZA system. The designer must determine how small to make the zones, how to match the size of the detection zone to the size of the hydraulic system zone, and how many zones must activate to cover the worst-case scenario. A water mist system consisting of individually thermally activated nozzles (as for the marine sprinkler systems) is in essence a zoned application system, in which each nozzle is a combined detector and control valve.

In a proposed water mist system for a 9-km cable tunnel in Auckland, New Zealand, fire testing had established nozzle spacing, positioning, and flow rate.⁸¹ A total compartment application was out of the question. It would not be possible to activate all open nozzles along the 9-km tunnel—the resulting water demand would require very large feed mains and intermediate booster pumps. Also, the cost of pumping all that water out of the tunnel after discharge would be considerable. The use of individually thermally activated nozzles to limit the number of nozzles activated would be defeated by the strong ventilation air movement of 5 m/s, which would carry heat along the tunnel away from the nozzles closest to the fire. The alternative was to release the system in zones that would extend upstream and downstream of the fire source. The difficulty lay in selecting a means of detecting a fire and pinpointing its source so that the nozzles in the immediate vicinity of the fire could be activated.

Often limitations in the detection technology in adverse environments dictate the minimum size of a zone. For the New Zealand tunnel project, the turbulence under normal ventilation mode made smoke and heat detection challenging. Thought must be put into how big a fire is needed to generate sufficient smoke or heat to be detectable, given the turbulent mixing rate. The detectable fire should not be so large that unacceptable fire damage will have already occurred before detection.

As with local application systems, and perhaps more so, the proper integration of the detection system and the hydraulic release system is critical to the performance of ZA water mist systems. The detection system and the hydraulic systems must be tested together. The penalty of failing to accurately locate the fire source and its extent is

that valuable water and pumping energy may be wasted on noninvolved parts of the facility.

It is this author's opinion that the engineering challenges involved in zoning water mist systems present a great opportunity for future innovation and invention. The detection problems require full understanding of the fire dynamics involved. There is great potential for invention in developing piping and valving strategies that are flexible and robust. Increasing the atomization efficiency of nozzles to make smaller drop sizes was only the first stage of the development of water mist technology. The next step is to develop the sophisticated but reliable detection and delivery systems needed to adapt these systems to difficult settings.

Pre-engineered versus engineered systems: A pre-engineered water mist system is one that has been developed for a hazard of a limited size and consistent features defining the compartment. For example, a water mist system may be tested in a mock-up of a turbine or diesel engine enclosure, with specific ceiling height, obstructions, ventilation openings, and fire scenarios. The number of nozzles, their locations, the amount of stored water required for an adequate duration of flow, and the diameters and maximum lengths of pipe or tubing are all pre-engineered. The installer need only stay within the limits stated for pipe diameter and length of run to install the system properly. No engineering calculations are required to ensure that nozzle pressures are adequate and that flow rates and water storage are sufficient for the hazard. Because the compartment conditions are well defined by the test protocol, the detection time and the size of fire upon detection will be predictable for a pre-engineered system. Engineered systems, on the other hand, must adapt basic nozzle spacing rules to a variety of compartments and fire hazards, and then perform the hydraulic calculations to confirm that minimum nozzle pressures and system flow rates are achieved. Not only must the hydraulic performance be calculated, but the implications of increased detection/activation time must also be evaluated.

Where a field application is close to the conditions of the test protocol to which a water mist system was validated, installation of a pre-engineered system is appropriate. In many cases, however, the situation in the field represents the same general fire hazard, but the compartment may be much larger or more cluttered than the test protocol anticipated. Although NFPA 750² discourages extrapolation beyond the listing, the reality is that the designer is under pressure to extrapolate from the pre-engineered system to fit the larger application. In some cases that may involve increasing the number of nozzles while maintaining the nozzle spacing, increasing pipe or tubing diameters, and increasing the water storage. Any extrapolation converts the design to an engineered system. It is important that the designer have a broad understanding of the fire dynamics involved and the fire protection engineering issues to be addressed.

Methods of spray generation: Water mist system equipment manufacturers have staked out their preferred means of mist generation. There are numerous ways to generate atomized sprays.³⁵ Research in the spray and atomization

literature uncovers exotic technologies such as electrostatic sprays, nebulizers, and ultrasonic devices. There are techniques that are suitable for atomization in the milligram range, with projection distances measured in millimeters. Spray generation methods more suitable for water mist fire suppression systems must generate mist in industrial quantities. Suitable nozzle types include multi-orifice pressure jet nozzles, impingement nozzles, and twin-fluid nozzles. Mass flow rates are typically measured in the range of 5 to 80 l/min. Cone diameters and projection distances are typically measured in meters. The atomization process must be sustained for tens of minutes in most cases, although explosion suppression systems may complete their discharge in a time scale matched to the velocity of the flame front—several hundred milliseconds. This section will highlight some of the engineering features of importance associated with different methods of generating water mist.

Twin-fluid versus single-fluid nozzles: Twin-fluid nozzles use two streams of fluid, one of water and one of compressed gas, which increases the energy available for the atomizing process. The compressed gas, which is referred to in NFPA 750^{1,2} as the "atomizing medium," is injected into the water stream at the nozzle. This discussion regards twin-fluid nozzles as having separate piping for water and compressed gas up to the nozzle. The air-to-liquid ratio (ALR) (ratio of the mass flow rate of air to the mass flow rate of water) at each nozzle can be held approximately constant throughout the discharge. By this definition, systems that inject compressed gas into a single conduit for the supply of water are not twin-fluid systems. Twin-fluid nozzles are used in the HVAC industry for humidity control, and in many other industrial applications for a variety of reasons. They provide a high degree of adjustability between the balance of liquid and gaseous streams—hence they can be easily tuned to maximize the quality of the spray at low water pressures. By utilizing the energy stored in the compressed gas, there is no need to boost water pressure to push water through small-diameter orifices or increase ejection velocity. Hence, twin-fluid nozzles have larger orifices that are less vulnerable to plugging than some single-fluid systems. On the negative side, twin-fluid nozzle systems require storage and delivery of media with distinctly different engineering characteristics. Calculations must be done for both compressible and incompressible fluids in the distribution system. A suggested approach to balancing the distribution of atomizing medium with the water flow is provided in Reference 89.

Single-fluid nozzles use water only. The water is ejected through one or more orifices and either disintegrates into mist due to velocity differences between the water jet and the surrounding air (pressure jet nozzles), or disintegrates into small particles on impact against an impingement surface (impingement nozzles). A more in-depth discussion of how fine water sprays are formed can be found in References 35 and 89. Single-fluid nozzles are more widely used for water mist systems than twin-fluid nozzles.

Manufacturers of nozzles for industrial applications have catalogs filled with different nozzle designs, delivery rates, and cone shapes. They have been manufacturing a

wide range of nozzles for many years. It is surprising therefore how much money and effort has gone into the custom design of water mist nozzles for water mist systems by fire protection specialists. Without exception, the water mist system manufacturers have developed their preferred nozzle design through extensive in-house research and development. Some off-the-shelf commercial nozzles have been adapted for water mist systems, albeit with customized selection of individual orifice sizes.^{23,29} The ability to add a thermal release device to a water mist nozzle allows the manufacturer to market its water mist technology in "sprinkler equivalent" systems as approved by IMO test protocols.

Mist generation by flashing of superheated water: Evidence that water mist with sufficiently small drop sizes may quell a dust explosion is found in work conducted at the Irish agricultural research facility involving dusts of dried milk products.^{90,91,92} The mist-generating method involves the flashing of superheated water released from a self-pressurized container.⁹³ Water is superheated to 175°C in a closed container up to 70 l (18.5 gal) in volume. As steam tables indicate, this puts the closed container at a pressure of approximately 10 bar (145 psig). When released to atmospheric pressure, a percentage of the water flashes directly to vapor phase, then condenses into fog-sized particles (<20 µm) as the cloud cools. There is a dynamic release of energy as the liquid flashes, which shatters the remainder of the mass of water into relatively fine spray (D_v 0.90, ~300 µm) (i.e., 90 percent of the volume of the spray as contained in drops less than 300 µm in diameter).⁹³ The energy exchange also results in intense cooling of the spray, so that 30 cm away from the discharge orifice, the mist temperature may be 35°C or less.⁹¹

The flashing process does not require a nozzle—simply an open orifice, and it results in a rapid distribution of "mist plus fog" throughout the protected space. The condensed fog is an order of magnitude finer than can be achieved by mechanical generation of spray—a relatively large mass fraction is distributed uniformly throughout the space. Full-scale fire suppression tests carried out by Mawhinney and Taber⁹¹ indicate that the ultrafine mist was not more effective than other mists at extinguishing pool fires in enclosures. It was suggested, however, that its success in dust explosion mitigation may be due to the high mass fraction of very small (~20 µm), closely spaced droplets, suggested by Zalosh³⁴ to be a prerequisite for explosion mitigation with water mist. Further experimental work is required to validate its potential for vapor/air explosion mitigation.⁹²

Pressure regimes: NFPA 750 distinguishes between low-, intermediate-, and high-pressure systems. Low-pressure systems operate at pressures below 12 bar (about 175 psig). In that range, standard sprinkler system installation practices can be followed, and conventional centrifugal fire pumps can be utilized to achieve system pressures. Intermediate-pressure systems have operating pressures that lie between 12 and 34 bar (175 and 500 psig). Pipe fittings and pump selection must be upgraded to handle this above-average pressure range, but in general piping practices are not much different from those of

low-pressure systems. High-pressure systems operate above 34 bar (500 psig). Selection of pipe or tubing, installation practices, and the engineering of high-pressure pump systems are quite different from traditional fire protection engineering practices. Twin-fluid systems operate in the low-pressure range, but they require familiarity with high-pressure gas cylinders, gas metering valves, and compressible fluid flow calculations. This section provides information on engineering factors encountered in these different pressure regimes.

There is considerable discussion about whether high-pressure water mist systems are better than low-pressure water mist systems, or vice versa. Proponents of one technology or the other will refer to test results that showed that their system performed better in a given scenario. If the nozzles are not situated or oriented optimally relative to the fire, they won't perform as well as ones that are better oriented, regardless of the pressure regime. It may be that the test results being referenced were optimized for the one pressure regime but not the other. Also, it may be that the difficulty of integrating the water mist systems with existing infrastructure in a facility makes it impractical to choose one pressure regime over the other. It is this author's experience that acceptable fire suppression can be achieved with both high- and low-pressure systems. The engineering and economic issues related to the different technologies will dictate which is the most cost-effective choice for a given application.

On the marketing end, water mist equipment manufacturers are usually committed to a particular technology, hence pressure regime. A manufacturer tooled to produce high-pressure equipment is not going to want to sell low-pressure nozzles, and vice versa. Also, there are engineering aspects of twin-fluid and high-pressure technologies that require specialist expertise with gas cylinders and releasing valves, or high-pressure pumps. It would be challenging for one manufacturer to cover the full range of expertise equally well.

Low- and intermediate-pressure systems: Standard sprinklers are capable of working at end nozzle pressures as low as 0.5 bar (7 psig). It is recognized that the piping system operating pressure will be higher than the minimum nozzle pressure. Therefore, even in sprinkler systems, the operating pressure of the system will typically be between 5 bar to 7 bar, sometimes higher. Pipe fittings will be rated for 8 bar at least, and in many cases 12 bar as standard practice. Some low-pressure water mist nozzles require nozzle pressures of 8 to 12 bar to achieve the desired drop size distribution. With 8- or 12-bar end pressures, the system operating pressure will generally be above 12 bar, that is, in the intermediate-pressure range. Pipe and fittings will have to be rated for the 21-bar range. Many of the low-pressure water mist nozzle manufacturers are edging toward 12- to 20-bar system operating pressures to achieve desired performance. Therefore, not many water mist systems are truly low-pressure systems.

So long as the engineer selects pipe, tubing, valves, and pumps rated for the operating pressure, the design procedures for low- and intermediate-pressure water mist systems do not differ much from standard sprinkler systems.

Some potential water mist system applications cannot support the cost of pumps to boost water pressure out of the low-pressure regime. Examples include heritage buildings, some libraries, and archival storage applications, which often have limited budgets for fire protection. The major advantage that water mist provides over standard sprinklers is that it reduces the water application rate. The end user will be willing to pay additional costs to increase system pressure only if that advantage is valued highly enough. One manufacturer is reported to have conducted tests with nozzle pressure reduced to less than 7 bar for an archival storage facility. However, considering that standard sprinklers can operate comfortably at 1 bar, a minimum nozzle pressure of 7 bar may still mean the existing water supply has to be augmented to meet the water mist system pressure requirement. Thus, even for the low-pressure water mist systems, the cost of increasing system pressure continues to be an economic disadvantage when compared to standard sprinklers.

Low- or intermediate-pressure systems may be connected to a constant pressure water supply, or they may be gas driven, working from a stored volume of water being expelled by a limited supply of compressed gas. The latter are declining pressure systems: the pressure drops continuously throughout the discharge period. The twin-fluid systems also work on a declining pressure principle, unless they are connected to plant air or plant water sources.

The possibility of accommodating larger friction losses in the piping system than normal for sprinkler piping is an incentive to go to higher system operating pressures. If the water mist nozzles use less flow than standard sprinklers, and there is pumping capacity to compensate for relatively high system friction losses, the designer may be able to use smaller diameter pipe or tube in the distribution system than is found in the competing sprinkler system. The designer may be able to extract a compensating advantage from the necessity to operate at a higher pressure range than sprinkler systems. It is not uncommon for a high-pressure system to incorporate head losses of 20 bar between the pump discharge header and the most remote nozzles, without compromising the effectiveness of the system. Generally, the potential to significantly reduce pipe sizes requires a transition into the high-pressure regime.

High-Pressure Systems: NFPA 750 defines high-pressure water mist systems as those that operate above 34 bar. They are installed extensively on passenger cruise ships as equivalents to sprinkler systems. They are also widely used in marine and industrial machinery and equipment spaces. There are two basic types—gas-driven pre-engineered systems for moderate-size compartments, and pump-driven engineered systems for large machinery spaces. Gas-driven systems operate over a declining pressure range, from approximately 140 bar at first release to 30 to 50 bar at the end of a 10-min discharge period. They have FMRC approvals for turbine enclosures, machinery spaces, and special hazard spaces. There is also a gas-driven pump that can extend the operation of a gas-driven high-pressure system for up to 1 hr, without the need for electric-motor or engine-driven pumps.⁹⁴

The design and installation of high-pressure water mist systems involve practices for pipe and tubing sys-

tems that until recently were not used in the fire protection field. Stainless steel tubing is used in conformance with the ASME/ANSI B31.1, *Power Piping Code*.⁹⁵ Good practices for tube bending, cleaning, and swabbing; supports; and make-up of compression fittings must be applied.

High-pressure water mist systems use motor- or engine-driven, positive displacement (PD) pumps to achieve the high system pressures. This is in contrast to the centrifugal fire pumps traditionally used in fire protection systems. Unlike centrifugal pumps, PD pumps put out a constant Q at a given rotational speed. Fire suppression systems generally have a variable demand, depending on the number of nozzles or groups of nozzles that open. Rather than use one pump driven by one motor for the full range of flows in a facility, as is possible with a centrifugal pump, PD pump systems divide the total load among a number of pumps that can be brought on line as needed to handle increasing load. The total power output of a single motor can be distributed among several small pumps. Then the discharge from each pump can be further split using pressure unloader valves, which divert all or some of the flow to a recirculation line if the pressure rises to its pressure setting. Figure 4-14.7 shows an arrangement in which four motors drive a total of eight pumps. Each motor has enough power to deliver the discharge from both pumps at a low pressure (75 bar), or the discharge from just one of the two pumps at twice that pressure (150 bar). The power requirement of the motor to achieve a particular flow and pressure is calculated as shown in Equation 3.

$$P = Q \times H / 600 \times E \quad (3)$$

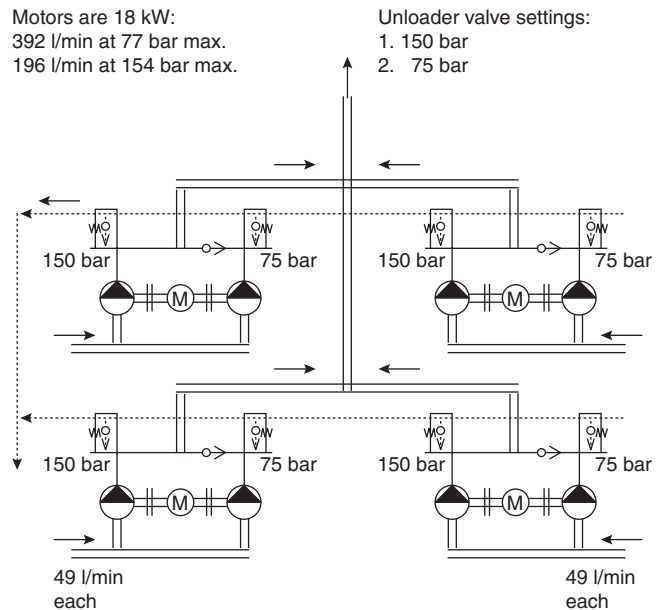

Figure 4-14.7. Arrangement of eight positive displacement pumps driven by four electric motors.

If the power of the motor is known, Equation 4 calculates the maximum possible pressure that the motor could deliver. Equation 4 is used to plot the power limit curve for a given motor-pump combination, as shown in Figure 4-14.8.

$$H = (P \times 600 \times E)/Q \quad (4)$$

where

P = power (kW)

Q = pump discharge (l/min)

H = pump discharge head (bar)

E = combined efficiency of the motor and pumps (ep × em)

Figure 4-14.8 is a graphical means of illustrating the performance of a PD pump arrangement. Each pump motor is set up to drive two pumps. Above the pressure of the lowest unloader setting, the high-pressure side holds the check valve on the low-pressure side closed. The system discharges only the flow from one of the two pumps. The discharge of the second pump is “unloaded” into the recirculation line, and therefore does not draw upon the power resource of the motor. The entire power output can go to increasing the pressure on the pump set for the highest pressure. By distributing the hydraulic demand over several motors, and by using numerous pumps with high and low unloader valve settings, the positive displacement pumping system automatically responds to a variable system demand.

Figure 4-14.8. Diagram to predict the operating point of a high-pressure water mist system with multiple positive displacement pumps.

Figure 4-14.8 illustrates the relationship between the supply provided by the pump(s) and the theoretical system demand as obtained by hydraulic calculations for a hypothetical installation. The calculated minimum demand is not the operating point for the given supply, however. An estimate of the operating point is obtained by extending the constant K line for the calculated system until it intersects the pump supply curve (a vertical line in this case). The K factor for the piping system determines the operating point for the pumping system.

Acceptance Testing of Water Mist Systems

Acceptance testing of twin fluid, declining pressure and pumped high-pressure water mist systems involves engineering analysis that is not typical of traditional sprinkler systems. NFPA 750 recommends that a full system discharge test be conducted if at all possible. This is particularly important for gas-driven, decaying pressure systems. The discharge test is intended to confirm that the operating point (pressure and flow) of the system meets the minimum requirement, and for gas-driven systems to ensure that the supplies of water and compressed gas are sufficient for the discharge duration. Without taking measurements, it is difficult to judge by visual indicators alone whether a system is operating properly.

Visual inspection of the mist conditions during a discharge can confirm only basic aspects of the system performance, such as that valves opened, pipes or nozzles were not plugged, and mist was produced. One can observe that water flows from individual nozzles and that the spray distribution looks acceptable. Only by measuring pressures, however, can one be sure that the system is performing as required, and that the stored quantities of compressed gas and water are adequate.

Figures 4-14.9(a) and 4-14.9(b) are plots of air and water pressure taken during the discharge of a twin fluid system involving cycled flow at the hydraulically most remote nozzle, and at a nozzle very close to the supply tank. The design called for six discharge cycles of 50 s each, with 40-s intervals between them. Air and water pressures at the nozzles should stay between 82 and 66 psig. The timing program in the control panel worked well. From visual and audio observations in the compartment, six discharges occurred. From the pressure traces, however, it was evident that the sixth discharge did not achieve the minimum nozzle pressures, particularly at the most remote nozzle. For the nozzle closest to the supply tank [Figure 4-14.9(b)], the minimum operating air and water pressures were achieved in the fifth, but not the sixth discharge. The differences between pressures at the closest and most remote nozzles indicate that the nozzles closest to the source were discharging considerably more air and water than the remote nozzles.

The recorded pressures of the discharge tests demonstrated that the system exhausted the supply of atomizing medium before the end of the fifth discharge, although not the supply of stored water. Additional cylinders of compressed gas were required to extend the operation for six discharges. A full understanding of the performance of the system and remedies for shortfalls could not have been identified from a partial trip test.

Figure 4-14.9(a). Pressure versus time plot of compressed gas and water pressures at the most remote twin-fluid nozzle location. Acceptable operating range is between 66 and 82 psig, with compressed gas pressure required to be approximately the same as the water pressure ($P_a/P_w = 1.0$).

Figure 4-14.9(b). Compressed gas and water pressures measured at a nozzle close to the source tank. Acceptable operating range is between 66 and 82 psig, with compressed gas pressure required to be approximately the same as the water pressure ($P_a/P_w = 1.0$).

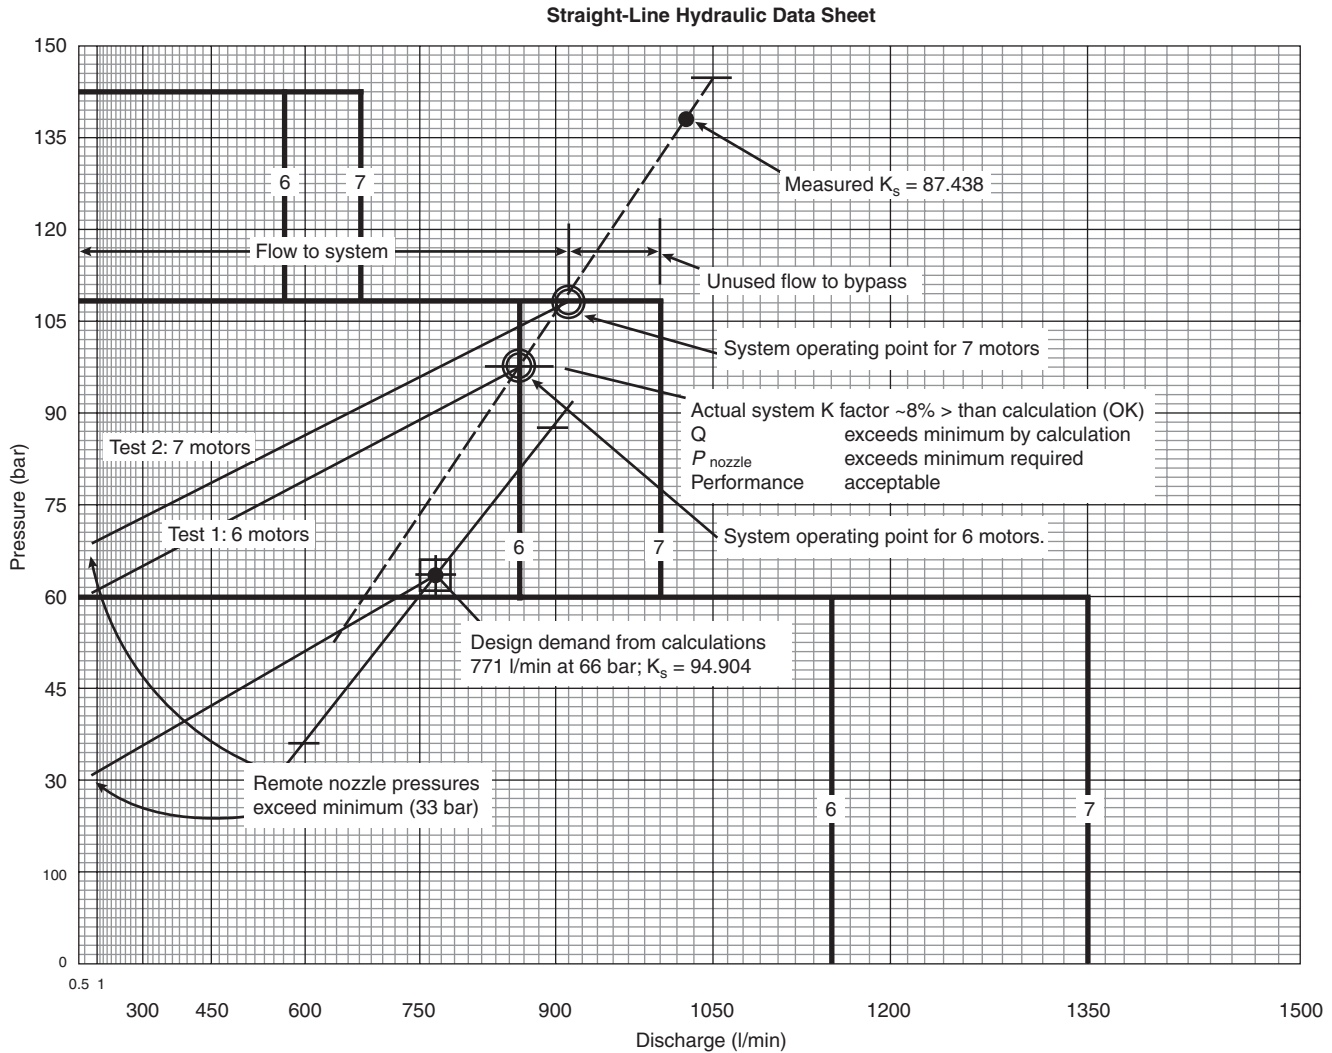

Figure 4-14.10. Example of acceptance test results for a high-pressure pumped water mist system.

Figure 4-14.10 shows data collected during a discharge test of a pumped high-pressure water mist system. The data recorded were the pressure at the pump discharge header, the pressure at the most remote nozzle(s), and confirmation of the number of motors operating. Working on the hydraulic straight-line graph paper, on which the supply curves for different numbers of motors were predrawn, the discharge pressure line was marked. Since it was known that 6 motors were operating, and the pressure reading was between the lowest and highest unloader settings, the system operating point had to lie on the vertical Q line for 6 motors operating, as shown. That operating point defines a K factor for the real system. To judge whether the operating point was “acceptable” or not, it was compared to the theoretical minimum flow condition obtained from hydraulic calculations. Since the calculated demand point was reasonably close to the constant K line determined by the actual operating point, one could conclude (a) that the system was operating above its minimum condition, and (b) that the hydraulic calcu-

lations were accurate and reflected the “as-built” piping system.

Conclusions

This chapter has reviewed some of the history behind the evolution of water mist fire suppression systems development over the last decade. The significant studies on how and why finely divided water sprays improved the efficiency of extinguishment had been done years before. Spurred on by the need to find halon alternatives and to develop efficient, lightweight suppression systems for ships, the 1990s saw some new ground broken in fire suppression systems design. Water mist emerged as a viable alternative for a number of halon applications, and the improved efficiency in use of water promised major reductions in the weight and volume of system hardware.

Water mist systems require that full-scale fire suppression testing be done to establish design parameters

for different fire scenarios. Based on the traditional approach to sprinkler systems design, the expectation was that testing would eventually reveal a range of optimum application rates that could be applied to all water mist systems. Interestingly, it was discovered that performers' equipment. One water mist system could meet suppression objectives at one flux density (application rate), but a second manufacturer, using a different type of nozzle, would succeed at a lower density. The specific spray characteristics of different nozzles or spray-generation methods have a bearing on the performance. Unfortunately, we cannot (yet) predict exactly what difference a particular change in spray characteristics will make to the suppression outcome. At this stage, the scientific challenge is to at least measure the differences in spray characteristics, in the hope that we will begin to understand the relationships. Thus, there is a need for more theoretical work on the dynamics of the interaction of water sprays and fires in real compartments.

Notwithstanding the limitations in our understanding, water mist system technology has advanced from a promising curiosity in 1990 to a major fire protection market in 2000. The strongest market exists in the international marine sector, where water mist is competitive with the only alternative—marine sprinkler systems. Ship owners are satisfied with the IMO test protocols as an approval base. Penetration of land-based markets has been much slower, particularly in North America, where potential end-users tend to require third-party approvals or listings, such as FMRC or UL, before they will accept the system. The absence of a sufficiently broad base of completed approvals is a major barrier to land-based application of water mist systems in the United States.

There are increasing niche markets for water mist systems in certain land-based sectors, most notably for heavy industry machinery space modules, turbine enclosures, metro-station mechanical rooms, and wet benches in clean rooms. Water mist is viewed as a halon alternative for those applications. Interest in using water mist in place of standard sprinklers in land-based applications is also growing. For example, work began in early 2000 on installation of a water mist system for a large hotel in London. The water mist system is an alternative to standard sprinklers and is reported to be competitive with sprinklers on a cost basis for this application. The water mist system offers the advantages of smaller diameter pipe than in sprinklers (permitting easier retrofit in a heritage building), reduced water demand, plus proof of performance through recent full-scale fire testing. Thus we see the beginnings of an acceleration in the transfer from the marine sector to land-based applications. It is only logical that the burst of innovation in systems design that has accompanied the growth of water mist systems will have benefits for more traditional water-based systems in the next decade.

CHAPTER 1

Introduction to Fire Risk Analysis

John M. Watts, Jr. and John R. Hall, Jr.

Introduction

The chapters in this section describe concepts and methods to be used in answering the three questions: What could happen? How bad would it be? How likely is it? This chapter in particular is intended to provide an overview of fire risk analysis as a whole, indicating how the subsequent chapters fit together and how a completed fire risk analysis connects to other evaluative and management activities. The purpose of this introductory chapter is threefold:

1. Introduce some generic terminology and fundamental concepts (building on the three questions raised above)
2. Provide an overview of the other chapters in this section
3. List some broad resources for conducting fire risk analysis (FRA)

What Is Risk?

Risk has always been a part of human endeavor, and for much of human history, the notion that risk could be actively controlled or prevented would have been considered mad or even blasphemous. Even today, when we increasingly expect protection against risk and use codes, regulations, insurance provisions, built-in and planned response mechanisms, and incentives, all to control or reduce risk, very few of our risk reduction and risk man-

agement actions proceed from a formal or quantitative risk analysis.

This aspect, too, is changing. Governments around the world are mandating risk analyses in areas of health and safety. Computations of the odds of harm are becoming a powerful force in decisions about activities involving risk.

Every decision related to fire safety is a fire risk decision, whether it is treated as such or not. And so, as our scientific understanding and our suite of quantitative engineering tools have rapidly expanded, we have discovered that we cannot make our fire safety decision-making process more scientific and quantitative unless we first place our new engineering tools into an appropriate fire risk analysis context. To do otherwise is to make many implicit assumptions about patterns of danger and preferences for certainty and for safety versus other human wants and needs.

Basing decisions on fire risk not only requires the challenging technical steps of fire risk estimation but also requires the identification of an acceptable level of risk, which is more a philosophical task than a technical one. Consider, for example, the recent fire loss experience of any country. Does this experience represent a level of fire risk acceptable to the citizens of that country? If the answer is no, then why is there so little attention paid to the problem? If the answer is yes, meaning we accept certain losses, then why is there a great clamor for change following every serious fire?

Accepting a level of risk requires a value judgment, and people have different value judgments. Consider four perspectives on the value of residential sprinklers: technical, societal, enforcer, and managerial.

Technical value judgments are made by experts based on the available technical information and their acquired expertise. Experts pretty much agree that residential sprinklers can significantly reduce the calculated fire risk. The experts most aware of the risk reduction potential of sprinklers are also most likely to evaluate the attractiveness of sprinklers based on that potential, more than on other

Dr. John M. Watts, Jr., holds degrees in fire protection engineering, industrial engineering, and operations research. He is director of the Fire Safety Institute, a not-for-profit information, research, and educational corporation located in Middlebury, Vermont. Dr. Watts also serves as editor of NFPA's *Fire Technology*.

Dr. John R. Hall, Jr., is assistant vice president for fire analysis and research at the National Fire Protection Association. He has been involved in studies of fire experience patterns and trends, models of fire risk, and studies of fire department management experiences since 1974 at NFPA, the National Bureau of Standards, the U.S. Fire Administration, and the Urban Institute.

bases. They may embrace residential sprinklers with great enthusiasm on that basis.

Societal value judgments are the judgments of ordinary people balancing benefits, costs, and risks of the full range of activities and events that affect their daily lives. Their estimation of the benefits and the negative side effects of sprinklers may be based on folklore more than the best thinking of the experts, and they are likely to attach more importance to costs and to other hazards and needs than the experts, having a specific focus, do. Currently, it appears that the reduced fire risk produced by a residential sprinkler system is not valued as highly, by the average citizen, as the increased benefit of a new car.

Enforcer value judgments are the judgments of a few professionals who are asked by society to protect their interests in a specific area. Enforcers are a special group within the larger group of individuals who provide *fire risk management*. An engineer performing a fire risk analysis will usually be working on behalf of a client with fire risk management responsibility, but the engineer cannot base his or her analysis on the values of the client alone. Instead, the fire risk analysis will need to address the client's values and societal values. Enforcers are often seen as the interpreters and guardians of societal values, but at the same time, their technical expertise and focused mission of providing fire safety give them a distinctive set of values. Their estimation of benefits and side effects are likely closer to those of the experts, but their evaluation of those benefits and side effects are likely closer to those of the general public, embodied in societal value judgments. And because they directly incur neither the costs nor the benefits of their decisions, they must factor in some other considerations having to do with when it is acceptable to dictate safety choices to people. Is it equitable to require automatic sprinklers in *all* residences? How can cost be fairly distributed? Who is responsible for system reliability? Should production, installation, and maintenance of sprinklers be regulated?

Managerial value judgments are the judgments of all the other professionals with special responsibilities relevant to fire risk management, which for residential fire sprinklers would include such groups as architects, builders, managers of hardware retail chains, and so forth. Their estimation of the benefits and side effects of sprinklers may be similar to the general public's, their estimation of the costs is probably more accurate than that of any other group, and, most importantly, they themselves are likely to be directly affected by those costs more than by the benefits or side effects. Different information and different goals and values are likely to lead to a different assessment—though still risk based like all the others—of the attractiveness of residential sprinklers.

The chapters of this section are designed to provide the practicing engineer with those contextual tools and supplementary information that will permit him or her to use the knowledge and tools embedded in all the earlier sections and to produce a sound evaluation of alternative choices.

Fire risk estimation is the scientific process of answering three questions: (1) What could happen? (2) How bad would it be if it did happen? (3) How likely is it to happen? Or, to put it another way, risk has two essential

components—exposure and undesired consequences. Exposure is a potential risk that becomes real with uncertainty, and so exposure refers to the likelihood or probability of experiencing a destructive event, for example, fire. Undesirable consequences, ranging from deaths or dollars of property damage, to significant intangible losses such as business interruption, mission failure, environmental degradation, and destruction of cultural artifacts, are also potential risks. They become real if exposure occurs. Thus when we speak of fire risk, we are referring to the uncertainty of loss.

Let's return to the three questions that opened this chapter.

What could happen? can refer to a sequence of events ending in a fire loss, the sequence as a whole being called a *scenario*, or to an object or other entity having the potential for a sequence of events ending in a fire loss. A *hazard* is such an object, and *hazard* itself is the potential for loss. *Fire hazard analysis* is a term often used to refer to analyses of what could happen and how bad it would be, without analysis of likelihood.

How bad would it be if it did happen? is often called *consequence* and sometimes called *hazard*, in the sense of a specific measure of potential for loss. The measure of consequence can be direct (e.g., property is damaged) or indirect (e.g., the company is out of business for several days). It can be objective (e.g., replacement cost in monetary units) or subjective (e.g., pain and suffering effects of injury, utility measures of damage).

How likely is it to happen? is usually called *probability*. Probability can be relative (e.g., likelihood of this loss is how much greater or smaller than likelihood of that loss) or absolute (e.g., how many times a year, given a population of people or property). Probability can be regarded as objective and measured objectively (e.g., how many occurrences per year in a recent period of time). It can be regarded as objective but measured subjectively (e.g., how many occurrences do we estimate will occur next year, given data on the number of occurrences last year and impressions on what has changed since last year). It can be regarded as and measured subjectively.

And both consequence and probability can be either explicit in a formal fire risk analysis or implicit and unquantified in a more simplified fire risk analysis (e.g., *fire risk index*).

For purposes of use by fire protection engineers, we assume that fire risk analysis is a scientific process, closely linked to calculations based on proven relationships and the collection and analysis of valid and appropriate data, to describe the form, dimension, and characteristics of the fire risk.

Fire risk analysis can take different approaches depending on the purpose and scope of the analysis or assessment. Some assessments look back to try to infer probabilities and other risk-related measures based on practices and fire loss experience after an event such as the introduction of home smoke alarms. Other assessments look ahead and try to predict what the practices and fire loss experience would be after an event such as legislating residential sprinklers in homes.

The approach taken to fire risk analysis can also differ based on the availability—quantity, quality, and detail—of

data for the purpose. Assessing the fire risk for U.S. residences, for example, one is able to draw on a very large number of documented fire events but with limited detail. Assessing the fire risk for U.S. nuclear power plants, by contrast, has far fewer fire events to draw upon but much more detail on each such event. And assessing the fire risk in any specific existing building will involve very few events in that building and questions of relevance for data from any other building or group of buildings.

In fire safety engineering, risk analysis is most generally used to evaluate fire protection strategies for a particular application or for a class of facility or operation. In other words, there are a sizeable number of buildings and some considerable relevant fire loss history to draw upon.

Terminology and Concepts

The terminology of fire risk analysis is not consistent. For example, a committee of the Society for Risk Analysis identified 17 different definitions of risk.¹ If one considers risk to be the full probability distribution of hazardous events and associated loss consequences associated with a building, product, or other entity to be studied, then all 17 definitions can be seen as alternative summary measures taken from that common distribution. The important point, however, is that for many people, a summary measure is not just a summary measure related to risk, useful for analysis; it *is* the risk.

As another example, the terms *analysis* and *assessment* are often used interchangeably, yet some sources make sharp distinctions. We will provide distinct definitions.

The rest of the chapters in this section also show some inconsistencies in definitions and concepts. These are largely a function of differences in the authors' backgrounds, topics, resources, and intents. In general, the definitions and concepts used are similar, even when they are not identical.

An overview of terms is best presented in the form of a glossary, but the list below is presented in what is meant to be a logical sequence, rather than alphabetically. More extensive glossaries can be found in Grose² and Rowe.³

Hazard: A hazard is a chemical or physical condition that has the potential for causing damage to people, property, or the environment.⁴ Hazard is any situation that has the potential for causing injury to life, or damage to property and the environment.⁵

Risk: Risk is the potential for realization of unwanted, adverse consequences to human life, health, property, or the environment. Estimation of risk (for an event) is usually based on the expected value of the conditional probability of the event occurring times the consequence of the event given that it has occurred.⁶ It follows that risk for a building, a product, or some other entity would be the probability distribution of events and associated consequences relevant to that building, product, or entity.

Probability: According to the frequency interpretation, probability is the proportion of the time an event will occur in the long run. According to the subjective interpretation

of probability, it is a measure of the strength of a person's belief concerning the occurrence or nonoccurrence of an event.⁷ Probabilistic analysis is not well established in fire protection engineering, where empiricism, heuristics, and, more recently, physics-based modeling are principally used to make decisions. Probabilistic analysis is more established in fields such as decision analysis, management science, operations research, industrial and systems engineering, and systems safety. The mathematics of probability allow us to formulate engineering models which recognize uncertainty and deal with it quantitatively and consistently. Probability and statistics are covered in Section 1, Chapters 11 and 12, of this handbook.

Consequence: Consequence is a measure of the expected effects of an incident outcome case.⁴

Perceived risk: Any measure of risk preferences in which the scale is not fully explainable by some objective measure of loss, direct or indirect, may be a measure of perceived risk. Studies of risk perception have identified a number of factors that consistently cause objectively equal risks to be perceived differently, including preferences for more certainty over less certainty (i.e., *risk aversion*), familiar over unfamiliar risks, voluntary over involuntary risks, readily detectable risks over undetectable or hidden risks, and common or ordinary risks over dramatic or memorable risks. The field of *risk communication* is devoted, in part, to finding ways for individuals and groups with differing ways of perceiving risks to communicate effectively, understand one another, and collaborate on mutually acceptable analyses and decisions.

Risk analysis: Risk analysis is the detailed examination, including risk assessment, risk evaluation, and risk management alternatives, performed to understand the nature of unwanted, negative consequences to human life, health, property, or the environment; an analytical process to provide information regarding undesirable events; and the process of quantification of the probabilities and expected consequences for identified risks.⁶

Risk assessment: Risk assessment is the process of establishing information regarding acceptable levels of a risk and/or levels of risk for an individual, group, society, or the environment.⁶

Risk estimation: Risk estimation is the scientific determination of the characteristics of risks, usually in as quantitative a way as possible. These characteristics include the magnitude, spatial scale, duration, and intensity of adverse consequences and their associated probabilities as well as a description of the cause and effect links.⁶ One complication is that a totally objective or scientific way to measure fire risk does not exist. Problem identification, data collection and reduction, and integration of information are all replete with subjective evaluations.

Risk evaluation: Risk evaluation is a component of risk assessment in which judgments are made about the significance and acceptability of risk.⁶

Risk identification: Recognizing that a hazard exists and trying to define its characteristics is called risk identification. Often risks exist and are even measured for some time before their adverse consequences are recognized. In other cases, risk identification is a deliberate procedure to review, and, it is hoped, to anticipate possible hazards.⁶

Acceptable risk: A value judgment applied to a particular scale for the measurement of risk yields a definition of acceptable risk. It therefore requires a prior decision on the scale and method used to estimate or measure risk and a second decision on the person or group whose views on acceptability are to be used. For a practicing engineer, acceptable risk is likely to be risk acceptable to the client. For an authority having jurisdiction (AHJ) or anyone answerable to an AHJ, acceptable risk is meant to be acceptable to society in general or to a particular community.

It is an axiom of fire risk analysis that zero risk is not an achievable goal. There are no risk-free alternatives available to individuals or organizations. No technology is 100 percent reliable or totally immune to misuse, and even if technological risk could be eliminated, natural catastrophes such as lightning strikes, wildland fires, earthquakes, and wind storms include the potential for fire loss. An important corollary is that reducing fire risk may increase other forms of risk. An obvious case is the potential damage to the ozone layer from use of halon.

The goal that comes closest to being a practical goal of zero risk is a goal of risk as low as is technically possible. For fire protection engineering, this goal may take the form of accepting the residual risk after all identified risk reduction strategies and choices have been adopted. Or, for individuals with special preferences for particular fire protection strategies (e.g., active systems over product or material requirements, or vice versa, and either over education and training), acceptable risk may be the residual risk after favored choices are in place. One complication is that the residual risk in these cases may be perceived as zero, implying no prior acceptance of the nonzero risk that actually remains.

A universally acceptable level of fire risk does not exist: No matter how one defines the term *acceptable level of fire risk*, it will be dependent on the problem context and on the individual judging acceptability, that is, on the alternatives and objectives. Individuals and organizations are inconsistent in their risk aversion. Surveys show wide variations with respect to factors such as voluntary versus involuntary risk and perceived versus calculated risk.

One contention is that the present public fire risk situation must be acceptable since otherwise there would be greater concern and call for action. This view is not a fully reliable generalization. People may have “accepted” the current risk because they believed it to be lower than it really is, believed no technically feasible alternative existed (which can change because technology changes or because perceptions of technology change), or saw no politically effective way to make their lack of acceptance known. Moreover, the current situation is a compromise among the greatly differing preferences of many individuals and groups, whose relative influence on the process of choice may also change. More elaborate discussion of

the issues associated with acceptable risk can be found in Lowrance⁸ and Fischhoff et al.⁹

Vulnerability: The susceptibility of life, property, and the environment to injury or damage if a hazard manifests its potential is vulnerability.⁵

Methods of Fire Risk Analysis

Fire risk analysis is basically a structured approach to decision making under uncertainty. Within this general structure, there are many techniques or approaches to both qualitative and quantitative fire risk analysis. Each application will want to individually consider the level of mathematical sophistication appropriate to meet objectives.

A generalized concept of fire risk analysis has these components:

1. Identify fire hazards.
2. Quantify consequence and probability of fire hazards.
3. Identify hazard control options.
4. Quantify impact of options on risks of hazards.
5. Select appropriate protection.

At each of the two stages of quantification, there is a wide range of possibilities of depth and detail, and the actual quantification can take place anywhere on a spectrum from a principal basis in hard data and established science to a principal basis in expert judgment.

Fire risk analysis begins—and for some applications may end—with the identification of fire hazards. A preliminary assessment of areas of potential concern in facility design and operational concepts may be organized by location (e.g., area of a plant) or by activity (e.g., manufacturing vs. office functions, wherever they occur). This identification provides a structure for subsequent estimates of the probability of occurrence of the events in each possible accident sequence and thereby of each possible deleterious consequence.

Formal fire risk assessment evolved with the insurance industry in the nineteenth century. Methods of fire risk analysis may be classified into four categories: (1) checklists, (2) narratives, (3) indexing, and (4) probabilistic methods.¹⁰ Checklists and narratives are nonquantitative approaches that may address Steps 1, 3, and 5 above while bypassing Steps 2 and 4. Indexing is a thorough quantification method that is heuristic rather than fundamentally based. Probabilistic methods have grown in use over the last third of a century but remain rare even today.

Checklists are a common accessory of fire safety consisting of a listing of hazards, usually with recommended practices. A checklist is usually less generic than a model code or standard. It may even be so specific that it is intended to apply to a single class of buildings under management of a single owner, reflecting the special concerns of that owner.

A checklist is a practical tool to support analysis of a building relative to a code or standard that forms the basis for the checklist. It is very seldom that all criteria in a code or standard apply to a single building. The fire protection engineer must focus on only those requirements that are applicable to a specific project. A checklist can aid

in this process. It also makes requirements easier to read, understand, and track to compliance.

Checklists face a trade-off between practicality and ease of interpretation. A long checklist might list 50 fire safety factors, with each item described in a manner that is readily visible or measurable, but those 50 items are not all likely to be comparably important. A short checklist, on the other hand, is usually comprised of conceptual features of fire safety, which may all be very important but may all require interpretation to be made measurable.

Moreover, checklists do not capture the interaction of fire risk factors, including the manner in which the importance of one fire risk factor will change as a function of performance on another factor. For example, the relative value of hydrants, sprinklers, and extinguishers is not constant but a function of other features of a structure's form and utility.

Narratives consist of a series of recommendations—things to do and not do—related to fire risk and safety. They are probably the earliest approach to fire risk assessment, stemming from the observation that fire is capable of destroying certain materials, such as wood, fur, and flesh. This realization would have led to a communication from parent to child on the avoidance of these fire dangers. In this earliest form, narratives were much simpler and less finished than checklists. They were not comprehensive with regard to hazards, and so they did not support a thorough review.

As the piecemeal parent's advice format evolved over the years, the narrative approach developed into the present multivolume set of the NFPA *National Fire Codes*® 2000 edition.¹¹ These contain the bulk of our present-day wisdom on fire safety. The information is presented in the form of descriptions of various hazardous conditions and ways to reduce or eliminate them. In this modern form, narratives are often more finished than checklists, which may be developed as simplified, practical tools to serve the more basic narratives.

Like checklists, narratives do not attempt to evaluate the fire risk quantitatively. A risk is judged acceptable if it is addressed in accordance with published recommendations. The criterion is one of pass or fail, and the residual risk remaining if you pass is never quantified or evaluated. Also like checklists, narratives cannot hope to cover the myriad conditions of human activity. While there is much common ground among different fire hazard situations, there is considerable variation in detail.

Indexing is representative of the quantitative fire risk assessment that originated with the insurance rating schedule. The approach has broadened to include a wide variety of applications. In general, fire risk indexing assigns values to selected variables based on professional judgment and past experience. The selected variables represent both positive and negative fire safety features and the assigned values are then operated on by some combination of arithmetic functions to arrive at a single value. This single value can be compared to other similar assessments or to a standard to rank the fire risk. Section 5, Chapter 10 covers the subject of fire risk indexing.

Some measures used in fire risk analysis, such as *probable maximum loss* (PML), sound more fundamentally grounded than fire risk indexes but may actually be less

so. There is no established consensus on how improbable a loss must be to be ineligible as the probable maximum loss, and the designation is sometimes given without benefit of any explicit or formal analysis. The resulting subjectivity of such a determination suggests that this value is more of an ordinal label than a quantitative measure of risk (which is not to say that it does not have usefulness).

Matrices and *contours* are methods that can fall between indexes and full-fledged probabilistic methods. A risk matrix typically provides a discrete partitioning of relative consequences along one dimension and relative likelihood along the other. The entry in each matrix cell may include a description of hazards known or believed to have that combination of consequence severity and likelihood, and may also be used to record judgments on the acceptability of such risks and/or recommendations on steps to take to reduce such risks. A risk contour is a continuous analogue to a risk matrix. Curves are drawn on a two-dimensional graph with one axis for consequence and one for probability, with a curve representing types of hazards or technically achievable states.

Probabilistic methods are the most informative approaches to fire risk assessment in that they produce quantitative values, typically produced by methods that can be traced back through explicit assumptions, data, and mathematical relationships to the underlying risk distribution that all methods are presumably seeking to address. Most of the chapters in this section of the handbook are devoted to engineering methods of use in executing a formal probabilistic analysis of fire risk. Some common, generic methods of fire risk analysis follow.

Event tree: An event tree is a graphical logic model that identifies and quantifies possible outcomes following an initiating event.⁴ The tree structure is organized by temporal sequence. Probabilities can be calculated from the tree, and consequences are typically assigned to the end states but may cumulate along the tree.

Fault tree: A fault tree is a method for representing the logical combinations of various system states that leads to a particular outcome.⁴ The tree structure is organized by logical dependency. Probabilities can be calculated from the tree. Consequences are typically defined in an either/or form (success or failure) so that the probabilities suffice to calculate the risk, as defined.

Decision tree: A decision tree is a method for representing the possible outcomes following a succession of events, combining points where the ensuing path is subject to choice and points where it is not. The analysis operates similarly to an event or fault tree, and the simplest decision trees consist of a set of initial choices and an event or fault tree associated with each.

Influence diagram: An influence diagram is a graphical representation of the relationship of the decisions and uncertainties in a decision problem.^{12,13} The diagram is more flexible and less unidirectional than any type of tree diagram. It is designed to focus more on the elements of decision making and less on relevant underlying physical phenomena.

Overview of the Section

This section of the handbook is organized into three broad areas that progress from the general to the specific. There are some basic tools that most approaches to fire risk analysis should consider if not incorporate. There are some examples of generic models applied to fire safety problems, and there are detailed descriptions of fire risk analysis procedures that have been adopted in several areas of application.

Section 5, Chapters 2 through 7 cover generic tools used in many other disciplines and inherent to fire risk analysis, but not typically included in more traditional approaches to fire protection.

The most common use of fire risk analysis is a basis to make choices. The choice may be between two alternative designs for a building or two alternative formulations for a model code or standard. The choice may be whether to tighten requirements on product type A or product type B. Section 5, Chapter 2 describes *decision analysis*, a generic field on forms of analysis that support this kind of decision making. *Cost-benefit analysis* is a specific type of decision analysis, in which a fire risk analysis provides estimates for some of the benefits, and other analysis quantifies corresponding costs.

Section 5, Chapter 3 addresses *reliability*. Fire risk analysis depends upon many types of probabilities. One is fire scenario probability, the estimation of likelihood for the initial conditions and ensuring major events in fire development. Another group of probabilities might be transitory conditions related to people, such as the locations and capabilities of occupants when a fire begins. A critically important set of probabilities have to do with status and capabilities of fire protection equipment, features, and arrangements. Is the battery working in the smoke alarm? Is the sprinkler valve open or closed? Is the fire door working or blocked open? These are all questions of reliability addressed in Section 5, Chapter 3.

Section 5, Chapter 4 addresses *uncertainty*. Early on, the comment was made that the term *fire risk* refers to the uncertainty of loss. The concept of safety itself is one of uncertainty. There is no such thing as absolute safety; human activity will always and unavoidably involve risks. Section 5, Chapter 4 addresses a narrower definition of uncertainty—not the uncertainty of the potential victim regarding the fact of fire loss but the uncertainty of the engineer or decision maker regarding estimates of the magnitude of fire risk.

Uncertainty may be caused by imprecision or bias in our techniques of observation or calculation, a lack of clarity in our goals, uncontrollable technological variation, or variations of natural phenomena, to name only the major components. The concept of fire is also uncertain. Unwanted combustion is perhaps the least predictable common physical phenomenon. Uncertainty analysis is the scientific calculation procedure that should underpin choices of *safety factors* and *safety margins*. It is central to the valid use of fire risk analysis—or any other form of engineering analysis—for code equivalency, design approval, or any other important decision in the real world.

Section 5, Chapter 5 addresses *data sources* for engineering analysis, particularly data useful for calculating

scenario probabilities, reliability probabilities, or any other probabilities needed for fire risk analysis.

Section 5, Chapter 6 addresses the *measurement of consequences in economic terms*. This measurement includes indirect losses, economic measures of the value of a lost life or of an injury, and the use of utility measures to capture people's desire to avoid uncertainty about loss, as well as loss itself, the implications for people's risk aversion for the basic mathematics of insurance, and so on. The common theme is treating consequences comprehensively and in a form that captures people's real preferences and can be readily compared to the costs of alternative choices. Section 5, Chapter 7 addresses *other economic topics* that arise in the practice of engineering analysis, with particular emphasis on monetary valuations over time (e.g., rate of return, interest, discounting).

Section 5, Chapters 8 through 10 describe the use of some examples of generic models of risk analysis and decision making that have been widely adapted and used for fire safety applications. Chapter 8 addresses special topics in the calculation of low probabilities, under the heading of *extreme value theory*. Chapter 9 describes techniques and available models using *computer simulation*, with special emphasis on those having a fire risk analysis basis, such as state-transition models. Chapter 10 describes less-quantified methods of fire risk analysis, involving *fire risk indexing*.

Section 5, Chapters 11 through 15 deal with specific applications of fire risk analysis that have been implemented in the areas of consumer products, buildings, chemical processes, nuclear facilities, and vehicles. Much of the information in these chapters can be extracted and adapted for other areas of application. Of particular note is how the tools in Section 5, Chapters 2 through 10 have been incorporated into the applications in these areas. Chapters 11 and 12, respectively, describe general techniques and available methods for *fire risk analysis of products or buildings*. Chapters 13 and 14 describe the much more specific methods tailored to applications in two industries where the use of fire risk analysis is far more common than in others, namely, *chemical process industries* and *nuclear power plants*. Finally, Chapter 15 describes new methods addressing consequence measurement for *transportation vehicles*, which now exists in a form ready for use in fire risk analysis.

Activities and Resources

Every major group involved in guidance related to fire safety now has a committee or a publication devoted to fire risk analysis, and the emphasis on risk-based or risk-informed approaches to decision making is growing rapidly. Thus, in addition to the many sources of specific models and methods mentioned in the subsequent chapters, there are a growing number of sources for generic work and guidance.

Among the more important activities are the following:

- SFPE addresses the basics of fire risk analysis in its publications on performance-based design. Several of the ongoing task groups of SFPE, intended to add the

next level of detail to already published guidance, are addressing elements of relevance to fire risk analysis.

- NFPA has a new committee, the Technical Committee on Fire Risk Analysis, whose purpose is to provide assistance and guidance to other committees on methods and concepts in fire risk analysis. One of the most widely cited and used fault tree formats in fire risk analysis is NFPA 550, *Guide to the Fire Safety Concepts Tree*, 1995 edition, developed by the now-defunct Systems Concepts Committee and now assigned for maintenance to this new committee. Development of fire risk analysis methods for general and specific purposes has been a recurring emphasis of projects organized by NFPA's Fire Protection Research Foundation.
- ASTM has a Standard E 1766 to guide the writing of fire risk assessment standards for burnable products.
- The International Organization for Standardization (ISO) TC 92 SC 4 has a new Working Group 10 on fire risk analysis. It has just begun to define a work program.
- The Society for Risk Analysis is the principal worldwide professional organization devoted to risk analysis. It devotes comparatively little emphasis to engineering applications and to acute outcomes, instead focusing more on long-term chronic illness consequences.
- The Institute for Operations Research and the Management Sciences (InFORMS) has areas of emphasis in decision analysis and applies and develops risk analysis concepts and methods through that activity.

CHAPTER 2

Decision Analysis

H. A. Donegan

Introduction

This chapter is devoted to some of the basic elements of decision analysis, a subject that has its roots firmly established in the area of management science, but now enjoys a much wider application. The present article, which is not intended as an exhaustive discussion paper, aims to introduce basic terminology and to illustrate some of the techniques that can be applied to situations in fire protection engineering, one of the many areas of application. The growth in application can be attributed to the significant developments that have taken place within information technology, particularly with regard to the ready availability of user-friendly decision support software. Practitioners interested in particular aspects of the subject and in software will find appropriate references listed in context. The reader should be aware at the outset that decision analysis is more general than risk analysis, which, in terms of fire protection, has its own extensive and highly specialized literature—see, for example, Castino and Harmathy,¹ Gretener,² Hall,³ Hirschler,⁴ Watts.^{5,6}

The engineering of fire protection necessitates a high degree of decision making at all levels of application, and because of the capricious nature of unwanted fire, it involves a high degree of subjectivity and therefore uncertainty. In practically every aspect of fire protection, the practitioner is faced with choices when presented with options or alternative courses of action, each of which has one or more consequences. If a choice is subjective, then it can be made only when the following pieces of information are known to the decision maker:

1. An understanding of each possible consequence
2. The likelihood of occurrence of each consequence
3. The method for combining values and probabilities of consequences into a meaningful course of action

Sometimes the sheer number of options will limit the time that can be spent on evaluating each single option, as when one is faced with large product lists—for example, smoke alarms or fire-resistant doors. Or the possible consequences of a course of action are difficult to enumerate, as in the case of increasingly complex new technology. Often the value of a consequence can be estimated only on the basis of sample information, for example, studying a selection of literature. In other cases, the value of a consequence may depend on many dimensions, such as choosing where to live—taxes, transport, amenities, employment, and so on. Or there may be several possible consequences distributed over time, and it is difficult to predict which one of them will occur and at what time—typically when the fire brigade is attempting to suppress a raging fire.

In complex problems, decisions often have to be made when there are several sources of difficulty interacting or competing. For example, deciding whether or not to build a nuclear power plant instead of a conventional alternative in the face of increasing energy demands is perhaps typical. In this situation, the decision makers have to deal with short- and long-term multidimensional consequences; they know that despite extremely low outcome probabilities, a small number of uncertain events could lead to a catastrophe. With the benefit of hindsight, it is a chilling reality that Chernobyl is the epitome of the above scenario and therefore a timely reminder to those engaged in subjective decisions that impact on life safety.

Consequences are often a reflection of the mathematical modeling strategy that underpins many decisions and are therefore only as valid as the appropriateness of the chosen model or, inclusively, the reliability of its input data. Moreover, the fact that much of the data are subjective places the opinion experts at a key point in the chain of responsibility for good decision making (see Winkler and Murphy⁷). In what follows, it is assumed that methodologies under the various decision classifications are supported by the best efforts of practitioners and software designers.

H.A. (Tony) Donegan is a reader in the Mathematics Division of the Faculty of Informatics at the University of Ulster, Northern Ireland.

Before proceeding to look at decision classifications, some key words that frequently appear in the literature of decision theory are now discussed. For example, in the above preamble, casual reference was made to the terms *subjectivity* and *uncertainty*, yet these are emotive words with a vast and formal literature—see, for example, Bunn,⁸ French,^{9,10} Lindley,¹¹ Raiffa,¹² Viek and Wagenaar.¹³

The concept of probability in decision theory embraces two distinct schools of probabilists—the frequentists and the subjectivists.

The *frequentists* believe that probability can only have meaning in the context of an infinitely repeatable experiment, in which the probability of an event A , namely $P(A)$, is taken to be its long-run relative frequency of occurrence in repeated trials of the experiment—termed *objective probability*. In the reality of risk assessment, approximations called actuarial estimates are used; the relative frequency of the number of times A has previously occurred in some finite experiment is taken as an indication of likely occurrences in the future. For example, if the statistics¹⁴ of residential fire deaths in the sample period (finite experiment) 1983 to 1987 show that on average 47.8 percent of the deaths are identified as occupants aged 65 years and over, then 0.478 is regarded as the probability that a fatal casualty in a residential fire is a person aged 65 or above. Approximations are common in production scenarios. For example, if A represents the event that a sprinkler head is defective, and during the inspection (finite experiment) of a random batch of 240 sprinkler heads 2 are found to be defective, then the chance of picking, at random, a faulty head from the batch is 2 in 240, yet $P(A)$ is stated in general as being 1/120 until revised in another finite experiment.

The *subjectivists* associate probability not with the system under observation, but with the observer of that system identifying probability as the degree or strength of belief that the system will adopt a certain state—termed *subjective probability*. For example, in the modeling of fire spread, the probability of flashover in the room of origin is a measure of opinion relating to the change of state from preflashover to postflashover. It would be decided by the modeler on the basis of experience regarding uncertainties associated with the fire variables in the room of origin. However, such decisions need considerable care; the article by Bunn⁸ addresses some of the fundamental issues regarding the assessment of subjective probabilities. A highly pertinent article by Noonan and Fitzgerald¹⁵ discusses the role of subjective probabilities in fire risk management studies.

Developments in artificial intelligence and in expert systems have shown that probability theory in itself is insufficient to cater for the advancement of theories relating to the management of uncertainty in knowledge-based systems. For example, lexical elasticity, which relates to the fuzziness of words in natural language, provides a clear example. A simple relation between X , Y , and Z expressed as

if X is small and Y is very large, then Z is not very small

does not lend itself to a simple interpretation within the field of probability theory. This is by reason of the lexical elasticity of the predicates *large* and *small*.¹⁶ Such developments have inspired the formation a new school of practi-

tioners focused on imprecision rather than uncertainty. The topics are rather specialized and outside the scope of the present article, but the interested reader will find appropriate background reading in Zadeh¹⁷ and in Klir and Folger.¹⁸

The term *uncertainty* is used prolifically in decision theory, and yet textbooks generally sidestep any attempt at a formal definition. This presentation will not dissent from that established pattern, but will nevertheless construct an interpretation from the axioms of probability. (The subject of probability is discussed elsewhere in this handbook.) The axioms are restated here for convenience:

Axiom 1: *Positiveness*—the probability of an event occurring must be non-negative.

Axiom 2: *Certainty*—the probability of an event that is certain to occur is 1.

Axiom 3: *Addition*—if events A and B are mutually exclusive, then the probability

$$P(A \text{ or } B) = P(A) + P(B)$$

Axioms 1 and 2 imply that the probability of an event occurring must be at least zero and no greater than 1. Hence uncertainty (for the purpose of this discussion) identifies with the probability of an event A such that $0 \leq P(A) < 1$. In a subjective environment, the location of $P(A)$ in the interval $[0, 1]$ lies within a subneighborhood of uncertainty, which is clearly articulated by Bell, Raiffa, and Tversky.¹⁹ They point to the confrontation between abstract theory and realistic behavior, particularly when subjective assessments are required. Real people do not behave like the models say they should. For example,

- Many experts are willing to answer hypothetical questions about uncertain quantities.
- Lay people and indeed experts do not calibrate well. By and large, assessed probability distributions are too tight; people think they know more than they really know and are surprised far too often.
- Some assessment methods lead to less distortion than others.
- It is extremely difficult to assess small probabilities.
- Subjects can learn to calibrate better if they are given systematic feedback.

It is intended that these observations, which are highly pertinent in fire safety, will alert the reader to the realization that decision making is as much an art as it is a science.

Decision Classifications

Broadly speaking, decision classifications can be characterized by the qualitative knowledge spectrum shown in Figure 5-2.1. Given that the spectrum ranges from ambiguous data to well-defined data, in

- Decision making under certainty—the data are known deterministically
- Decision making under risk—the data are described statistically
- Decision making under uncertainty—the data cannot be assigned relevant weights

Figure 5-2.1. Qualitative knowledge spectrum.

		State of nature (event)
Alternatives	Contract A	$v(A) = v(B) + 4000$
	Contract B	$v(B)$

Figure 5-2.3. Contract payoff matrix.

Alternatives a_i	States of nature s_j		
	s_1	s_2	s_n
a_1	$v(a_1, s_1)$	$v(a_1, s_2)$	$v(a_1, s_n)$
a_2	$v(a_2, s_1)$	$v(a_2, s_2)$	
a_m	$v(a_m, s_1)$		$v(a_m, s_n)$

Figure 5-2.2. Payoff matrix.

Decision making under any condition involves alternatives whose payoffs (outcomes) depend on the states of nature, which may be random events. Specifically, the *payoff matrix* of a decision problem with m alternatives and n states of nature can be represented as in Figure 5-2.2. The element a_i represents the alternative i , and the element s_j represents state of nature j . The payoff or outcome associated with a_i and s_j is denoted by $v(a_i, s_j)$.

Decision Making under Certainty

Decision making under certainty means the decision maker knows with certainty the consequence of every alternative or decision choice. For example, a fire engineering consultant with resources to take on a single contract has the choice of two 1-yr guaranteed contracts A and B, each with similar conditions and each capable of being carried out within the consultant’s office environment. If the value of A exceeds that of B by \$4,000, then there is certainty that contract A will maximize the consultant’s well-being. Of course, there is the classic and perhaps paradoxical phrase that accompanies any certainty, “all other things being equal.” The payoff matrix would take the form shown in Figure 5-2.3.

Such matrices are clearly unnecessary for straightforward decision making. However, they offer decision makers a useful structure when the choice of alternative is compounded by more than one state of nature, as in decision making under risk or uncertainty.

Decision Making under Risk

Decision making under risk assumes that the payoff (gain or cost) associated with each alternative, for a given state of nature, has an associated probability. The payoff is usually based on the expected value criterion, which seeks the maximization of expected (average) gain or the minimization of expected cost among the alternatives. The procedure stems from the concept of expectation, perhaps the

most important concept in decision theory, which is discussed in elementary textbooks on probability.

Basically, *expectation* is a weighted average, and to compute its value, one takes the following steps:

1. List all possible alternatives a_i and states of nature (exclusive events) s_j together with the corresponding probabilities $P(s_j)$.
2. Relative to a given fixed state of nature, note the value of each alternative $v(a_i, s_j)$.
3. Calculate $P(s_j) \times v(a_i, s_j)$ as j ranges across all states for each fixed i .
4. Add and note the products for each alternative i .

Consider the situation where a building’s lease has just been extended for a 10-yr period, and although the building is fire-safety compliant, the management, in reviewing a number of factors, invite consultants to assess the fire risk with respect to stock. The results of their inquiry are summarized in Table 5-2.1, which reveals pessimistic and optimistic discrete probability distributions for large, medium, and small fires, conditional on there being a fire within the observed stock. The article by Noonan and Fitzgerald¹⁵ discusses such a risk assessment for a warehouse.

The management, who have some understanding of decision theory, agree in the light of the consultant’s report to examine the following alternatives:

- Upgrade using a sprinkler system (UUS).
- Upgrade without sprinklers (UWS).
- Retain the existing building (REB).

Increasing the degree of fire protection requires additional investment, and for simplicity it is assumed that a proportion of upgrade costs (dollars) are included in the potential loss values as estimated by management. Also, management, who are neither pessimistic nor optimistic, settle on the following mean probabilities of fire size risk: $P(\text{large fire}) = 0.5$, $P(\text{medium fire}) = 0.3$, and $P(\text{small fire}) = 0.2$. The payoff matrix takes the form shown in Figure 5-2.4.

Hence the expectation for each alternative is given by

UUS: $0.5 \times 24,000 + 0.3 \times 16,000 + 0.2 \times 8,000 = \$18,400$

UWS: $0.5 \times 18,000 + 0.3 \times 11,000 + 0.2 \times 4,000 = \$13,100$

REB: $0.5 \times 30,000 + 0.3 \times 15,000 + 0.2 \times 5,000 = \$20,500$

Table 5-2.1 Probability Distribution for a Large, Medium, or Small Fire

Probability of Fire Type	Large Fire	Medium Fire	Small Fire
Pessimistic case	0.6	0.2	0.2
Optimistic case	0.4	0.4	0.2

		States of nature		
		Large fire	Medium fire	Small fire
Alternatives		$P(\text{large fire})$	$P(\text{medium fire})$	$P(\text{small fire})$
		0.5	0.3	0.2
UUS		24,000	16,000	8,000
UWS		18,000	11,000	4,000
REB		30,000	15,000	5,000

Figure 5-2.4. Payoff matrix showing various outcomes.

Based on this information, the management would opt for upgrading without sprinklers. The reader should note that the expected value for an alternative is the average cost to the company that would be expected if the decision were repeated a large number of times—it is not the value that would be returned every time. Clearly, if the decision is made only once, the loss could be any of the three values \$18,000, \$11,000, or \$4,000.

Such problems can be represented using a decision tree, as shown in Figure 5-2.5. Taha²⁰ recommends the following nodal notation—a square (□) to represent a decision point and a circle (○) to represent a chance event. Shields and Silcock²¹ offer a tree structure in fire safety terminology. See also the *Guide to Fire Safety Concepts TREE*, NFPA 550.²²

Decision Making under Uncertainty

Decision making under uncertainty differs from decision making under risk in that in the probability distribu-

Figure 5-2.5. Decision tree to illustrate decision making under risk.

tion associated with the states of nature, s_j is either unknown or cannot be determined. To overcome this dearth of information, the following models have been developed:

- Laplace paradigm
- Wald (minimax/maximin) paradigm
- Savage paradigm
- Hurwicz paradigm

Each reflects the degree of conservatism exhibited by the decision makers in the face of uncertainty.

The Laplace²³ paradigm: This paradigm is based on the principle of insufficient reason.¹⁰ This simply means that, because the probability distribution of the states of nature are not known, there is no reason to believe that they are different. Hence, the j alternatives are evaluated using the optimistic belief that $P(s_j) = 1/n$, where n is the number of states of nature. If the payoff $v(a_i, s_j)$ represents cost (as opposed to gain), then the best alternative is the one that yields

$$\min_{a_i} \left[\frac{1}{n} \sum_{j=1}^n v(a_i, s_j) \right]$$

with min changing to max in a gain situation.

The Wald²⁴ (minimax/maximin) paradigm: The Wald paradigm stems from the conservative attitude of caution—it is a pessimistic criterion of choice in so far as it assumes that the worst will happen. The paradigm aims to get the best out of the worst possible conditions. Given as before, that $v(a_i, s_j)$ is a cost, then the most appropriate alternative selected conforms to

$$\min_{a_i} \left\{ \max_{s_j} v(a_i, s_j) \right\}$$

In a gain situation, the operators min and max are transposed.

The Savage²⁵ paradigm: Often referred to as the Savage regret criterion, the Savage paradigm aims at moderating the pessimistic outlook of Wald's paradigm. Here the payoff matrix $[v(a_i, s_j)]$ is replaced with a regret matrix $[r(a_i, s_j)]$, where the function r is defined as follows:

$$r(a_i, s_j) = \begin{cases} \max_{a_k} [v(a_k, s_j)] - v(a_i, s_j) & \text{if } v \text{ is a gain} \\ v(a_i, s_j) - \min_{a_k} [v(a_k, s_j)] & \text{if } v \text{ is a cost} \end{cases}$$

Regret is the difference between actual outcome and best possible outcome, as in the trivial example of a student who gets 85 percent instead of 100 percent; the student's regret is 15 percent. Likewise, a home owner who pays \$300 for house insurance, when a neighbor insures a similar house with a different company for \$250, experiences a regret of \$50.

The subtlety of moderation in the case of the Savage paradigm over the Wald criterion becomes clear in the following contrived situation. Consider a potential cost matrix where the choice is between a property with smoke

	s_1	s_2	Row max
a_1	90	21,000	\$21,000
a_2	20,000	20,000	\$20,000 → Minimax

Figure 5-2.6. Potential cost matrix.

	s_1	s_2	Row max
a_1	0	1,000	\$1,000 → Minimax
a_2	20,910	0	\$20,910

Figure 5-2.7. Regret matrix.

alarms adjacent to the fire brigade (a_1) or one with smoke alarms but 50 miles from the fire brigade (a_2), and the states of nature are s_1 (alarm works) and s_2 (alarm fails) (see Figure 5-2.6). It is clear from the minimax criterion that alternative a_2 with a definite loss of \$20,000 is preferable. However, a_1 looks attractive if s_1 is realized with a chance loss of only \$90. Clearly, the a_2 alternative is totally conservative.

Now, using Savage’s paradigm, the regret matrix in Figure 5-2.7 emerges. The minimax criterion applied to the regret matrix now selects a_1 —the less pessimistic option.

The Hurwicz²⁶ paradigm: This paradigm reflects a range of attitudes from the most optimistic to the most conservative. Letting $v(a_i, s_j)$ represent a cost (or loss), and if t is an index of optimism such that $0 \leq t \leq 1$, then Hurwicz claims that the most appropriate alternative conforms to

$$\min_{a_i} \left\{ t \min_{s_j} v(a_i, s_j) + (1 - t) \max_{s_j} v(a_i, s_j) \right\}$$

In a gain situation, the operators min and max are interchanged. If $t = 0$, the criterion reduces to the Wald condition, and when $t = 1$, the result is totally optimistic in selecting the best of the best. The decision maker has control over the choice of t , which, in the absence of strong feelings, is taken as 0.5.

Summary Example

The Faculty of Inferno Research Engineers (FIRE) is planning an international conference in Geneva, and FIRE estimates that there are four likely bands of attendance: 150, 200, 250, and 300 attendees. The cost of organization will be a minimum if FIRE can select a venue in Geneva that meets the demand exactly. Clearly, deviations above or below the demand levels incur additional costs resulting from unused seating capacity or lost income opportunities when some of the demand is not satisfied. At the proposed date set for the conference, the organizing committee of FIRE can select one of four appropriate venues

that match the corresponding attendance bands. Letting $a_1, a_2, a_3,$ and a_4 represent the alternative venues with respective seating capacities (150, 200, 250, and 300), and letting s_1 through s_4 represent the levels of attendance (150, 200, 250, or 300), the payoff matrix in Figure 5-2.8 summarizes the relative seating and venue costs to FIRE in hundreds of dollars.

The organizing committee applies the above four methods with the results shown below.

- *Laplace paradigm:* If $E(a_i)$ denotes the expectation associated with a_i , then

$$E(a_1) = 1/4(4 + 9 + 17 + 24) = \$1,350$$

$$E(a_2) = 1/4(7 + 6 + 11 + 22) = \mathbf{\$1,150} \text{ (Optimum)}$$

$$E(a_3) = 1/4(20 + 17 + 11 + 20) = \$1,700$$

$$E(a_4) = 1/4(28 + 22 + 18 + 14) = \$2,050$$

- *Wald paradigm:* See the matrix in Figure 5-2.9.
- *Savage paradigm:* The regret matrix (See Figure 5-2.10.) is determined by subtracting 4, 6, 11, and 14 from columns 1 through 4, respectively.
- *Hurwicz paradigm:* The data in Table 5-2.2 summarizes the picture for arbitrary t .

		States of nature			
		s_1	s_2	s_3	s_4
Alternatives	a_1	4	9	17	24
	a_2	7	6	11	22
	a_3	20	17	11	20
	a_4	28	22	18	14

Figure 5-2.8. Cost payoff matrix.

	s_1	s_2	s_3	s_4	Row max
a_1	4	9	17	24	\$2,400
a_2	7	6	11	22	\$2,200
a_3	20	17	11	20	\$2,000 (Optimum)
a_4	28	22	18	14	\$2,800

	s_1	s_2	s_3	s_4	Row max
a_1	0	3	6	10	\$1,000
a_2	3	0	0	8	\$800 (Optimum)
a_3	16	11	0	6	\$1,600
a_4	24	16	7	0	\$2,400

Figure 5-2.10. Regret matrix resulting from the Savage paradigm.

Table 5-2.2 Outcome of the Hurwicz Paradigm

Alternative	Row min	Row max	$t(\text{Row min}) + (1-t)(\text{Row max})$
a_1	4	24	$24 - 20t$
a_2	6	22	$22 - 16t$
a_3	11	20	$20 - 9t$
a_4	24	28	$28 - 14t$

If you were chairman of FIRE, how would you interpret the above set of results and hence advise your committee on what decision to make?

Multi-Objective Decisions

The above classification examples have one property in common; they all belong to the class of problems where the desired alternative is chosen exclusively on the basis of a single objective—to either minimize cost or maximize gain. When a problem involves two or more objectives, the decision maker must decide on the relative importance of each before analyzing the merits of each alternative. Multiple objectives are often conflicting; for example, a fire authority, in citing a new fire station, might have to balance key objectives such as minimizing cost, minimizing risk, and minimizing travel distance. A problem of this kind never has a correct solution, but the nature of its analysis can offer the stakeholders considerable insight into the quality of any emerging decision.

Terminology

There is a profusion of terminology used in connection with such decision making. For instance, the formal literature uses the terms *multi-attribute decision making*, *multi-objective decision making*, and *multicriteria decision making* (the terminology preferred by this author) almost interchangeably, and the inexperienced practitioner could well be forgiven for being confused. However, the following definitions should assist the reader who is trying to come to terms with multicriteria decision theory.

Objectives: Objectives are task actions, such as

- To reduce the number of deaths due to unwanted fire
- To improve the level of fire safety in public assembly buildings
- To minimize the number of toxic hazards in the event of a fire
- To maximize the efficiency of fire modeling

French¹⁰ claims that an objective has a dimension together with an indication of the “good” and “bad” ends of the dimension. Thus, to minimize toxic hazards is an objective that indicates that a reduced number of hazards is preferred. This concurs with Keeney and Raiffa,²⁷ who described an objective as an indication of the preferred direction of change. The performance of a stated objective is measured by its attributes.

Attributes: Synonymous with criteria, attributes are the dimensions of an objective along which alternatives are

represented.¹⁰ For example, if alternatives are to be judged against three attributes, picture these as the three axes X , Y , and Z . Then an alternative $\mathbf{a} = (a_1, a_2, a_3)$ is effectively a point in three-dimensional space such that a_1 is in the X dimension, a_2 is in the Y dimension, and a_3 is in the Z dimension. For example, Donegan et al.²⁸ list the attributes of domestic fire safety evaluation as Occupants, Doors, Communications, Internal Planning, Travel Distance, and Flues/Ducts. In mathematical terms, these represent a six-dimensional attribute space in which, for example, a domestic norm $\mathbf{n} = (n_1, n_2, n_3, n_4, n_5, n_6)$ can be used as a comparator against which to judge the m alternatives $\mathbf{a}^k = (a_1^k, a_2^k, a_3^k, a_4^k, a_5^k, a_6^k)$, where $1 \leq k \leq m$. It is not the intention of this article to dwell on mathematical formalism; the interested reader will find a full axiomatic treatment in French.¹⁰

Value and utility: For each alternative facing a decision maker, it is conventional to measure the alternative’s attractiveness by means of a numerical score aggregated from the attribute scores. If the decisions involve no element of risk or uncertainty, scores are described as *values* of the course of action; otherwise they are known as *utilities* of the course of action. This article, given its introductory status, will restrict its illustrations to the former. For an introduction to utility theory and an excellent account of its application in decision making, with special reference to insurance risk, see Ramachandran.²⁹

Weighting: Although the decision maker has chosen, or agreed on, a set of attributes, it does not mean that each attribute has the same merit. Each attribute will rate a degree of importance, but the actual cardinal priority of the attributes is seldom obvious. Although a decision maker familiar with the task in hand might intuitively identify the ordinal priority, it is usually necessary to employ a formal process to arrive at credible weights. Such a process may be as informal as the Delphi method³⁰ or as formal as the eigenvector technique of the analytic hierarchy process.³¹ More will be said of these processes later in this chapter. Figure 5-2.11 summarizes the problem environment.

Dominance: An alternative X is dominated if another alternative Y is “better” in at least one attribute and performs equally with respect to the remaining attributes. This definition permits the initial screening of alternatives in so far as all dominated alternatives are discarded.

Satisficing: The word *satisficing* is probably a contraction of *sufficient to satisfy*,³² although Watts³³ believes the term was coined by Simon³⁴ for identifying a solution that is good enough although not necessarily optimal. The method of satisficing, often referred to as the conjunctive method, is purely a screening technique. In order for an alternative to be acceptable, it must exceed stated performance thresholds for all attributes. This compares with the norm strategy used by Shields et al.³⁵ in their fire safety evaluation of public assembly buildings.

Disjunctive: The term *disjunctive* also applies to screening. Disjunctiveness is the logical complement of satisficing in that an acceptable alternative must exceed a given performance threshold for at least one attribute.

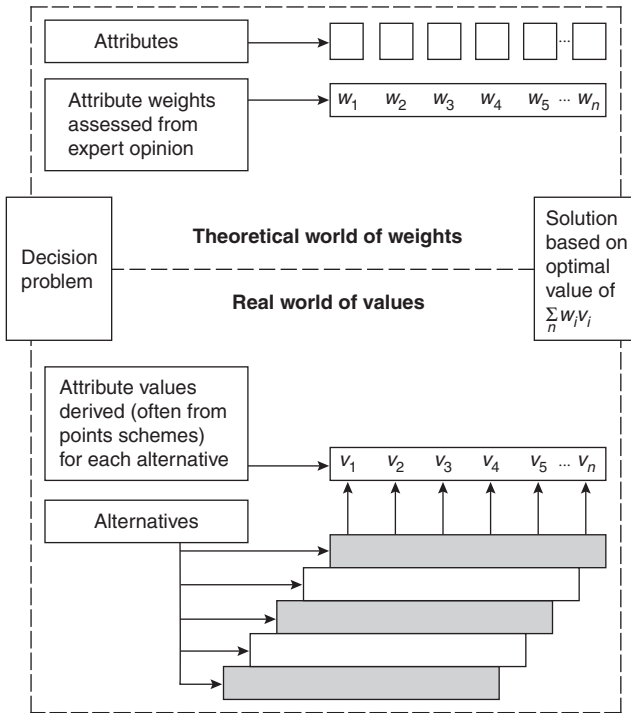

Figure 5-2.11. Attributes, values, and weights.

Additive weighting: The additive weighting method will be demonstrated later in this chapter. Basically, the score attached to an alternative is equal to the weighted sum of its attribute preference valuations (frequently, the generic term *utilities* is used, albeit in the absence of probability distributions). The weights are subjective percentages of importance given to each attribute label. The resulting weighted sums for each alternative can be used to rank, screen, or choose an alternative. It has been shown that, provided trade-offs among the attributes in any subset of the attributes do not depend on the levels of the remaining attributes, the additive weighting model can be applied without reservation. The trade-off proviso is described by Keeney and Raiffa²⁷ as preferential independence, which is neatly formalized in French.¹⁰

Simple Multicriteria Illustration

Consider the situation where a new fire station is to be located in a large conurbation offering five potential sites—A, B, C, D, E. Deciding on the most appropriate site is a nontrivial matter, and as with any building project, there are costs and benefits to be considered. This illustration will focus only on the benefits of siting, with considerable simplification to ensure transparency of the methodology. The technique is based on the Simple Multi-Attribute Rating Technique (SMART) of Edwards,³⁶ and the stages in the process are outlined as follows:

Nominate the decision maker(s) (DM): In this case, an architect is charged with this responsibility. Group decision making is possible (see Goodwin and Wright³⁷).

Recognize the alternatives: The alternatives correspond to the siting locations A, B, C, D, E.

Identify the attributes: The attributes are usually finalized with the assistance of a value tree, such as Figure 5-2.12. Here the architect identifies two main predesign attributes, called Site and Situation, and also specifies their subattributes, that is, criteria that can be readily assessed or valued with respect to each site—Spatial Access, Road Infrastructure, Area Fire Statistics, Site Dimensions, Site Bearing Capacity, and Planning Freedom.

Assess each alternative: Using the six attribute labels, the architect assesses each site (alternative) and assigns to it a corresponding attribute value, $v_i (1 \leq i \leq 6)$. The valuation of site attributes can be carried out using direct measurement (if appropriate), a logical points scheme, or, as the architect chose to do in this case, a simple linear rating scale from zero, meaning horrible, to 100, meaning best possible. Attribute valuation using the linear rating scale approach is succinctly discussed in Edwards and Newman.³⁸ An interesting and instructive observation made by these authors is that a curved (nonlinear) value function almost never makes any difference to the decision. The architect's survey reveals the matrix of values shown in Figure 5-2.13.

Determine a weighting factor $w_i (1 \leq i \leq 6)$ for each attribute: The weighting factor could reflect the decision maker's point of view, or a consensus point of view derived from experts. In any event, there are a number of specialized techniques for obtaining such weights, and these will be discussed later in this article. Suffice for the present example that the architect has access to weights. Thus, Spatial Access (26%), Road Infrastructure (34%),

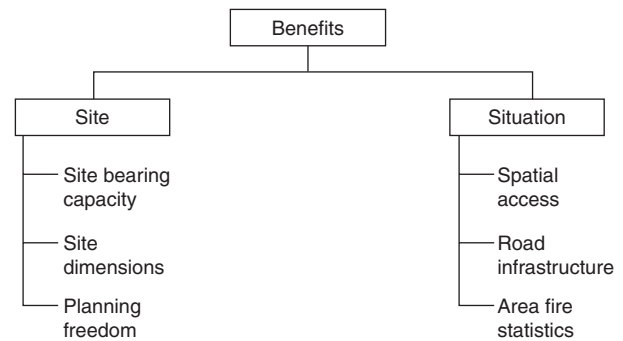

Figure 5-2.12. Value tree for fire station location problem.

	A	B	C	D	E
Spatial access	70	75	65	45	55
Road infrastructure	95	15	75	65	35
Area statistics	25	95	05	25	55
Site dimensions	45	25	05	50	95
Bearing capacity	60	05	05	25	85
Planning freedom	70	25	95	85	65

Figure 5-2.13. Architect's attribute-scale values.

Table 5-2.3 Values and Weights for Each Site

Attribute	Weight	Site				
		A	B	C	D	E
Road infrastructure	0.34	95	15	75	65	35
Spatial access	0.26	70	75	65	45	55
Bearing capacity	0.19	60	5	5	25	85
Site dimensions	0.10	45	25	5	50	95
Area statistics	0.08	25	95	5	25	55
Planning freedom	0.03	70	25	95	85	65
Aggregate benefits		70.50	36.4	47.10	48.10	58.20

Area Statistics (8%), Site Dimensions (10%), Bearing Capacity (19%), Planning Freedom (3%). Note that the weights are in percentages, which must sum to 100 percent, or if stated in decimal format, they should sum to 1.

Take a weighted average of the values assigned to each site (alternative): See Table 5-2.3. The weighted average will give the architect a measure of how well a particular site performs over all the attributes. The weighted average (aggregate benefit) is obtained from the sum $\sum_{i=1}^6 w_i v_i$.

Make a provisional decision: The apparent answer is site A, but the architect must be reassured, and therefore must check the robustness of the results as follows.

Carry out a sensitivity analysis to test the robustness of the decision: The sensitivity analysis is an important aspect of the analysis that is often overlooked in practice, yet it is perhaps the most revealing part of the process and can contribute significantly to the decision maker's understanding of the problem. It is imperative that the procedure not be haphazard. The following strategy is recommended in Goodwin and Wright.³⁷

The architect, upon reflecting on the above results, notices that the Situation attribute accounts for 34% + 26% + 8% = 68% of the benefit's weighting, whereas Site features account for the remaining 32%. Accordingly, before giving a formal decision, the architect proceeds to investigate the consequences of varying the weight attached to Situation. Figure 5-2.14 summarizes how the value of benefits for the different sites varies with changes in the Situation weights. The graphical technique is based on the following proposition: If Situation, for example, had a weight of zero, this would imply that the three corresponding attributes (Spatial Access, Road Infrastructure, Area Statistics) would each have zero weights. Correspondingly, the weights of the six lowest attributes would be Spatial Access (0), Road Infrastructure (0), Area Statistics (0), Site Dimensions (10), Bearing Capacity (19), and Planning Freedom (3). When normalized and rounded, these amount to 0, 0, 0, 60, 31, and 9, respectively, as shown in Table 5-2.4. It is not difficult to draw the corresponding graphs for each site, as shown in Figure 5-2.14.

It is evident from the graphs that a zero weighting on Situation would immediately elevate site E to priority status. This status would maintain so long as the weight attached to Situation is less than 48.2 percent. However, this

Figure 5-2.14. Sensitivity analysis for weight attached to Situation.

Table 5-2.4 Values and Weights When Situation Is Zero Weighted

Attribute	Weight	Site				
		A	B	C	D	E
Road infrastructure	0.00	95	15	75	65	35
Spatial access	0.00	70	75	65	45	55
Bearing capacity	0.60	60	5	5	25	85
Site dimensions	0.31	45	25	5	50	95
Area statistics	0.00	25	95	5	25	55
Planning freedom	0.09	70	25	95	85	65
Aggregate benefits		56.25	13.00	13.10	38.20	86.30

is clearly significantly lower than the professionally judged figure of 68 percent. The tangibility of the attributes in this example provides little scope for opinion variance, particularly among experts, and therefore it is unlikely that the opinion swing required to put site E in the frontier of consideration is likely to happen. The architect would be justified in the recommendation of site A.

A similar approach could be taken with the lower-level weights. For example, the architect may be instructed to explore the effect of varying the weights attached to Road Infrastructure and Spatial Access while keeping the weight attached to Area Statistics constant. Such in-depth analyses are clearly worthwhile when large amounts of resources are being expended. The reader is reminded that this example dealt only with the multicriteria related to benefits; it did not address the issue of costs and the relationship between costs and benefits. A useful discussion on trade-off between costs and benefits, pitched at the level of this example, can be gleaned from Goodwin and Wright.³⁷

Fire Safety Attribute Weighting

Rational solutions for many of today’s decision-making problems in fire safety evaluation are difficult to formulate. This is often due not only to the complexity of the problems themselves, but also to the vagueness (also referred to as “fuzziness”) of certain concepts. Despite the increased accessibility of modern computing technology, the complexity factor can be handled only by the introduction of a multi-attribute structure into the elements of a problem. Consistent judgments of weight and value must be made on individual fire safety attributes to enable an overall assessment; and it is important to distinguish the tasks involved (see Figure 5-2.11). Finding attribute weights is a theoretical exercise that, for many evaluation problems, reduces to finding a cardinal ranking of criteria (see Watts⁶). On the other hand, finding the corresponding values for each alternative is a real-world exercise, which can involve complex points schemes and specialized economic functional analysis. The buoyant literature devoted to both tasks is conveniently reviewed by Watts.³⁹ Definitive articles are presented by Nelson and Schibe,⁴⁰ Marchant,^{41,42} Stollard,⁴³ Shields et al.,⁴⁴ and Dodd and Donegan.^{45,46}

The generally accepted attribute levels—objectives, tactics, and components—are shown in Figure 5-2.15, with nomenclature attributed to Marchant.⁴¹ The levels conform to a hierarchical structure with decreasing generality from the apex.

The Hierarchy Philosophy

The example in the preceding section, “Simple Multi-criteria Illustration,” did not discuss strategies for obtaining the weights of criteria or attributes. These strategies have a vast and specialized literature within the realm of decision theory, but the accepted nature of attribute decomposition within fire safety evaluation has enabled the following distillation of methods.

These all hinge on the structure of a fire safety evaluation hierarchy, shown in Figure 5-2.15. Typically, if the key objective or policy is “fire safety,” the next level of the hierarchy lists the secondary, or supporting, objectives—“to save lives” and “to protect property.” Sometimes a third objective, “to prevent conflagration,” is included, but this will be dictated by the environment of the problem. These objectives are very general, and their balance of importance can be crucial to the ranking outcome of a

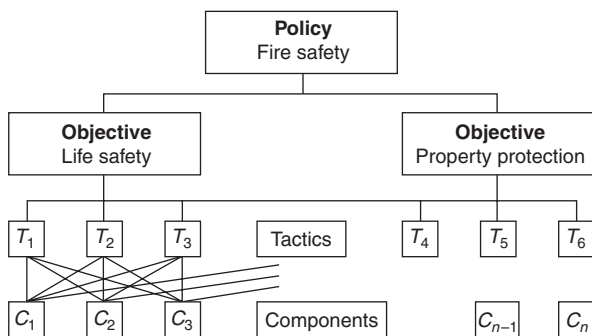

Figure 5-2.15. Typical fire safety evaluation hierarchy.

set of weights (see Dodd and Donegan⁴⁵). The next reduced level of generality comprises the tactics that would be employed by a safety analyst in support of the objectives. For example, “to improve egress capability” or “to facilitate rescue” would be recognized tactics in support of “life safety.” At the components level, usually the lowest level, the criteria are chosen to identify with the tactics, but at a much lower level of generality. Each component is seen as a pragmatic dimension to which an engineer can attach a value when surveying an alternative. Most components have long lists of subcomponents, which are useful when seeking an attribute value. The value emerges as a synthesis of scores or points attached in some logical manner to each subcomponent. A typical component could be “doors” and these would be valued on the basis of subcomponents such as “dimensions,” “fire resistance,” “glazing,” or “intumescent stripping.”

Effectiveness Matrices

Effectiveness matrices are opinion matrices. (The term *effectiveness matrix* is taken from Lai and Hopkins.⁴⁷) Already, it has been stated that attributes are dimensions along which alternatives can be represented. However, it is possible, as follows, to extrapolate this idea to cater for the cardinal ranking of fire safety components relative to the stated policy. Assume that there are *m* components, *n* tactics, and *k* objectives. A decision maker (DM) can represent each component as a vector of tactics, and, a fortiori, the set of components as an effectiveness matrix $[c_{ij}]_{m \times n}$ in which the rows represent components, and the columns represent tactics. The element c_{ij} is the numerical equivalent of DM’s opinion as to the importance of the *i*th component relative to the *j*th tactic. Similarly, each tactic can be represented as a vector of objectives, the set of tactics being represented by the effectiveness matrix $[t_{ij}]_{n \times k}$, where t_{ij} represents the importance of the *i*th tactic relative to the *j*th objective. Finally, DM declares the importance of each objective relative to the stated policy in the effectiveness matrix $[o_{ij}]_{k \times 1}$ (vector, since there is only a single policy). The product of the three effectiveness matrices,

$$[c_{ij}]_{m \times n} \times [t_{ij}]_{n \times k} \times [o_{ij}]_{k \times 1}$$

yields the components-to-policy vector, which, when linearly normalized gives the required attribute weightings.

The preceding numerical routine is the same for all weighting methods. Any differences in the routine relate to the determination of the effectiveness matrices. These are discussed in the next section using notation that has previously appeared in fire research literature.

Weighting Methods Used in Fire Safety Evaluation

The hierarchical model is amenable to either cross impact analysis or analysis involving pairwise comparisons. These two analysis methods will be discussed in some depth. In either case, the aim is the attachment of subjective weights to all of the objectives, tactics, and components, so that in vector form, components are pri-

oritized with respect to each tactic; tactics are prioritized with respect to each objective, and finally, objectives are prioritized with respect to policy. Ultimately, the decision weight vectors at each level are grouped in matrix format (effectiveness matrices) such that, if they are identified as

C/T—the components-to-tactics matrix

T/O—the tactics-to-objectives matrix

O/P—the objectives-to-policy matrix

then the matrix product $C/T \times T/O \times O/P$ yields a components-to-policy vector that, when normalized, gives the desired prioritization weights.

Edinburgh Cross-Impact Analysis

This unformalized approach used in the Edinburgh model, attributed in the main to Marchant,⁴¹ is perhaps the most basic form of cross-impact analysis. The decision maker uses a pseudo Likert scale having values from 0 (least important) to 5 (most important). A Likert scale (named after its inventor) is used to measure a respondent's level of agreement on some issue. The values may be considered to be ordinal, ranging from least agreement to most agreement.⁴⁸ The decision maker uses the Likert scale to assess the importance of each element on a given hierarchical level relative to each element of the next-highest level, and produces a corresponding effectiveness matrix. When more than one decision maker is involved (as is usually the case), a consensus matrix that summarizes all the decisions can be calculated. The dimensions of all the resulting matrices for the complete hierarchy permit their consecutive multiplication, as shown in the previous section. It is noteworthy that Edwards et al.⁴⁹ have shown that judgments of magnitude, while amenable to semantic scaling (classical Likert), "are best when made numerically." This characterizes the pseudo Likert scale (see the discussion in the subsection titled "Interval Scale" later in this chapter).

The simplicity of the cross-impact approach has an obvious appeal because of its acquiescence with intuition. The input data are essentially bias-free, absolute values chosen from a Likert-type scale; there is no limit to the number of elements at a single level, and reasonable precision can be used in determining scores. The lack of uniformity among experts in their perceptions of component independence is accommodated by an *interaction percentage contribution matrix (IPCM)*. This is a component-to-component square matrix showing the degree to which the contribution of a component to fire safety is enhanced by the interaction of other components. The reader will find an example in Stollard.⁴¹

Hierarchical Cross-Impact Analysis (HCIA) Methodology

Hierarchical cross-impact analysis (HCIA) is a multi-attribute weighting strategy developed at the University of Ulster using a similar philosophy to the Edinburgh approach. The characterization of HCIA, fully developed by Donegan et al.,²⁸ addresses the cross-impact approach at two levels—the fundamental level and the pragmatic level. In the *fundamental level*, a pseudo axiomatic approach is taken to

- Define a hierarchy in relation to fire safety
- Explain the meaning of interactive importance
- Propose the notion of a partial impact
- Define a total impact
- Introduce sequential perturbations

In the *pragmatic level*, a modeling approach is taken to

- Maintain the assessment interval through each stage of the quantification
- Stretch the component ranking intervals to enhance the important components and decrease the psychological significance of the less-important components
- Perturb consensus weightings with interaction noise

HCIA methodology formalizes many aspects of the Edinburgh approach. It uses a similar hierarchical cross-impact analysis over the different levels in the system, but allows for interactions between issues at the same level by the use of perturber matrices. Again, it can be used only for hierarchical networks.

Using the attribute terminology outlined above, the partial impact of tactic T_j on component C_i relative to the r th objective O_r is written and defined as

$$\partial I(C_i/T_j)_{O_r} = (C_i/T_j)(T_j/O_r)$$

The total impact of the collection of tactics on C_i relative to O_r is then defined as

$$\sum_{j=1}^n \partial I(C_i/T_j)_{O_r} = \sum_{j=1}^n t_{ij}\sigma_{jr}$$

which is clearly a matrix product. The elimination of the tactics collection of attributes is completed by defining the interaction

$$C_i/O_r = \sqrt{\frac{1}{n} \sum_{j=1}^n t_{ij}\sigma_{jr}}$$

thus giving a components-to-objectives interaction matrix. Similarly, the objectives collection of attributes is eliminated leaving a components-to-policy vector.

The pairwise comparison perturbation matrices, utilized at all the levels in the hierarchy to eliminate the problems of interdependence of issues, are symmetric and generally sparse. These adjust for "noise" in the system resulting from vagueness in the definitions of the attributes at each level.

While the forced stretching of the final vector as described in Donegan et al.²⁸ was purely subjective and appeared to have some significance at that time, it was recognized that such a strategy was contextually motivated and, unless unanimously adopted by the fire research community, could result in serious obfuscation. Research reported in Dodd and Donegan⁴⁵ points to indigenous stretching as a naturally occurring feature of some scales and therefore a factor in scale choice. Although research by Saaty and Vargas⁵⁰ illustrates how particular measurement techniques are more appropriate in certain situations, there is the concomitant psychological impact on scoring that results from the manner in which a question is posed—see, for example, the paper by Salo and

Hämäläinen.⁵¹ Insufficient contextual research to date leaves this psychological issue unresolved.

In spite of its formality, HCIA, just like its parent the Edinburgh model, suffers from one serious drawback—the absence of a consistency check. Even in the short time taken to score a set of issues, mood changes, tiredness, or lack of concentration can influence judgment. Short of an alternative to cross-impact analysis, no reliable quality measure has yet been devised to allay this shortcoming. It was this concern that prompted Shields and Silcock⁵² to consider using the analytic hierarchy process due to Saaty.³¹

Analytic Hierarchy Process (AHP)

The analytic hierarchy process (AHP) is a procedure that has been widely recognized and used as a method of prioritizing the elemental issues in complex problems in a variety of applications (see, for example, Rahman and Frair,⁵³ Liu and Xu,⁵⁴ and Vachnadze and Markozashvili⁵⁵). Unlike traditional multi-attribute techniques, AHP permits the integration of alternatives into the hierarchy, a merging of the real and theoretical worlds depicted in Figure 5-2.11, though this is not an essential requirement of the process. AHP can also be used as a means of weighting attributes, if desired; it is this latter option that is of concern here. The procedure entails the comparison of all the pairs of individual attributes at each level relative to each attribute in the superior level. The intrinsic complexity of the process prohibits a simple description.

The technique is based on the fact that for a square matrix, **C**, of nonnegative real numbers representing, for example, pairwise comparisons of the importance of component attributes of the hierarchy with respect to one element of the next-higher tactics level, there is a dominant eigenvalue, λ , and a corresponding right eigenvector, **x**, emerging from the characteristic equation $\mathbf{C}\mathbf{x} = \lambda\mathbf{x}$. Given that $\mathbf{C} = (c_{ij})$, where $c_{ij} > 0$ and $i, j = 1, 2, 3, \dots, m$; and given that $c_{ij} = 1/c_{ji}$ and the consistency condition $c_{jk} = c_{ij} \times c_{ik}$; $i, j = 1, 2, 3, \dots, m$ holds; then it is easily shown that $\lambda = m$ and, by virtue of the fact that **C** is of unit rank, the remaining $m - 1$ eigenvalues are each zero. For such a matrix, any column is essentially the dominant right eigenvector of priorities (weights). In reality, it is unreasonable to expect decision makers to be perfectly consistent, although a fair degree of consistency is expected. Variations from perfect consistency in **C** perturb the eigenvalues such that $\lambda > m$,³¹ the proximity of the maximum eigenvalue to the order of **C** being an indication of the consistency.

The corresponding eigenvector is normalized and the procedure repeated for each tactic in the tactics collection. The set of dominant eigenvectors is considered as an effectiveness matrix of priorities (C/T) between components and tactics. Similarly, priority effectiveness matrices are established for tactics to objectives (T/O) and for objectives to policy (O/P). A combined matrix multiplication (C/T)(T/O)(O/P) yields a component-to-policy priority (weighting) vector. In the calculation of such priorities, the matrix entries are selected from a statistically optimized set of Saaty's weightings:

$$S = \left\{ \frac{1}{9}, \frac{1}{8}, \frac{1}{7}, \frac{1}{6}, \frac{1}{5}, \frac{1}{4}, \frac{1}{3}, \frac{1}{2}, 1, 2, 3, 4, 5, 6, 7, 8, 9 \right\}$$

Consider, for example, the situation where five components, C_1 to C_5 , must be prioritized with respect to, say, tactic T_3 . The decision maker indicates the relative importance of C_1 and C_2 , C_1 and C_3 , C_1 and C_4 , and so on, on a scale of 1 to 9. A score of 1 on this scale implies that the two components being compared are "of equal importance," whereas a score of 9 signifies that one of the components is "of absolute importance" relative to the other. The intermediate scores indicate varying degrees of importance between the two extremes. Obviously, the importance of any component relative to itself is unity, and the law of reciprocity holds; that is, if C_1 rates a score of 3 against C_2 , then C_2 rates a score of 1/3 against C_1 , and so on. Thus, these pairwise criteria comparisons by the decision maker can be incorporated into a "positive reciprocal" (terminology used by Saaty³¹) decision matrix, as shown here.

	C_1	C_2	C_3	C_4	C_5
C_1	1	3	2	2	1
C_2	$\frac{1}{3}$	1	$\frac{1}{4}$	$\frac{1}{4}$	2
C_3	$\frac{1}{2}$	4	1	$\frac{1}{2}$	3
C_4	$\frac{1}{2}$	4	2	1	$\frac{1}{5}$
C_5	1	$\frac{1}{2}$	$\frac{1}{3}$	5	1

Such a matrix is a typical response from a decision maker; if it were perfectly consistent, then the eigen-spectrum would be {5,0,0,0}. However, a simple calculation shows the spectrum to have a right dominant eigenvalue, λ , of 6.7 and a corresponding normalized dominant right eigenvector of [0.25, 0.14, 0.19, 0.19, 0.24] in this case. Saaty³¹ defines a consistency index,

$$CI = \frac{\lambda - k}{k - 1}$$

where k is the order of the matrix, and a corresponding consistency ratio

$$CR = \frac{CI}{\text{Random consistency number}}$$

Saaty³¹ provides a list of random consistency numbers, which are reviewed and updated by Donegan and Dodd.⁵⁶

The consistency check is designed to provoke the decision maker into reconsidering the entries in the decision matrix should the consistency ratio be unacceptable—for example, greater than 10 percent.

Difficulties with AHP: The main user criticism that can be labeled against the procedure is the number of questions that must be posed to busy experts in the exhaustive completion of a questionnaire structured around a given hierarchy. This is particularly frustrating to a research manager who may experience attrition of experts on having to elicit expert opinions on a number of rounds in pursuit of consensus. The availability of convenient AHP

analysis software such as Expert Choice (by Decision Support Software Inc., in Pittsburgh) does not reduce this particular inconvenience at present. Perhaps, with increasing World Wide Web facilities and new methods in survey computing, the problem will not be so manifest. Implicit in this main criticism is the problem associated with obtaining group consensus in AHP. The question of whether to obtain consensus among experts before inputting the data into AHP, or whether to seek vector consensus when each expert's weighting vector has been evaluated, is discussed with an illustration of both methods in Tung.⁵⁷

Criticisms of a theoretical nature continue to be debated in the technical literature stemming from the paper by Dyre,⁵⁸ but these are really of academic interest only and should not inhibit the potential user. Perhaps the most abused criticism is that of *rank reversal*, which, among other things, refers to the possibility that ordinal changes can take place in a list of remaining attributes when one is removed from the analysis. The debate is far from being settled, but as AHP was developed by Saaty, it is not unreasonable to quote his view on the concept of rank reversal:⁵⁹

An important question in decision making is whether adding new alternatives to a decision structure should or should not affect the rank of the old ones. It was once thought that irrelevant alternatives should not affect their rank. But experiments reported in the literature have shown that rank reversal can occur for many different reasons. The decision to preserve rank depends on whether the number of alternatives added, and how good they are, influences preference among the old ones. The AHP has a procedure to preserve rank, as in buying a best computer even if there are many like it, and another to allow rank to change, as in buying a beautiful tie if there are many like it.

The different opinions and complex arguments are beyond the scope of this article, but users of proprietary AHP software will have a mode selection option that will facilitate either rank reversal possibilities or absolute rank preservation.

Measurement

Measurement is defined as the assignation of a number to the entity under consideration in accordance with a rule; this number then reflects the measured property of the entity.⁶⁰ In mathematical terminology, the measurement is the image under a *monotonic*, that is, order-preserving, mapping of the dimensional property into a real line. Measurement of the physical entities encountered in experimental work presents a large number of fundamental problems that must be recognized by researchers. For example, the precision of the result cannot exceed the precision of any of the data used in its calculation. Thus, a result to ten significant digits is pointless when even one item of the contributory data is approximated to two significant figures. This is why 10.000 is not the same as 10; the former indicates that the measuring equipment allowed for measurements of three decimal

places, and the "correct" result is therefore between 9.9995 and 10.0005, whereas the latter shows much less precision—between 9.5 and 10.5.

Further allowance must be made for experimental error. Many external factors (e.g., heavy road traffic outside the laboratory) can introduce random elements into the measuring process. These factors, however small, must be taken into account in the result. Systematic errors, caused by a bias in the measurement process, assume an even greater significance with the introduction of opinions, which can compromise the work and should be eliminated. The opinion problem is present in most questionnaire design. These opinions, or psychological components, where linearity is less measurable can jeopardize experimental results (see detailed discussion in Vieck and Wagenaar¹³).

Scaling

The four types of scale most relevant to fire protection engineering are (1) nominal, (2) ordinal, (3) interval, and (4) ratio. Each scale, in order, represents progressively stronger properties.⁶¹

Nominal scale: The values on a *nominal scale* classify or categorize the objects represented; in other words, no information on size is implied. For example, the number identifying food items on a menu or the room number in an office block might be regarded as nominal scales. The property common to such items is the *category property*. Many coding systems are nominal scales. For example, the computer system of a car dealer might store car type as a single digit: 01 for Ford, 02 for General Motors, 03 for Lincoln, 04 for Buick, and so on. Such a number does not reflect the size or power of the car; it merely indicates the manufacturer. Similarly, fire extinguishers might be classified by type: 1 for water, 2 for CO₂, 3 for halon, and so on. However, the numbers 1 to 3 have no implications with regard to quality.

Ordinal scale: The *ordinal scale* not only characterizes the entities represented, but also ranks or orders them. However, proportion is not necessarily maintained. This type of scale is exemplified by examination grades: in a descending scale, a grade 2 is better than a grade 3, but one cannot say by how much. Glenburg⁶¹ offers the stripes on military personnel as an ordinal scale: a sergeant (3 stripes) is "superior" to a corporal (2 stripes), but it is nonsense to argue that the sergeant is one and a half times as authoritative. Ordinal scale examples abound in organizations; one example is the ranking of daily tasks in order of priority.

Interval scale: More mathematically tractable and, hence, of greater importance in quantitative assessments, the interval scale is a continuous scale between two points, for example, from 0 to 10, or 1 to 5. Relative difference is maintained; that is, equal intervals of the scale have the same meaning. For example, the effective difference between 1 and 2 is exactly the same as the effective difference between 4 and 5. An example of an interval scale is a ruler or similarly graduated device. Celsius and Fahrenheit temperature scales are interval, and the *equal*

intervals property, or *relative difference property*, is essential when one scale is converted to the other. Arithmetic-based operations involving addition, subtraction, and multiplication by a scalar (a number with no units) can be used on numbers from an interval scale.

Not infrequently, the integer range from 0 to 5 has been used to assign relative values of importance to the attributes of a fire safety hierarchy. The adoption of this numerical range over a spectrum of attributes, described in the literature (e.g., Dunn Rankin⁶² and Torgenson⁶³) as a Likert-type scale, entails a consideration of its validity in terms of the measurement it achieves. Strictly speaking, the scale is ordinal since it cannot be taken for granted that the distances between attributes are equal. Kumar⁶⁴ states that a Likert scale is based on the assumption that each item (attribute) has a priori equal attitudinal value (importance or weight) in terms of reflecting an attitude (from 0 to 5) toward the issue in question, which in the context of fire safety attribute weighting is not the case. Nevertheless, the work of Schiebe et al.³⁰ has demonstrated that the error in assuming the equal interval property is not significant. Hence, the results obtained from such measurements can be used in combinatorial calculations.

Ratio scale: The *ratio scale* is an interval scale with the *absolute zero property*; in other words, one end is fixed so that the values on it are absolute rather than relative. For example, the Kelvin (K) scale relates temperature to absolute zero temperature, at which all motion ceases. This scale is fundamental to the operation of AHP (see the previous section titled "Analytical Hierarchy Process"), and due consideration must be given to the entity of measurement. For example, a body having a temperature of 40°C indicates twice the temperature of another body at 20°C, but not twice the heat content, which must be referred to the absolute zero of temperature, -273°C.

Panels of Experts

The development of expert systems and case-based reasoning tools implies an underlying assumption as to the meaning of expertness. Consequently the assessment of expert opinion using, for example, a Delphi process, may lead to conclusions that, without some formal insight, could on some occasions be considered ambiguous. A review of Delphi literature (Rowe and Wright⁶⁵) will not solve this problem, since Delphi researchers fail to define the term *expert* as applied to their study. If, in simplistic terms, an expert is regarded as one practiced or skillful within the area of consideration, there is an intuitive extrapolation as to the notion of expertise, and the assessment of expert opinion relies to some extent on a global understanding of this extrapolation. In general, the expert response must conform to some form of measurement criterion in relation to consensus if any conclusion is to be reached on any issue that is the subject of expert opinion.

On the assumption that more heads are better than one in achieving a balanced view, many different forums for assessing group opinion have been utilized over the years (see Schiebe et al.³⁰). Some of the most common means of assessing group opinion are discussed as follows.

Committee

The traditional method of forming group opinion is the committee. Under the guidance of a (impartial) chairperson, the issue is isolated (if necessary) and debated, with consensus determined by a majority vote. Besides the obvious discrepancy that a majority and consensus are not synonymous, the recognized difficulties with the method are the existence of one dominant member, and group pressure upon an individual to conform (the herd instinct). Thus, the resultant group pronouncement may not be at all representative of the group.

Nominal Group

A committee is strictly a subgroup of a large organization from which its authority is derived. More relevant to a panel of experts, that is, the pooling of considered opinion, are nominal groups and variations thereof. In this situation, the alternatives are created by the panel members when they are each outside the group context. The individual members' lists, circulated before meetings, are then pooled. Personality issues are reduced, the dominant member should be the member best prepared, authorship of ideas is on record and cannot be disputed, and preconsideration should reduce the herd instinct.

Delphi Panel

Of more rigorous delineation is the Delphi panel (Linestone and Turoff,⁶⁶ Render and Stair,⁶⁷ Wheelwright and Makridakis,⁶⁸ Rowe and Wright⁶⁵), devised as a method of obviating the practical difficulties inherent in the committee concept. In the Delphi panel, the group members never meet physically; all communication is through a group controller or coordinator who selects the members of the panel, presents the basic problem, and informs the individuals in the group of progress to date (feedback). When the atomic or elemental issues that constitute the main problem have been determined (the qualitative phase), consensus is sought on the quantitative value to be ascribed to each of these issues (statistical response).

A series of rounds of voting is held. After each round the group controller returns to each panel member his or her scores together with a measure of the group opinion on each issue. The panel members are then asked if they wish to revise their opinions. The process is repeated until group opinion has converged sufficiently to be described as consensus, or until it is recognized that a consensus is unattainable. Unanimity is less important in the method than the absence of group pressure.

The two essential characteristics in a Delphi panel are (a) the anonymity of panelists and (b) feedback (histograms, measures of central tendency, or analytic consensus). The former eliminates the problem of the dominant member and group pressure to conform. However, a new problem is introduced—a considerable time scale is involved in the sending and receiving of questions and answers. While this (at least) theoretically guarantees a considered opinion, a substantial attrition rate is almost inevitable. Members of the group lose interest, change jobs, or become otherwise indisposed. Also, the group

controller has a role of far greater significance than a committee chairperson; only a high level of awareness on his or her part can prevent the unconscious bias that might be introduced. Other doubts about and difficulties with the method are summarized by Marchant,⁶⁹ Shields et al.,⁷⁰ Sackman,⁷¹ and Ayton et al.⁷²

Computer Conferencing

Modern technology enables remote participation in group discussion. Participants input their views into a computer system, and their views are circulated to the other panelists for comment and reply. A suitable schedule allows either a quick result or a more leisurely, considered process. Anonymity is optional.

This concept can be combined with others, for example, the Delphi method, with a reduction of time scale and consequent diminishing of attrition (i.e., drop-outs). Further, if a computer system for analyzing these data exists, the results may be obtained almost instantaneously. Hence, the group may have access to the consequences of their polling before their views are forgotten. The almost universal availability of the Internet and ISDN developments in survey computing are already having a considerable impact on this type of conferencing.

DACAM Group

A DACAM group⁷³ is an alternative method of overcoming the problem with committees. Here, the group meets physically but is divided (usually systematically) into subgroups for discussion sessions. Between each session, representatives from the subgroups meet to compare progress and coordinate the agenda for the next session. In this way, the dominant member, being limited to one subgroup, is less influential on the group decision.

While this method guarantees a quick result (e.g., in a day), the facility to organize such a group is dependent on at least substantial goodwill, if not considerable finance.

Consensus

The notion of consensus is very much an intuitive one. In politics, there is "consensus" on a policy that is acceptable to a majority. If no consensus exists, then it can often be achieved by broadening the policy. However, the concept is very largely negative in that the emphasis is on avoidance of what is intolerable to others.

The nature of consensus depends on the context or terms of reference of the problem. For example, the arrangement of a number of options in order of importance or preference (comparative consensus) is essentially different from assessing the importance of a single elemental issue within the problem (definitive consensus).

Definitive Consensus

Definitive consensus involves panel members who assign to each issue a score chosen from a Likert-type scale, that is, a range of values, such as (0,10) or (0,5). For example, one might say that a very definite consensus

had been reached if a comfortable majority (say, 60 percent) agreed on an exact value, or if a substantial majority (say, 75 percent) agreed on a small range, or if all agreed to within a slightly larger range. Thus, there is a balance between the number conforming to the view and the range permitted.

The essential problem, however, is finding mechanisms for representing and assessing the opinions on each individual issue for the complete panel, in other words, mechanisms that provide the following for the set of scores for each issue:

- A profile of the scores
- A focal point of agreement (if any)
- A measure of the agreement at that point

Additional problems arise if the panel is divided into several groups, each of which is in internal accord. This is referred to as *split consensus*, or a *multimodal* situation. The interested reader will find a mathematical function (neighborhood consensus) that addresses these issues in Donegan and Dodd.⁷⁴

Traditionally, a histogram was generally used as a profile, and the presence or absence of consensus was determined by a statistical measure of dispersion. Chatterjee and Chatterjee⁷⁵ discuss mean- and median-based methods together with the compromises referred to as the trimmed and windsorized means. A *trimmed mean* excludes extreme values, and in a *windsorized mean*, the extreme values are replaced by the second-most extreme values. Some of the assumptions and drawbacks of these measures, for example, the nonrepresentativeness of the mean, the instability of the mode, and the inconsistency and precision-dependence of the median, are described in Dodd and Donegan.⁷⁶

It is worth pointing out here the difference between consensus and compromise. If on a scale of 0 to 5, one half of a group selects 0 and the other half selects 5, then 2.5 is a compromise score. It would be inaccurate, however, to describe 2.5 as a consensus score, since this figure is not representative of any members of the group and, therefore, not a measure of the group itself. There is, in fact, no consensus among the group.

Alternative Stability Approach

A major problem with, for example, Delphi studies is that stability may set in before consensus has been achieved, and the latter might therefore never be reached. When seeking consensus on a large number of issues, this is highly likely for some of the issues and quite consistent with Delphi philosophy, which is more concerned with narrowing the spread of diverse opinions than enforcing an artificial consensus.

It is possible and perhaps simpler to use a definition of stability (based on a comparison of successful rounds) as the termination criterion for a Delphi panel. This would also allow item/individual/tactic/group stability to be considered. The definition of stability might be based on the ratio of total scores for two rounds, for example, the average of the moduli of the differences between the rounds. Linstone and Turoff⁶⁶ suggest the quadratic mean as a refinement of this. Alternatively, if

the data were normalized (i.e., translated and magnified to fit a uniform distribution), it might be simpler to use Pearson's correlation coefficient.

The principal advantage of the alternative stability approach is that stability is almost certain to be achieved, and fairly rapidly. It is generally recognized that stability is normally achieved within four polling rounds in most Delphi panels (see Render and Stair⁶⁷).

Comparative Consensus

Comparative consensus involves a panel of individuals who must decide on an arrangement of n issues (or objects) in order of importance or merit. For the sake of simplicity, let the issue be a number from 1 to n . Each panel member decides on an arrangement that might be expected to differ from the arrangements of others. Two problems can arise—(a) establishing a universally acceptable arrangement, and (b) the amount of agreement among the panel. A typical example of this situation might be the selection of an agreed priority list from 10 independent lists returned by experts whose task is to rank in order of importance the following safety features: fire extinguishers, smoke alarms, sprinklers, flashing lights, and direction signs.

Comparative consensus⁷⁷ also involves only the ranking of a number of issues (in contrast to the simpler notion of definitive consensus, as described above, in which the agreement of a panel on a single issue is assessed). The obvious question in the situation where several panelists judge several issues is whether (a) it is preferable to determine the agreement on each issue on the basis of scores and then determine rank on the basis of the consensus scores, or whether (b) each panel member should rank all the issues on the basis of his or her scores and subsequently look for consensus on the set of rankings. This has never been satisfactorily resolved.

Compound Consensus

Compound consensus arises when, for example, a panel is required to produce an agreed ranking (with weightings) for a set of issues. This type of consensus can occur when AHP is used by a relatively small panel to produce a set of rankings. The obvious question is whether it is better to (a) find (definitive) consensus among the panel on the issue and then rank the issue for the whole panel, or (b) let each panel member rank the issues and then seek (comparative) consensus on the rankings. Compound consensus allows a weighting of each of the issues to be taken into account.

CHAPTER 3

Reliability

 Mohammad Modarres and Francisco Joglar-Billoch

Introduction

Reliability has two connotations. One is probabilistic in nature; the other is deterministic. This chapter generally deals with the probabilistic aspect. First reliability must be defined. The most widely accepted definition of reliability is the *ability of an item (product, system, etc.) to operate under designated operating conditions for a designated period of time or number of cycles*. Consequently, the reliability of systems or components in fire conditions can be expressed as the ability of an item to operate at fire-induced stresses, such as high temperatures and high concentrations of products of combustion. The *ability* of an item to operate can be (1) designated through a probability (the probabilistic connotation) or (2) designated deterministically. The deterministic approach, in essence, deals with understanding how and why an item fails, and how it can be designed and tested to prevent such failures from occurring or recurring. This includes analyses, such as deterministic analysis and review of field failure reports, understanding physics of failure, the role and degree of test and inspection, performance redesign, or performance reconfiguration. In practice, this is an important aspect of reliability analysis.

The probabilistic treatment of an item's reliability according to the definition above can be represented by

$$R(t) = Pr(T \geq t | c_1, c_2, \dots) \quad (1)$$

where

$$R(t) = \text{reliability of the item}$$

Pr = probability

T = time to failure or cycle to failure of the item

t = designated period of time or cycles for the item's operation (mission time)

c_1, c_2, \dots = designated conditions, such as environmental conditions

Often, in practice, c_1, c_2, \dots are implicitly considered in the probabilistic reliability analysis and, thus, Equation 1 reduces to

$$R(t) = Pr(T \geq t) \quad (2)$$

This chapter addresses the basic elements of component and system reliability evaluation, including the classical frequency approach to component reliability, important aspects of component reliability analysis, system reliability models, and logic trees.

Component Reliability

The probabilistic notion is used to quantitatively measure the reliability of an item and treats reliability as the conditional probability of the successful achievement of an item's intended function, given designated conditions. The probabilistic definition of reliability given in Equation 1 is its mathematical representation. The right-hand side of Equation 1 denotes the probability that a specified failure time, T , exceeds a specified mission time, t , given that conditions c_1, c_2, \dots exist (or are met). Practically, random variable T represents *time-to-failure* of the item, and conditions c_1, c_2, \dots represent conditions (e.g., design-related conditions) that are required, a priori, for successful performance of the item. Other representations of random variable T include *cycle-to-failure*, *stress-to-failure*, and so on. In fires different kinds of stresses applied to items are generated. For example, high temperatures and concentrations of combustion products can be considered fire-induced stresses. Although time is an agent of failure in

Dr. Mohammad Modarres is a professor of reliability and of nuclear engineering and a cofounder of the Reliability Engineering Program at the University of Maryland, College Park. He is the director of the Center for Reliability Engineering at the University of Maryland. A consultant to government, industry, and international organizations, he is the author or coauthor of more than 100 professional papers in reliability and risk assessment.

Dr. Francisco Joglar-Billoch is a fire and risk analyst at Science Applications International Corporation (SAIC).

reliability analysis, when fire conditions exist, a different approach should be adopted in order to evaluate an item's reliability. For example, the stress-strength interference model may be introduced to account for the reliability of items subjected to stresses generated by fires. Conditions c_1, c_2, \dots are often implicitly considered; therefore, Equation 1 is written in a nonconditional form of Equation 2. Equation 2 is used in the remainder of this chapter.

Reliability Function

Time as an Aggregate Agent of Failure

Let's start with the formal definition given in Equation 1. Furthermore, let $f(t)$ denote a probability distribution function representing the random variable T . $f(t)$ is obviously characterized by the design (e.g., strength), operational, and environmental (e.g., stress) effects of the item. The probability of failure of the item as a function of time can be defined by

$$Pr(T \leq t) = \int_0^t f(\theta) d\theta = F(t), \quad \text{for } t \geq 0 \quad (3)$$

where $F(t)$ denotes the probability that the item will fail sometime up to time t . Based on Equation 2, Equation 3 is the *unreliability* of the item. Formally, $F(t)$ is called the *unreliability function*. Conversely, one can find the *reliability function* by writing

$$R(t) = 1 - F(t) = \int_t^\infty f(\theta) d\theta \quad (4)$$

Provided one can obtain the probability distribution function, $f(\theta)$, one can then obtain $R(t)$. Basic characteristics of the probability distribution function and $R(t)$ can be helpful to create some useful definitions. The *mean time to failure* (MTTF), for example, is defined as the expected value of $f(t)$. This illustrates the expected time during which the item will perform its function successfully (sometimes called *expected life*) as

$$MTTF = E(t) = \int_0^\infty tf(t) dt \quad (5)$$

If $\lim_{t \rightarrow \infty} R(t) = 0$, then it is easy to show that a more compact form of Equation 5 is given by

$$E(t) = \int_0^\infty R(t) dt \quad (6)$$

MTTF refers to the mean time from first use of a new item to first and only failure. MTTF is different from *mean time between failures* (MTBF), which is the mean time between two consecutive item failures. MTBF includes the time to discover the earlier failure, the time to repair that failure, and the time until it fails again. If discovery and repair are essentially instantaneous and repair is as good as replacement (as with changing a light bulb), then the repaired or replaced item will behave like a new item, and MTBF will equal MTTF. In general, discovery and repair are not instantaneous, repair is not perfect, and MTBF involves very complex modeling.

Stress-Strength Interference Model

During the operation of a system or a component, interactions with its environment effectively subject the system or component to *stress*. While the system is operating successfully, it presents an internal capacity to withstand stress. One form of this capacity is called *strength*. To predict reliability of a system or a component, in which a failure occurs when the stress exceeds the strength, we have to know the nature of both the stress and the strength. If the stress is considered a random variable, and the strength is either a fixed value or another random variable, reliability calculations can be performed.

Random stress and fixed strength: In the case where the stress is a random variable S associated with the probability distribution $f(S)$ and the strength is a fixed value S_0 , the reliability is the area in the probability distribution to the left of the strength value. Figure 5-3.1 illustrates this concept. The reliability of the component can be expressed as the probability of S being lower than S_0 or

$$Pr(s < S_0) = \int_{-\infty}^{S_0} f(s) ds = 1 - \int_{S_0}^{\infty} f(s) ds \quad (7)$$

where $f(S)$ is the probability distribution for the stress random variable. In this approach, the value S_0 can be, for example, the damage temperature of a component and $f(S)$ the distribution for the temperature of the component associated to the impact of the fire.

Random stress and random strength: If the strength is represented by another random variable R associated to a probability distribution $f(R)$, similar to the case presented above, the probability distribution for the strength may be the damage temperature of a component considering uncertainty in the value. The overlapped area between the two distributions will be an indicator of the probability of failure of the component. But the probability of failure is not equal to the common area between the two distributions. Figure 5-3.2 illustrates this concept. The reliability of the system can be expressed as

$$\begin{aligned} R &= P(S \leq R) = \int_0^\infty \int_0^R f(S, R) dS dR \\ &= \int_0^\infty \int_0^S f(R, S) dR dS \end{aligned} \quad (8)$$

Figure 5-3.1. *Random stress and fixed strength.*

Figure 5-3.2. Random stress and random strength.

where $f(S, R)$ is the joint probability distribution for the two random variables. If S and R are statistically independent random variables, then

$$f(S, R) = f(S) \cdot f(R) \quad (9)$$

Another useful formulation is to define a random variable $Z = R - S$.

$$R = P(S \leq R) = P(Z > 0) = 1 - F_z(0) \quad (10)$$

The cumulative distribution function of Z can be found as follows:

$$\begin{aligned} F_z(Z) &= P(Z \leq z) = P(R - S \leq Z) \\ &= \int_0^\infty \int_0^{S+Z} f(S, R) dR dS \end{aligned} \quad (11)$$

Finally, differentiating $F_z(z)$, we obtain a simpler expression derived from the joint pdf of s and z .

$$f_z(Z) = \int_0^\infty f_s(S) f_r(S + Z) dS \quad -\infty < Z < \infty \quad (12)$$

$$R = \int_0^\infty f_z(Z) dZ = \int_0^\infty \int_0^\infty f_s(S) \cdot f_r(S + Z) dS dZ \quad (13)$$

Stresses induced by fires usually change with time in the course of the accident. This fact suggests that a probability distribution for stress is not static. For example, if the component temperature changes with time, the probability of failure will also change. In this case we might expect the stress distribution to shift to the right.

EXAMPLE 1:

Find the reliability and the probability of failure of a component subjected to a normally distributed temperature random variable with the mean and standard deviation of 55°C and 10°C , respectively. The component has the capability to withstand temperatures up to a level described by another normally distributed random variable with mean of 60°C and standard deviation of 5°C .

SOLUTION:

First the joint probability density function of the stress and the strength is defined. Assuming both random variables are independent,

$$\begin{aligned} f(R, S) &= f(S) \cdot f(R) \\ &= \frac{1}{\sqrt{2\pi}\sigma_S} e^{-1/2[(S-\mu_S)/\sigma_S]^2} \cdot \frac{1}{\sqrt{2\pi}\sigma_R} e^{-1/2[(S-\mu_R)/\sigma_R]^2} \end{aligned}$$

where

$$\mu_R = 60^\circ\text{C}$$

$$\sigma_R = 5^\circ\text{C}$$

$$\mu_S = 55^\circ\text{C}$$

$$\sigma_S = 10^\circ\text{C}$$

Defining the random variable $Z = R - S$, and using Equation 12

$$\begin{aligned} f_z(Z) &= \int_0^\infty f_s(S) \cdot f_r(S + Z) dS \\ &= \frac{1}{2\pi\sigma_R\sigma_S} \int_0^\infty e^{-1/2[(S-\mu_S)/\sigma_S]^2} \cdot e^{-1/2[(S+Z)-\mu_R]/\sigma_R]^2} dS \end{aligned}$$

Once an expression for $f_z(Z)$ is obtained, Equation 13 can be used to obtain the reliability.

$$R = \int_0^\infty f_z(Z) = 0.673$$

Therefore, the probability of failure is $1 - R = 0.327$.

Failure Rate and Hazard Rate

Failures can occur due to many physical processes or mechanisms. In probabilistic reliability, all these mechanisms of failure are accounted for through a function called *instantaneous failure rate* or *hazard rate*, $h(t)$. The hazard rate can be interpreted as the probability of the first and only failure of an item in the next instant of time, given that the item is presently operating. Clearly, this only applies to nonrepairable items in which only one failure can occur. For repairable items the most appropriate term is failure rate, or more correctly, the *rate of occurrence of failure*. Hazard rate function is obtained via *life test data*. The rate of failure for a component c is defined as $\lambda = 1/\Delta t$ (probability that c will fail between t and $t + \Delta t$, given that no failure is observed before t). The instantaneous failure rate (hazard rate) for component c is defined as the limit of the rate of failure as the interval Δt approaches zero. $h(t)$ is obtained from

$$h(t) = \frac{f(t)}{R(t)} \quad (14)$$

Here, $f(t)$ represents the time to failure probability distribution function of a component, and $R(t)$ is its reliability function. Hazard rate is an important function in reliability analysis, since it shows changes in the probability of failure over the lifetime of a component.

In practice, $h(t)$ often exhibits a bathtub shape and is referred to as a *bathtub curve*. A typical bathtub curve is shown in Figure 5-3.3.

Generally, a bathtub curve can be divided into three regions. The *burn-in failure* region exhibits a *decreasing rate of failure*, characterized by early failures attributable to defects in design, manufacturing, or construction. The *chance failure* region exhibits a reasonably *constant rate of failure*, characterized by random failures of the component. In this period, many mechanisms of failure due to complex underlying physical, chemical, or nuclear phenomena give rise to this approximately constant rate of failure. The third region, called *wear-out failure*, exhibits an *increasing rate of failure*, characterized mainly by complex aging phenomena. Here the component deteriorates (e.g., due to accumulated fatigue) and is more vulnerable to outside shocks. One interesting observation is that these three regions are different for different types of components. Figures 5-3.4 and 5-3.5 show typical bathtub curves for electrical and mechanical devices, respectively. Electrical devices exhibit a relatively higher rate of failure during the chance failure period. Figure 5-3.6 shows the effect of various levels of stress on a device. As stress level increases, the chance failure region decreases, and premature wear-out occurs. Therefore, it is important to minimize stress factors, such as harsh operating environments, to maximize reliability.

Next, the mathematical relationship between $h(t)$ and $R(t)$ needs clarification. Recall that from Equation 4, $R(t) = 1 - F(t)$, or $dR(t) = -dF(t) = -f(t)$. By integrating both sides of Equation 7 from 0 to t ,

$$\int_0^t h(x) dx = -\ln R(t) + \ln R(0)$$

By assuming that a component is totally reliable at the beginning of life [i.e., $R(0) = 1$], then

$$\int_0^t h(x) dx = -\ln R(t) \tag{15}$$

and

$$R(t) = \exp\left(-\int_0^t h(x) dx\right) \tag{16}$$

If the beginning of life is not at $t = 0$, but rather at $t = t_1$, then the integrands of Equation 15 will be between

Figure 5-3.3. Typical bathtub curve.

Figure 5-3.4. Bathtub curve for typical electrical devices.

Figure 5-3.5. Bathtub curve for typical mechanical devices.

Figure 5-3.6. Effect of stress on a typical bathtub curve.

t_1 and t . If any one of $f(t)$, $h(t)$, or $R(t)$ is known, the other two can be computed by using Equations 14, 15, and 16.

EXAMPLE 2:

A component is known to have an instantaneous failure rate, $h(t)$, as shown below. Determine the probability distribution function and the reliability function.

SOLUTION:

For $0 \leq t \leq 200$, $h(t) = 5 \times 10^{-6}t^2 - 10^{-3}t + 0.1$

$$\begin{aligned} \int_0^t h(t') dt' &= \int_0^t (5 \times 10^{-6}t'^2 - 10^{-3}t' + 0.1) dt' \\ &= \left[\left(\frac{5 \times 10^{-6}}{3}\right)t'^3 - \left(\frac{10^{-3}}{2}\right)t'^2 + 0.1t' \right]_0^t \\ &= 1.66 \times 10^{-6}t^3 - 5 \times 10^{-4}t^2 + 0.1t \end{aligned}$$

thus,

$$R(t) = \exp(-1.66 \times 10^{-6}t^3 + 5 \times 10^{-4}t^2 - 0.1t)$$

Using Equation 14,

$$f(t) = (5 \times 10^{-6}t^2 - 10^{-3}t + 0.1) \times \exp(-1.66 \times 10^{-6}t^3 + 5 \times 10^{-4}t^2 - 0.1t)$$

Common Distributions and Parameter Estimation

To represent component failure probabilities as a function of time, the most common distributions are exponential, lognormal, and Weibull probability distribution functions. The exponential distribution is used to model component time to failure when failures have a constant arrival rate. When the mean time to failure of a component is the same, no matter how much time has already passed, the exponential model is reasonable and the parameter estimation should proceed.

The lognormal distribution is useful, in part, because the product of two lognormally distributed variables also has a lognormal distribution. This is useful for a unit whose failure occurs only after the failure of several of its constituent parts. If each part has a lognormal failure probability, then so will the unit. Reflecting this underlying phenomenology, the lognormal distribution can be used for failure probability distributions with very large variances. It is not unusual in such a distribution to see probability values separated by orders of magnitude. The Weibull distribution has three parameters. This creates the greatest challenge but also the greatest flexibility in setting a specific distribution. In particular, the Weibull distribution is flexible enough to depict the distribution for a unit that shows pronounced changes in reliability during the wear-out stage or whose reliability improves over time.

This section introduces common distributions and deals with statistical methods for estimating model parameters, such as λ of the exponential probability distribution function, μ and σ of the lognormal probability distribution functions, and α and β of the Weibull probability distribution function. The objective is to find a *point estimate* and a *confidence interval* for the parameters of interest. It is important to realize why one needs to consider confidence intervals in the estimation process. In essence, this need stems from the fact that there is only a limited amount of information (e.g., times to failure), and thus one cannot state the estimation with certainty. Therefore, the confidence interval is highly influenced by the amount of data available. Of course other factors, such as diversity in the sources of data and accuracy of the selected model and the data sources, also influence the state of uncertainty regarding the estimated parameters.

Exponential Distribution

This distribution is widely used in reliability evaluation to model a random variable representing time to failure of a device (often a device composed of several in-

dependent units). The distribution is a one-parameter probability distribution function defined by

$$f(t) = \begin{cases} \lambda \exp(-\lambda t) & \lambda, t > 0 \\ 0, & t \leq 0 \end{cases} \quad (17)$$

It is easy to show that requirements $\int_{\text{all } t} f(t) dt = 1$ and $f(t) > 0$ for a valid probability distribution function are met for this distribution. Figure 5-3.7 illustrates the exponential distribution for a value of λ .

EXAMPLE 3:

A component has a constant failure rate of 10^{-3} /hr. What is the probability that this component will fail before $t = 1000$ hrs? Determine the probability that it works for at least 1000 hrs.

SOLUTION:

$$\begin{aligned} Pr(t < 1000) &= \int_0^{1000} \lambda \exp(-\lambda t) dt = \exp(-\lambda t) \Big|_0^{1000} \\ &= 1 - \exp(-1) = 0.632 \\ Pr(t > 1000) &= 1 - Pr(t < 1000) = 0.368 \end{aligned}$$

Epstein¹ has shown that, if the time to failure is exponentially distributed with parameter λ , the quantity $2r\lambda/\lambda = 2\lambda T$ has a chi-square distribution with $2r$ degrees of freedom for the Type II (failure-terminated) failure data and $(2r + 2)$ degrees of freedom for the Type I (time-terminated) failure data, where r is the number of failures observed, T is the total accumulated operation time, and λ is the point estimator for the parameter λ .

$$\hat{\lambda} = \frac{r}{T} \quad (18)$$

Consequently, for the two-sided confidence interval for the $1 - \alpha/2$ and $\alpha/2$ confidence levels of the chi-square distribution,

$$Pr \left[\chi_{\alpha/2}^2(2r) \leq \frac{2r\lambda}{\hat{\lambda}} \leq \chi_{1-\alpha/2}^2(2r) \right] = 1 - \alpha \quad (19)$$

By rearranging and using Equation 18,

$$Pr \left[\frac{\chi_{\alpha/2}^2(2r)}{2T} \leq \lambda \leq \frac{\chi_{1-\alpha/2}^2(2r)}{2T} \right] = 1 - \alpha \quad (20)$$

Figure 5-3.7. Exponential distribution.

Equation 20 shows the *two-sided confidence interval* for the true value of λ . Another alternative to Equation 19 is the *one-sided confidence interval*,

$$Pr \left[0 \leq \hat{\lambda} \leq \frac{\chi_{1-\alpha}^2(2r)}{2T} \right] = 1 - \alpha \quad (21)$$

Accordingly, confidence intervals of MTTF and $R(t)$ at $t = t_0$ can also be obtained for both one-sided and two-sided confidence intervals from Equations 20 and 21.

It is possible to show that the upper confidence limit of λ for the Type I (time-terminated) test is obtained from a chi-square distribution with $(2r + 2)$ degrees of freedom. The lower confidence limit is obtained from the chi-square distribution with $2r$ degrees of freedom. Thus for Type I tests, the two-sided confidence interval is

$$Pr \left[\frac{\chi_{\alpha/2}^2(2r)}{2T} \leq \lambda \leq \frac{\chi_{1-\alpha/2}^2(2r+2)}{2T} \right] = 1 - \alpha \quad (22)$$

The one-sided confidence interval is

$$Pr \left[0 \leq \lambda \leq \frac{\chi_{1-\alpha}^2(2r+2)}{2T} \right] = 1 - \alpha \quad (23)$$

It should be emphasized here that Equations 19 through 23 apply only when the failure rate is constant. Otherwise, a Weibull model or other appropriate distribution should be used.

If no failure is observed, $\hat{\lambda} = 0$ or $MTTF = \infty$. This cannot realistically be true, since one may have had a small or restricted test. Had the test been continued, eventually a failure would be observed. An upper level estimate for both one-sided and two-sided confidence limits can be obtained with $r = 0$. However, the lower limit for the two-sided confidence limit cannot be obtained with $r = 0$. It is possible to relax this limitation by conservatively assuming that a failure occurs in the very next instant. Then $r = 1$ can be used to evaluate the lower two-sided confidence limit. This conservative modification, although sometimes used to allow a complete statistical analysis, lacks firm statistical basis. Welker and Lipow² have shown methods to determine approximate point estimates in these cases.

EXAMPLE 4:

Twenty-five units are subjected to a reliability test that lasts 500 hrs. In this test, eight failures occur at 75, 115, 192, 258, 312, 389, 410, and 496 hrs. The failed units are replaced. Find $\hat{\lambda}$, one-sided and two-sided confidence limits on λ , and MTTF at the 90 percent confidence level, and one-sided and two-sided 90 percent confidence limits on reliability at $t_0 = 1000$ hrs.

SOLUTION:

This is Type I data. The accumulated time T is given by

$$T = 25 \times 500 = 12,500 \text{ component hrs.}$$

$$\hat{\lambda} = \frac{8}{12,500} = 6.4 \times 10^{-4} \text{ hr}^{-1}$$

One-sided confidence limits on λ are

$$0 \leq \lambda \leq \frac{\chi^2(2 \times 8 + 2)}{2 \times 12,500}$$

$$\chi_{0.9}^2(18) = 25.99, \quad 0 \leq \lambda \leq 1.04 \times 10^{-3}$$

Two-sided confidence limits on λ are

$$\frac{\chi_{0.05}^2(2 \times 8)}{2 \times 12,500} \leq \lambda \leq \frac{\chi_{0.95}^2(2 \times 8 + 2)}{2 \times 12,500}$$

$$\chi_{0.05}^2(16) = 7.96, \quad \text{and} \quad \chi_{0.95}^2(18) = 28.87$$

Thus,

$$3.18 \times 10^{-4} \leq \lambda \leq 1.15 \times 10^{-3}$$

One-sided 90 percent confidence limits on $R(1000)$ are

$$\exp(-1.04 \times 10^{-3} \times 1000) \leq R(1000) \leq 1,$$

or

$$0.35 \leq R(1000) \leq 1$$

Two-sided 90 percent confidence limits on $R(t)$ are

$$\exp(-1.15 \times 10^{-3} \times 1000) \leq R(1000) \\ \leq \exp(-3.18 \times 10^{-4} \times 1000)$$

or

$$0.32 \leq R(1000) \leq 0.73$$

Lognormal Distribution

A random variable is said to be lognormally distributed if its logarithm is normally distributed. The lognormal distribution has considerable application in engineering. One major application of this distribution is to present random variables that are the result of the product of many independent random variables.

The transformation $T = \ln Y$ or $Y = \exp(T)$ transfers the normal probability distribution function representing random variable T with mean μ_t and standard deviation σ_t to a lognormal probability distribution function.

$$f(y) = \frac{1}{\sigma_t y \sqrt{2\pi}} \exp \left[\frac{-1}{2\sigma_t^2} (\ln y - \mu_t)^2 \right] \quad (24)$$

$$y \leq 0, \quad -\infty < \mu_t < \infty, \quad \sigma_t > 0$$

If μ_t and σ_t are not known, and instead μ and σ of a normal distribution are known, the following equations can be used to obtain μ_t and σ_t :

$$\mu_t = \ln \left(\frac{\mu_y}{(1 + \sigma_y^2/\mu_y^2)^{1/2}} \right) \quad (25)$$

$$\sigma_t = \left[\ln \left(\frac{1 + \sigma_y^2}{\mu_y^2} \right) \right]^{1/2} \quad (26)$$

Figure 5-3.8. Lognormal distribution.

Figure 5-3.8 shows the probability distribution function of the lognormal distribution for different values of μ_t and σ_t .

A lognormal distribution is usually used to represent the occurrence of events in time. For example, a random variable representing the length of time required for repair of hardware follows a lognormal distribution. Because the lognormal distribution has two parameters, parameter estimation poses a more challenging problem than for the exponential distribution. It is easy to prove through the maximum likelihood estimation method that point estimators for the two parameters of the lognormal distribution can be obtained from

$$\hat{\mu}_t = \sum_{i=1}^n \frac{\ln(t_i)}{n}, \quad \text{and} \quad \hat{\sigma}_t^2 = \frac{\sum_{i=1}^n [\ln(t_i) - \hat{\mu}_t]^2}{n-1} \quad (27)$$

where t_i is the time that the i th failure in a set of n failures has occurred. The confidence interval for μ_t is

$$\Pr \left[\chi_{\alpha/2}^2(2r) \leq \frac{2r\hat{\lambda}}{\hat{\lambda}} \leq \chi_{1-\alpha/2}^2(2r) \right] = 1 - \alpha \quad (28)$$

Similarly, the confidence interval on σ_t is

$$\Pr \left[\chi_{\alpha/2}^2(2r) \leq \frac{2r\hat{\lambda}}{\hat{\lambda}} \leq \chi_{1-\alpha/2}^2(2r) \right] = 1 - \alpha \quad (29)$$

EXAMPLE 5:

A component fails if its surface temperature reaches 150°C. According to experimental results, a fire can induce surface temperatures in the component between 92°C and 140°C. Assuming these temperature values correspond to the 5th and 95th percentiles of a lognormal distribution, find the mean and standard deviation of the temperature distribution. Calculate the reliability of the component subjected to this condition.

SOLUTION:

In order to solve the first part of this problem, a system of two equations must be solved for the unknown variables μ and σ . The two equations are

$$0.05 = \int_0^{92} \frac{1}{\sqrt{2\pi\sigma_t T}} e^{-1/2\{[\ln(T)-\mu_t]/\sigma_t\}^2} dT \quad (30)$$

$$0.95 = \int_0^{140} \frac{1}{\sqrt{2\pi\sigma_t T}} e^{-1/2\{[\ln(T)-\mu_t]/\sigma_t\}^2} dT \quad (31)$$

An easier way to obtain the values of μ and σ is to use the standardization equation for the normal distribution and use the standard normal percentile table.

For the 5th percentile of a standard normal distribution,

$$-1.64 = \frac{92 - \mu}{\sigma} \quad (32)$$

For the 95th percentile of a standard normal distribution,

$$1.64 = \frac{140 - \mu}{\sigma} \quad (33)$$

Solving these two equations for μ and σ , we obtain the values 116°C and 14.6°C respectively. These values now are transformed to a log scale in order to use them in the lognormal distribution. Using Equations 25 and 26, the following results are obtained: $\mu_t = 4.74$ and $\sigma_t = 0.126$.

Once we have the average and standard deviation of the distribution, the reliability of the component can be found by integrating the lognormal distribution from 0°C to 150°C according to Equation 7. Accordingly, the reliability is found to be 0.983.

Weibull Distribution

The Weibull distribution is widely used to represent the *time to failure* or *life length* of the components in a system, measured from a start time to the time that a component fails. The continuous random variable T representing the time to failure follows a Weibull distribution if

$$f(t) = \frac{\beta(t-\gamma)^{\beta-1}}{\alpha^\beta} \exp \left[-\left(\frac{t-\gamma}{\alpha} \right)^\beta \right] \quad \alpha, \beta > 0; t > \gamma \quad (34)$$

$$= 0 \quad \text{otherwise}$$

The parameter γ serves only to reset the starting time and so is of limited value. The simplified variation of the Weibull distribution used here has $\gamma = 0$.

$$f(t) = \frac{\beta t^{\beta-1}}{\alpha^\beta} \exp \left[-\left(\frac{t}{\alpha} \right)^\beta \right] \quad t, \alpha, \beta > 0 \quad (35)$$

$$= 0 \quad \text{otherwise}$$

Figure 5-3.9 shows the Weibull distribution for various parameters of α and β . A careful inspection of these graphs reveals that the parameter β has a considerable effect on the shape of the distribution. Therefore, β is referred to as the *shape parameter*. The parameter α , on the other hand, controls the scales of the distribution. For this reason, α is referred to as the *scale parameter*. If $\beta = 1$, the Weibull distribution reduces to an exponential distribution with $\lambda = 1/\alpha$. For values of $\beta > 1$, the distribution becomes bell shaped with some skew.

Figure 5-3.9. Weibull distribution.

A Weibull distribution can be used for data believed to have an increasing, decreasing, or constant rate of failure. This distribution is a two-parameter distribution, and estimation of the parameters is rather involved. It can be shown that, under the situation where all \$n\$ units under test or observation have failed, the maximum likelihood estimates of \$\beta\$ and \$\alpha\$ parameters of the Weibull distribution can be obtained from

$$\frac{\sum_{i=1}^n (t_i)^{\hat{\beta}} \ln t_i}{\sum_{i=1}^n (t_i)^{\hat{\beta}}} - \frac{1}{\hat{\beta}} = \frac{1}{n} \sum_{i=1}^n \ln t_i, \tag{36}$$

$$\hat{\alpha} = \left(\frac{\sum_{i=1}^n (t_i)^{\hat{\beta}}}{n} \right)^{1/\hat{\beta}}$$

where \$t_i\$ is the time that the \$i\$th failure in a set of \$n\$ failures has occurred.

The solution of Equation 36 is not trivial and may require a trial and error process to obtain \$\hat{\beta}\$. Estimation of the confidence intervals of \$\beta\$ and \$\alpha\$ is very involved. Readers are referred to Bain³ and Mann et al.⁴

If a lot of failure data is available, the analyst should first fit the data into a distribution that best represents the data. The analyst should then proceed with the estimation of the distribution's parameters. However, when data are not enough, the analyst should check the adequacy of a distribution. Therefore, the exponential, lognormal, or other distribution should only be selected when the adequacy of a distribution fit can be justified. For example, when we have only five sample points for the times required for maintenance, one can theoretically fit these points to several types of distributions. However, we can assume that since the data occur in multiples of time, they can be adequately represented by a lognormal distribution. An accurate representation can only be determined if there are enough data to test the adequacy of the selected model.

System Reliability

Assessment of the reliability of a system from its basic elements is one of the most important aspects of reliability analysis. A system is a collection of items (sub-

systems, components, units, blocks, etc.) whose proper, coordinated function leads to the proper functioning of the system. In reliability analysis, it is therefore important to model the relationship between various items as well as the reliability of the individual items to determine the reliability of the system as a whole. Previous sections addressed the reliability analysis at a basic item level (one for which enough information is available to predict its reliability). This section addresses methods to model the relationship between system components, which allows the determination of overall system reliability.

The physical configuration of an item that belongs to a system is often used to model system reliability. In some cases, the manner in which an item fails is important for system failure, and should be considered in the system reliability analysis. For example, in a system composed of two parallel electronic units, if a unit fails, the system will fail; but for most other types of failures of the unit, the system will still be functional, since the other unit functions properly.

There are several system modeling schemes for reliability analysis. *Reliability block diagram* methods include series, parallel, standby, shared load, and complex systems. *Logic tree* methods include fault tree and success tree methods, which include the method of construction and evaluation of the tree. *Event tree* methods include modeling of multisystem designs and complex systems whose individual units should work in a chronological or approximately chronological manner to achieve a mission. Failure mode and effect analysis and the master logic diagram (MLD) are also used for reliability analysis.

Reliability Block Diagram Methods

Reliability block diagrams are frequently used to model the effect of items failing (or functioning) on system performance. They often correspond to the physical arrangement of items in the system. However, in certain cases, the arrangement may be different. For instance, when two resistors are in parallel, the system fails if one fails short. Therefore, the reliability block diagram of this system for the "fail short" mode of failure would be composed of two series blocks. However, for other modes of failure of one unit, such as open failure mode, the reliability block diagram is composed of two parallel blocks.

Series systems: A reliability block diagram is in a series configuration when failure of any one item (according to the failure mode of each item, on which the reliability block diagram is based) results in the failure of the system. Accordingly, for functional success of a series system, all of its items must successfully function during the intended mission time of the system. Figure 5-3.10 shows the reliability block diagram of a series system consisting of \$N\$ units.

Figure 5-3.10. Series system reliability block diagram.

The reliability of the system in Figure 5-3.10 is the probability that all N units succeed during its intended mission time, t . Thus, probabilistically, the system reliability, $R_s(t)$ for independent units is obtained from

$$R_s(t) = R_1(t) \cdot R_2(t) \cdot \cdots \cdot R_N(t) = \prod_{i=1}^N R_i(t) \quad (37)$$

where $R_i(t)$ represents the reliability of the i th unit. The hazard rate (instantaneous failure rate) for a series system is also a convenient expression. The hazard rate of the system, $h_s(t)$, is

$$h_s(t) = \sum_{i=1}^N h_i(t) \quad (38)$$

Assume a constant hazard rate model for each unit (e.g., assume an exponential time to failure for each unit). Thus, $h_i(t) = \lambda_i$. According to Equation 37, the system constant rate of failure is

$$\lambda_s = \sum_{i=1}^N \lambda_i \quad (39)$$

Equation 39 can also be easily obtained from Equation 37 by using the constant failure rate reliability model for each unit, $R_i(t) = \exp(-\lambda_i t)$.

$$R_s(t) = \prod_{i=1}^N \exp(-\lambda_i t) = \exp\left(-\sum_{i=1}^N \lambda_i t\right) \quad (40)$$

Accordingly, the MTTF of the system ($MTTF_s$) can be obtained from

$$MTTF_s = \frac{1}{\lambda_s} = \frac{1}{\sum_{i=1}^N \lambda_i} \quad (41)$$

EXAMPLE 6:

A system consists of three units whose reliability block diagram is in a series. The failure rate for each unit is constant, as follows: $\lambda_1 = 4.0 \times 10^{-6} \text{hr}^{-1}$, $\lambda_2 = 3.2 \times 10^{-6} \text{hr}^{-1}$, $\lambda_3 = 9.8 \times 10^{-6} \text{hr}^{-1}$. Determine the following parameters of the system:

1. λ_s
2. $R_s(1000 \text{ hrs})$
3. $MTTF_s$

SOLUTION:

1. According to Equation 39,

$$\begin{aligned} \lambda_s &= 4.0 \times 10^{-6} + 3.2 \times 10^{-6} + 9.8 \times 10^{-6} \\ &= 1.7 \times 10^{-5} \text{hr}^{-1} \end{aligned}$$

2. $R_s(t) = \exp(-\lambda_s t) \exp(-1.7 \times 10^{-5} \times 1000) = 0.983$, or unreliability of $F_i(1000) = 0.017$

3. According to Equation 41, $MTTF_s = 1/\lambda_s = 1/1.7 \times 10^{-5} = 58,823.5 \text{ hrs}$

Parallel systems: A reliability block diagram is in a parallel configuration when the failure of all units in the system results in system failure. Accordingly, for a parallel system, success of only one unit would be sufficient to guarantee the success of the system. Figure 5-3.11 shows a parallel system consisting of N units.

According to the definition of a parallel system, failure of all units results in the failure of the system. Thus, for a set of N independent units,

$$F_s(t) = F_1(t) \cdot F_2(t) \cdot \cdots \cdot F_N(t) = \prod_{i=1}^N F_i(t) \quad (42)$$

Since $R_i(t) = 1 - F_i(t)$ [i.e., $F_i(t)$ is the unreliability of the units], then

$$R_s(t) = 1 - F_s(t) = 1 - \prod_{i=1}^N [1 - R_i(t)] \quad (43)$$

The hazard rate can be determined by using $h(t) = -d \ln R_s(t)/dt$. The resulting form of $h(t)$ is rather complex.

To address various characteristics of system reliability, consider a special case where the instantaneous failure rate is constant for each unit (exponential time-to-failure model), and the system is composed of only two units. Since $R_i(t) = \exp(-\lambda_i t)$, then according to Equation 43,

$$\begin{aligned} R_s(t) &= 1 - [1 - \exp(-\lambda_1 t)][1 - \exp(-\lambda_2 t)] \\ &= \exp(-\lambda_1 t) + \exp(-\lambda_2 t) - \exp[-(\lambda_1 + \lambda_2)t] \end{aligned} \quad (44)$$

Since $h_s(t) = f_s(t)/R_s(t)$ and $f_s(t) = -d[R_s(t)]/dt$, then using Equation 44,

$$\begin{aligned} h_s(t) &= \frac{f_s(t)}{R_s(t)} = \frac{-d[R_s(t)]/dt}{R_s(t)} = \\ &= \frac{\lambda_1 \exp(-\lambda_1 t) + \lambda_2 \exp(-\lambda_2 t) - (\lambda_1 + \lambda_2) \exp[-(\lambda_1 + \lambda_2)t]}{\exp(-\lambda_1 t) + \exp(-\lambda_2 t) - \exp[-(\lambda_1 + \lambda_2)t]} \end{aligned}$$

The MTTF of the system can also be obtained from

$$\begin{aligned} MTTF_s &= \int_0^{\infty} R_s(t) dt \\ &= \int_0^{\infty} \{ \exp(-\lambda_1 t) + \exp(-\lambda_2 t) \\ &\quad - \exp[-(\lambda_1 + \lambda_2)t] \} dt \\ &= \frac{1}{\lambda_1} + \frac{1}{\lambda_2} - \frac{1}{\lambda_1 + \lambda_2} \end{aligned}$$

Figure 5-3.11. Parallel system block diagram.

Accordingly, one can use the binomial expansion to derive the MTTF for N parallel units:

$$\begin{aligned} \text{MTTF}_s &= \left(\frac{1}{\lambda_1} + \frac{1}{\lambda_2} + \dots + \frac{1}{\lambda_N} \right) \\ &\quad - \left(\frac{1}{\lambda_1 + \lambda_2} + \frac{1}{\lambda_1 + \lambda_3} + \dots + \frac{1}{\lambda_{N-1} + \lambda_N} \right) \quad (45) \\ &\quad + \left(\frac{1}{\lambda_1 + \lambda_2 + \lambda_3} + \dots + \frac{1}{\lambda_{N-2} + \lambda_{N-1} + \lambda_N} \right) \dots \\ &\quad + (-1)^{N+1} \frac{1}{\lambda_1 + \lambda_2 + \dots + \lambda_N} \end{aligned}$$

In the special case where all units are identical with a constant failure rate λ (e.g., in an active redundant system), Equation 43 simplifies to the following form

$$R_s(t) = 1 - [1 - \exp(-\lambda t)]^N \quad (46)$$

and from Equation 45,

$$\text{MTTF}_s = \text{MTTF} \left(1 + \frac{1}{2} + \dots + \frac{1}{N} \right) \quad (47)$$

It can be seen from Equation 47 that, in the design of active redundant systems, the MTTF_s exceeds the MTTF of an individual unit. However, the contribution to the MTTF_s from the second unit, the third unit, and so on would have a diminishing return as N increases. That is, there would be an optimum number of parallel units by which a designer can balance the reliability and the cost of the component in its life cycle.

Consider a more general form of a series and parallel system—the so-called K -out-of- N system. In this type of system, if any combination of K units out of N independent units works, it guarantees the success of the system. For simplicity, assume that all units are identical (which, by the way, is often the case). The binomial distribution can easily represent the probability that the system functions

$$\begin{aligned} R_s(t) &= \sum_{r=K}^N \binom{N}{r} [R(t)]^r [1 - R(t)]^{N-r} \\ &= 1 - \sum_{r=0}^{K-1} \binom{N}{r} [R(t)]^r [1 - R(t)]^{N-r} \quad (48) \end{aligned}$$

EXAMPLE 7:

Three sprinkler heads connected in series are the only automatic suppression protection a corridor has. Although the heads are connected in series, the reliability analysis is addressed using a parallel system approach. The corridor will not have automatic suppression protection only if all the heads fail to work. Using the data from example 5, find the unreliability and the MTTF_s of the system.

SOLUTION:

According to Equation 43,

$$\begin{aligned} R_s(t) &= 1 - (1 - e^{-\lambda_1 t})(1 - e^{-\lambda_2 t})(1 - e^{-\lambda_3 t}) \\ F_s(1000) &= 1 - R_s(1000) \\ &= 1 - (1 - e^{-4.0 \times 10^{-6} \times 1000}) \\ &\quad \cdot (1 - e^{-3.2 \times 10^{-6} \times 1000})(1 - e^{-9.8 \times 10^{-6} \times 1000}) \\ &= 1.25 \times 10^{-7} \\ \text{MTTF}_s &= \left(\frac{1}{\lambda_1} + \frac{1}{\lambda_2} + \frac{1}{\lambda_3} \right) \\ &\quad - \left(\frac{1}{\lambda_1 + \lambda_2} + \frac{1}{\lambda_1 + \lambda_3} + \frac{1}{\lambda_2 + \lambda_3} \right) \\ &\quad + \frac{1}{\lambda_1 + \lambda_2 + \lambda_3} = 4.35 \times 10^5 \text{ hrs} \end{aligned}$$

EXAMPLE 8:

How many components should be used in an active redundancy design to achieve a reliability of 0.999 such that, for successful system operation, a minimum of two components is required? Assume a mission of $t = 720$ hrs for a set of components that are identical and have a failure rate of 0.00015/hr.

SOLUTION:

For each component $R(t) = \exp(-\lambda t) = \exp(-0.00015 \times 720) = 0.8976$. According to Equation 48,

$$\begin{aligned} 0.999 &= R_s(t) = 1 - \sum_{r=0}^1 \binom{N}{r} (0.8976)^r (0.1024)^{N-r} \\ &= 1 - (0.1024)^N - N(0.8976)(0.1024)^{N-1} \end{aligned}$$

From the above equation, $N = 5$, which means that at least five components should be used to achieve the desired reliability over the specified mission time.

Standby redundant systems: A system is called a standby redundant system when some of its units remain idle until they are called for service by a sensing and switching device. For simplicity, consider a situation where only one unit operates actively and the others are in standby, as shown in Figure 5-3.12.

In Figure 5-3.12, unit 1 operates constantly until it fails. The sensing and switching device recognizes a unit failure in the system and switches to another unit. This

Figure 5-3.12. Standby redundant system.

process continues until all standby units have failed, in which case the system is considered failed. Since units 2 to N do not operate constantly (as is the case in active parallel systems), one would expect them to fail at a much slower rate. This is because the failure rate for components is usually lower when the components are operating than when they are idle or dormant.

It is clear that system reliability is totally dependent on the reliability of the sensing and switching device. The reliability of a redundant standby system is the reliability of unit 1 over the mission time, t (i.e., the probability that it succeeds the whole mission time), plus the probability that unit 1 fails at time t_1 prior to t and the probability that the sensing and switching unit does not fail by t_1 and the probability that standby unit 2 does not fail by t_1 (in the standby mode) and the probability that standby unit 2 successfully functions for the remainder of the mission in an active operation mode, and so on.

Mathematically, the reliability function for a two-unit standby device according to this definition can be obtained from

$$R_s(t) = R_1(t) + \int_0^t f_1(t_1) dt_1 \cdot R_{ss}(t_1) \cdot R'_2(t_1) \cdot R_2(t - t_1) \quad (49)$$

where $f_1(t)$ is the probability distribution function for the time to failure of unit 1, $R_{ss}(t_1)$ is the reliability of the sensing and switching device, $R'_2(t)$ is the reliability of unit 2 in the standby mode of operation, and $R_2(t - t_1)$ is the reliability of unit 2 after it started to operate at time t_1 .

If all units are identical with perfect switching, then the reliability of the system is

$$R_s(t) = \exp(-\lambda t) + \lambda t \exp(-\lambda t) = (1 + \lambda t) \exp(-\lambda t) \quad (50)$$

Shared load systems: A shared load system refers to a parallel system whose units equally share the system function. For example, if a set of two parallel pumps delivers x gpm of water to a reservoir, each pump delivers $x/2$ gpm. If a minimum of x gpm is required at all times, and one of the pumps fails at a given time t_1 , then the other pump's speed should be increased to provide x gpm alone. Other examples of load sharing are multiple load-bearing units (such as those in a bridge), and load-sharing multi-unit electric power plants. In these cases, when one of the units fails, the others should carry its load. Since these other units would then be working under a more stressful condition, they would experience a higher rate of failure.

Assume that two units share a load (i.e., each unit carries half the load), and the time-to-failure distribution for both units to work is $f_h(t)$. When one unit fails (i.e., one unit carries the full load), the time-to-failure distribution is $f_f(t)$. Further, call the corresponding reliability functions during full-load and half-load operation $R_f(t)$ and $R_h(t)$, respectively. The system will succeed if both units carry half the load, or if unit 1 fails at time t_1 and unit 2 carries a full load thereafter, or if unit 2 fails at time t_1 and unit 1 carries the full load thereafter. Accordingly, the system reliability function, $R_s(t)$, can be obtained from

$$R_s(t) = [R_h(t)]^2 + 2 \int_0^t f_h(t_1) R_f(t_1) R_h(t - t_1) dt_1 \quad (51)$$

In Equation 51, the first term shows the contribution from both units working successfully, with each carrying a half load. The second term represents the two equal probabilities that unit 1 fails first and unit 2 takes the full load at time t_1 , or vice versa.

If there are switching or control mechanisms involved to shift the total load to the unfailed unit when one unit fails, then similar to Equation 49, the reliability of the switching mechanism can be incorporated into Equation 51.

In the special situation where an exponential time-to-failure model with failure rates λ_f and λ_h can be used for the two units for full- and half-load cases, respectively, then Equation 38 can be simplified to

$$R_s(t) = \exp(-2\lambda_h t) + \frac{2\lambda_h \exp(-\lambda_f t)}{(2\lambda_h - \lambda_f)} \exp[-(2\lambda_h - \lambda_f)t] \quad (52)$$

Complex systems: Most practical systems are not parallel or series, but exhibit some hybrid combination of the two. These systems are often referred to as *parallel-series systems*. Figure 5-3.13 shows an example of such a system.

A parallel-series system can be analyzed by dividing it into its basic parallel and series modules, and then determining the reliability function for each module separately. The process can be continued until a reliability function for the whole system is determined. Another type of complex system is one that is neither series nor parallel alone, nor parallel-series. Figure 5-3.14 shows an example of such a system.

For the analysis of all types of complex systems, Shooman⁵ describes several analytical methods for com-

Figure 5-3.13. Complex parallel-series system.

Figure 5-3.14. Complex nonparallel-series system.

plex systems. These are the *inspection method*, *event space method*, *path-tracing method*, and *decomposition*. These methods are good only when there are not a lot of units in the system. For analysis of large numbers of units, fault trees would be more appropriate.

A computationally intensive method for determining the reliability of a complex system involves the use of *path set* and *cut set* methods. A path set (or tie set) is a set of units that include a connection between input and output when traversed in the direction of the reliability block diagram arrows. Thus, a path set provides a path through the graph. A minimal path set (or minimal tie set) is a path set that would not provide a connection between the input and output points if any of its units were removed. For example, in Figure 5-3.14, path set $P_1 = (1,3)$ is a minimal path set; but $P_2 = (1,3,6)$ is not, since units 1 and 3 are sufficient to guarantee a path.

A cut set is a set of units that interrupts all possible connections between the input and output points. A *minimal cut set* is the smallest set of units needed to guarantee an interruption of flow. In practice, minimal cut sets show a combination of unit failures that cause a system to fail. For example, in Figure 5-3.14, the minimal path sets are $P_1 = (2)$, $P_2 = (1, 3)$, $P_3 = (1, 4, 7)$, $P_4 = (1, 5, 8)$, $P_5 = (1, 4, 6, 8)$, and $P_6 = (1, 5, 6, 7)$. The minimal cut sets are $C_1 = (1, 2)$, $C_2 = (4, 5, 3, 2)$, $C_3 = (7, 8, 3, 2)$, $C_4 = (4, 6, 8, 3, 2)$, and $C_5 = (5, 6, 7, 3, 2)$. If a system has m minimal path sets denoted by P_1, P_2, \dots, P_m , then the system reliability is given by

$$R_s(t) = \Pr(P_1 \cup P_2 \cup \dots \cup P_m) \quad (53)$$

where each path set P_i represents the event that units in the path set survive during the mission time, t . This guarantees the success of the system. Since many path sets may exist, the union of all these sets gives all possible events for successful operation of the system. The probability of this union clearly represents the reliability of the system. It should be noted here that, in practice, the path sets, P_i s, are not disjoint, which poses a problem for determining the left-hand side of Equation 53. However, a useful upper bound on the system reliability may be obtained by assuming that the P_i s are highly disjoint. Thus,

$$R_s(t) \leq \Pr(P_1) + \Pr(P_2) + \dots + \Pr(P_m) \quad (54)$$

Expression 54 yields better answers when using small reliability values. Since this is not usually the case, Equation 54 is not a good bound for use in practical applications.

Similarly, system reliability can be determined through minimal cut sets. If the system has n minimal cut sets denoted by C_1, C_2, \dots, C_n , then the system reliability is obtained from

$$R_s(t) = 1 - \Pr(C_1 \cup C_2 \cup \dots \cup C_n) \quad (55)$$

where C_i represents the event that units in the cut set fail sometime before the mission time, t . This guarantees system failure. The term $\Pr(C_1 \cup C_2 \cup \dots \cup C_n)$, on the right-hand side of Equation 55, shows the probability that at least one of all possible minimal cut sets exists before time

t . Thus, it represents the probability that the system fails sometimes before t . By subtracting this probability from 1, the reliability of the system is obtained. Similar to path sets, cut sets are not usually disjoint. Again, Equation 55 can be written in the form of its lower bound, which is a much simpler expression given by

$$R_s(t) \geq 1 - [\Pr(C_1) + \Pr(C_2) + \dots + \Pr(C_n)] \quad (56)$$

Notice that each element of a path set represents the *success* of a unit, whereas each element of a cut set represents the *failure* of a unit. Thus, for probabilistic evaluations, the reliability function of each unit should be used in connection with path set evaluations (i.e., Equation 54) while the unreliability function should be used in connection with cut set evaluations (i.e., Equation 56).

The bounding technique used in Equation 56, in practice, yields a much better representation of the reliability of the system than Equation 54, because most engineering units have reliabilities greater than 0.9 over their mission time, making the use of Equation 56 appropriate.

In cases that deal with very complex systems that have multiple failure modes for each unit and complex physical and operational interactions, the use of reliability block diagrams is difficult. The method of fault tree and success tree analysis is more appropriate in this context, especially if the role of humans in the operation of the system needs to be modeled.

Logic Tree Methods

Fault tree (FT), success tree (ST), and master plant logic diagram (MLD) are three of the most popular logic tree methods. This section discusses the basic concepts of these logic tree methods by pointing out the differences between them. A simple example (a fire protection system) is discussed for illustration.

Fault tree and success tree: Fault and success trees are deductive processes that have tree-like hierarchical structures. In such a tree-like structure, the basic underlying principles of a complex system are represented. Each node in the tree represents an event (a goal) or a function. As shown in Figure 5-3.15, the top event of system failure or system success can be decomposed to subevents, subgoals, or subfunctions that have, in turn, their own subevents, subgoals, or subfunctions, and so on, until some lowest level of elementary components is reached. A set of symbols similar to the ones shown in Figure 5-3.16 is used to develop a logic tree.

Logically, it must be recognized that logic trees can be developed equally well in success or failure space, so that the tree analysis can proceed with either success or failure orientation. However, experience has shown that success orientation is preferable, since it tends to lead to better and more succinct definition of system functions and operation.

However, when one is attempting to understand the failure characteristics of a piece of equipment or an industrial process, fault descriptions are more easily grasped than the success space descriptions of the system,

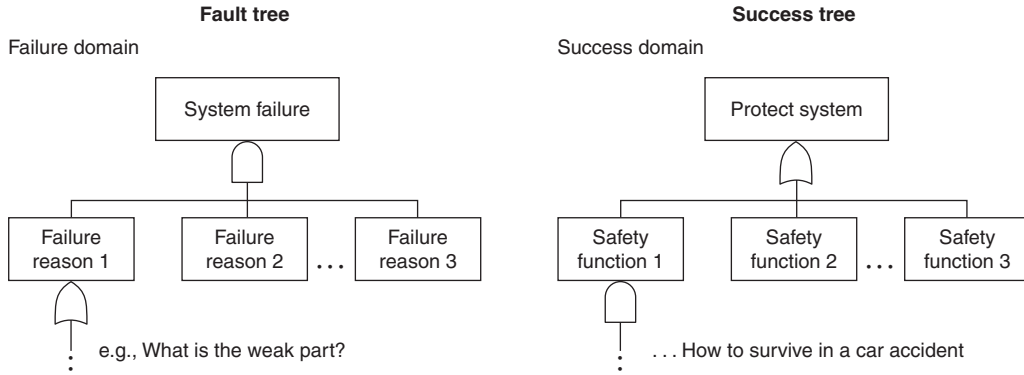

Figure 5-3.15. *Fault tree vs. success tree.*

because the process is typically being viewed externally, from the perspective that a failure has already occurred. This means that the person is likely to be looking at the system in a deductive manner and tries to find in what way such a failure may occur.

For a more detailed discussion of the construction and evaluation of fault trees, refer to the *Fault Tree Handbook*. The goal tree–success tree structure was initially developed as part of Department of Energy–sponsored research⁶ to assess and improve information systems in a nuclear plant. Subsequently, it has been further developed and extended to a number of other applications.^{7,8,9}

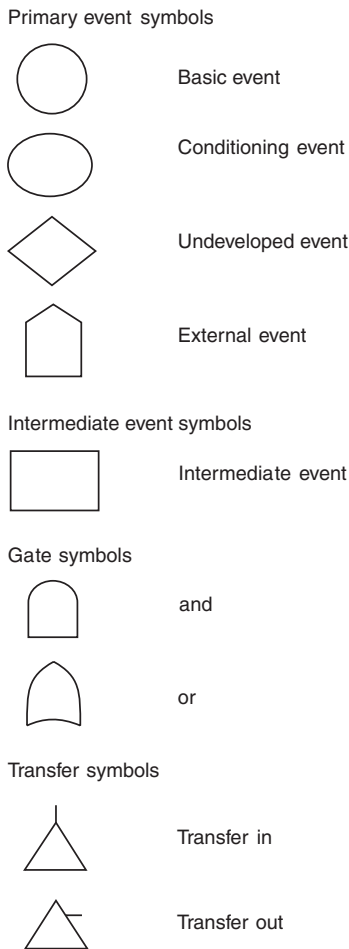

Figure 5-3.16. *Primary event, gate, and transfer symbols.*

Master plant logic diagram (MLD): The hardware or human activities in the success tree often are associated with other support equipment, and since more often than not challenges to systems or processes originate from other support equipment, it is important to include these relationships in the success tree. A single visual display of the plant logical relations is represented by an MLD model.¹⁰ This logic diagram shows all of the interrelationships among the so-called front-line systems and support systems. Front-line systems are those that perform main functions of the system or process. Support systems are those that either cool, actuate, power, lubricate, or control the front-line systems. As shown in Figure 5-3.17, the MLD diagram is also developed hierarchically in a top-down manner. Therefore, most of the characteristics of the success tree are equally applicable to this diagram. Computer software called REVEAL_W has been developed to perform the MLD modeling.

EXAMPLE 8:

Consider the fire protection system shown in Figure 5-3.18. This system is designed to extinguish all possible fires in a plant with toxic chemicals. Two physically independent water-extinguishing nozzles are designed such that each is capable of controlling all types of fires in the plant. Extinguishing nozzle 1 is the primary method of injection. Upon receiving a signal from the detector/alarm/actuator device, pump 1 starts automatically, drawing water from the reservoir tank and injecting it into the fire area in the plant. If this pump injection path is not actuated, plant operators can start a second injection path manually. If the second path is not available, the operators will call for help from the local fire department. (The detector also sends a signal to the fire department.) However, due to the delay in the arrival of the local fire de-

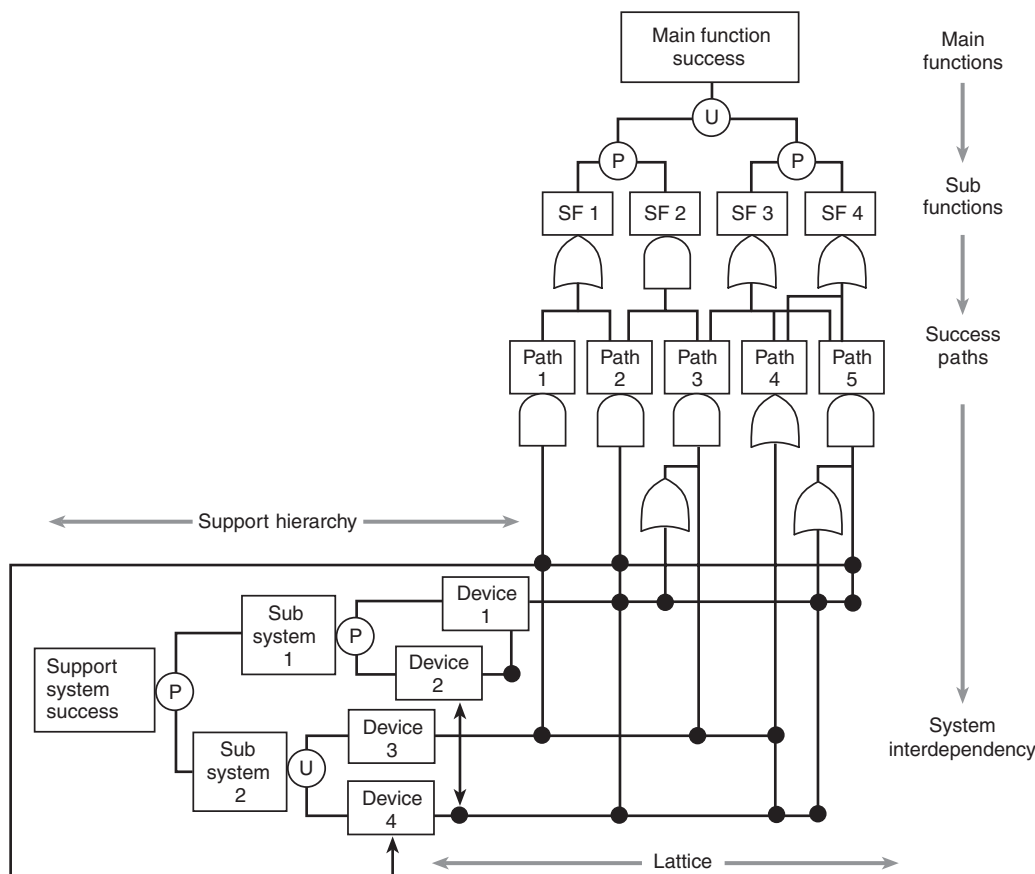

Figure 5-3.17. Master logic diagram.

partment, the magnitude of damage would be higher than it would be if the local fire-extinguishing nozzles were available to extinguish the fire. Under all conditions, if the normal off-site power is not available due to the fire or other reasons, a local generator would provide electric power to the pumps. The power for the detector-alarm-actuator system is provided by batteries, which are constantly charged by the off-site power. Even if the ac power is not available, the dc power provided through the battery is expected to be available at all times. The manual valves on the two sides of pump 1 and pump 2 are normally open, and only remain closed when they are being repaired. The entire fire system and generator are located outside of the reactor compartment, and are therefore not affected by an internal fire.

SOLUTION:

For reliability analysis, one should explain the cause and effect relationship between the fire and the progression of events following the fire, and should identify all failures (equipment or human) that lead to failure of the event-tree headings (on-site or off-site protective measures).

For example, Figure 5-3.19 shows the fault tree developed for the on-site fire protection system failure. In this fault tree, all basic events that lead to the failure of the two

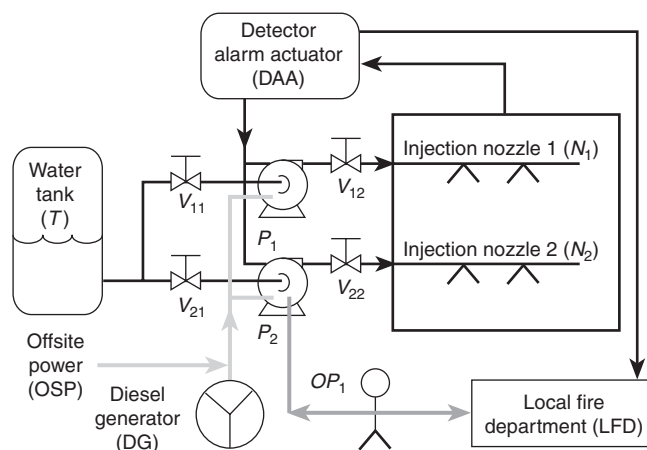

Figure 5-3.18. A fire protection system.

independent paths are described. Note that MAA, electric power to the pumps, and the water tank are shared by the two paths. Clearly these are considered physical dependencies, which are taken into account in the quantification step of the risk analysis. In this tree, all external event failures and passive failures are neglected.

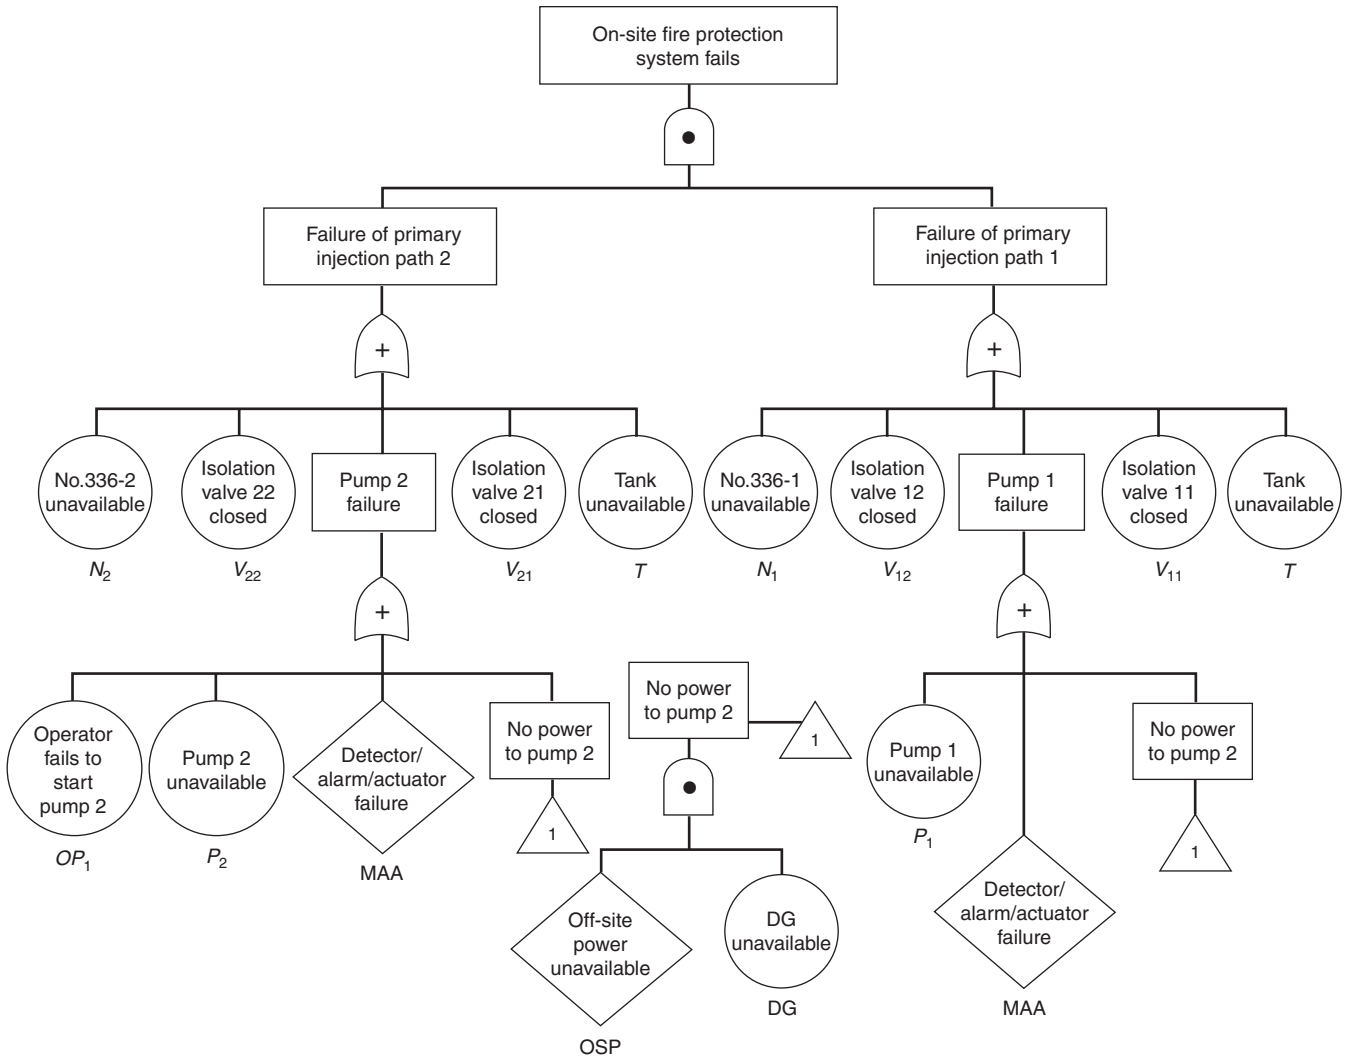

Figure 5-3.19. Fault tree for on-site fire protection system failure.

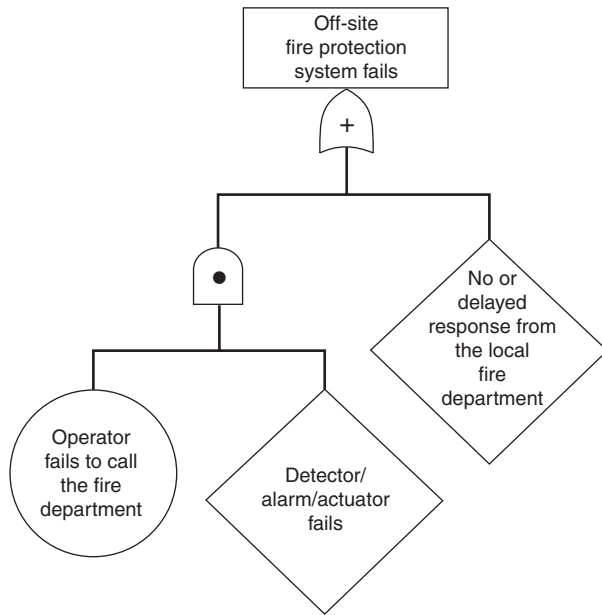

Figure 5-3.20. Fault tree for off-site fire protection system failure.

Figure 5-3.20 shows the fault tree for the off-site fire protection system failure. This tree is simple, since it only includes failures that do not lead to an on-time response from the local fire department. It is also possible to use the MLD for system analysis. An example of the MLD for this problem is shown in Figure 5-3.21.

CHAPTER 4

Uncertainty

Kathy A. Notarianni

Introduction

The treatment of uncertainty is key to ensuring and maintaining an appropriate level of public safety while allowing the flexibility necessary to reduce costs. This is true for all fire safety engineering calculations whether conducted to meet a performance-based code, to aid in the establishment of a prescriptive requirement, or to compare a performance option to its prescriptive counterpart. However, at present, no method exists for the treatment of uncertainty in a fire safety engineering calculation. Proper treatment of uncertainty will assist engineers and architects in the design process, and assist code officials by increasing confidence in the acceptance of a performance calculation. It will aid researchers in prioritizing enhancements to both the physics and structure of fire models, and aid policymakers by incorporating scientific knowledge and technical predictive abilities in policy decisions.

This chapter is made up of several sections. The first section, Understanding Uncertainty, covers basic concepts of uncertainty and variability in order to develop a common language for discussion among fire safety professionals. It then presents motivating examples that show the importance of dealing with uncertainty in the application of our scientific tools. It is shown how variations in analysis parameters, assumptions, or model inputs can lead to changes in the acceptability of a fire safety design. This is termed *switchover*.¹ A taxonomy is presented in this section that is useful as a framework for understanding, identifying, and investigating uncertainties.

Another section, Treatment of Uncertainty in Design Calculations, discusses the treatment of uncertainty with

safety factors as well as quantitative techniques for the treatment of uncertainty in fire protection design calculations. The use of safety factors in both prescriptive and performance-based codes is discussed. Guidance is given on selecting an appropriate factor of safety and on combining safety factors. Quantitative techniques are presented for the treatment of uncertainties in measurement; in analysis parameters, assumptions, and values; and in complex fire models.

A methodology for the application of an uncertainty analysis to a fire safety engineering calculation is suggested. It is shown how results of this type of analysis are used to create distributions of time to untenability, to demonstrate the effect of selecting various sets of performance criteria, to compare two designs, and to provide insight to model development.

The last section of this chapter, Treatment of Uncertainty in Cost-Benefit and Decision Analysis Models, discusses the application of uncertainty analysis to cost-benefit and decision analysis models. An example of a cost-benefit model that incorporates uncertainty is provided.

Understanding Uncertainty

Uncertainty is a broad and general term used to describe a variety of concepts including but not limited to lack of knowledge, variability, randomness, indeterminacy, judgment, approximation, linguistic imprecision, error, and significance. These and many other facets of uncertainty are discussed in more detail in Chapter 4 of the book *Uncertainty*.¹ The variety of types and sources of uncertainty, along with the absence of agreed-upon terminology, generates considerable confusion in the fire protection engineering world. Many facets of uncertainty can be understood through statistical and scientific concepts, some of which are presented below. However, uncertainties in the engineering design process, such as those surrounding the selection of performance criteria, are best understood by their ability to change the accept-

Dr. Kathy A. Notarianni leads the Integrated Performance Assessment Research Group in the Building and Fire Research Laboratory of the National Institute of Standards and Technology in Gaithersburg, Maryland. Her work has focused on topics such as smoke detection, water-based suppression, fire modeling, and uncertainty and performance related to fire regulations.

ability of a design. Finally, to fully understand uncertainty in fire safety engineering, one must be cognizant of the difficulties in conducting a complete uncertainty analysis.

Nature and Sources of Uncertainty

Uncertainty is often discussed as though it was synonymous with measurement uncertainty, that is, doubt about the validity of the result of a measurement. Measurement uncertainties are characterized from both a statistical analysis of a series of observations (to determine the random error) and from systematic effects associated with corrections and reference standards (to determine the systematic error). The total error is defined as a combination of random and systematic errors. Much work has been done to reach an international consensus on the evaluation and expression of measurement uncertainty. General rules for evaluating and expressing uncertainty in measurement are provided in a guide published by the American National Standards Institute and the National Conference of Standards Laboratories.² An example of dealing with measurement uncertainty in fire protection engineering is found in a study of the uncertainty surrounding the use of thermocouples to measure temperature.³

However, uncertainty also arises from a variety of other sources to which standard techniques for the evaluation and expression of uncertainty do not always apply. Uncertainty can arise from a lack of complete knowledge. What is the heat release rate or radiative fraction of a mixed-fuel package? We have not measured and cannot reliably predict the value of these quantities for all potential fuel packages. Furthermore, the heat-release rate and radiative fraction vary with parameters such as geometry, source and strength of ignition, and ventilation conditions. Uncertainty may arise from *randomness*, such as where and how the fire will start. Uncertainty may arise from *indeterminacy*, defined as the inability to know what will happen in the future. For example, building occupancy and furnishings may differ 10 or 20 years after they were first constructed. Uncertainty may arise due to the unpredictability of human behavior. It is unknown what actions each occupant will take upon discovering a fire or hearing an alarm. Uncertainty can arise because of disagreement between information sources. Rates of generation of products of combustion per gram of fuel burned vary from study to study and even from test to test in the same study using the same instruments.

Uncertainty may arise from difficulties in defining the problem. For example, a goal may be established to provide an equivalent level of fire safety. However, equivalency may be defined as providing the same time available for egress, providing the same level of property protection, providing the same level of fire safety for fire fighters entering the building, or all of the above. Uncertainty may also arise from *linguistic imprecision*. It is difficult to determine exactly what is meant by "flame spread should be limited." Uncertainty often refers to *variability*, for example, the ambient temperature and the total number of deaths from fire. These quantities vary in time by season, month, and day. They also vary in space by region of the country and community size. Even if we had com-

plete information, we may be uncertain because of simplifications and approximations introduced due to computational limitations.

There are also important questions related to understanding uncertainties in perceptions, attitudes, and values toward risk. "In addition to being uncertain about what exists in the external world, we may be uncertain about individual preferences, uncertain about decisions relating to potential solutions, and even uncertain about the level and significance of our uncertainty."¹ Uncertainties inherent in the performance-based analysis and design process are discussed in *Introduction to Performance-Based Fire Safety*.⁴

Understanding the level and significance of our uncertainty is crucial to making good fire safety design decisions. It is therefore important that the fire protection engineering community understands basic concepts of probability and statistics, and that the community agrees on terminology for use in discussing uncertainty.

Terminology for Probability and Statistics

The mathematical concept of probability is used to quantify uncertainty. Elements of probability allow us to quantify the strength of, or confidence in, our conclusions. There are two views of probability, the frequentist (or classical) and the subjectivist (or Bayesian). Each of these are useful in quantifying uncertainties in fire protection engineering. Likewise, inferential statistics has produced an enormous number of analytical tools that allow the engineer or scientist to better understand the systems that generate data. Inferential statistics allows us to go beyond merely reporting data, and enables the drawing of conclusions about the scientific system. Concepts essential to the understanding of uncertainty such as distribution, mean, standard deviation, errors, corrections, correlation, and independence are presented in Section 1 of this handbook. A full treatment of probability concepts is presented in Section 1, Chapter 11, and concepts of statistical analysis are presented in Section 1, Chapter 12.

Probability/frequentist view: The probability of an event's occurring in a particular scenario is defined as the frequency with which it occurred in a long sequence of similar trials. For example, the probability of a fire pump failure may be defined by failure data for that pump in many fires.

Probability/Bayesian view: The probability of an event is the degree of belief that a person has that it will occur, given all relevant information currently known to that person. For example, the probability that a new fire detector will save lives may be based on the judgment of an expert in both fire detection and the nature of fire deaths (who may or may not have frequency data to support such a belief in the classical sense).

Random error and statistical variation: No measurement of an empirical quantity such as the burning rate of jet fuel can be absolutely exact. Imperfections in the measuring instruments and observational technique will inevitably give rise to variations from one observation to

the next. The resulting uncertainty depends on the size of the variations between observations and the number of observations taken. Classical, statistical techniques such as standard deviation, confidence intervals, and others can be used to quantify this uncertainty.

Aleatory uncertainty: Aleatory uncertainty is due to random variations and chance outcomes and has also been referred to as *randomness*,⁵ as *stochastic uncertainty*,⁶ and as *statistical uncertainty*.⁷ In principle, aleatory uncertainty cannot be reduced but can be better characterized through exhaustive study. Stochastic uncertainty has been defined as “the totality of occurrences that can take place in the particular universe under consideration together with a probabilistic characterization of the likelihood of these occurrences.”⁸

Epistemic uncertainty: Epistemic uncertainty arises because of lack of knowledge. It has also been referred to as *imprecision*,⁵ as *knowledge uncertainty*,⁶ as *engineering uncertainty*,⁷ and as *subjective uncertainty* because expert judgment is often needed to represent the uncertainty when full knowledge is lacking. In principle, epistemic uncertainty can be reduced through gaining additional information or data. It has been stated that this type of uncertainty often arises due to the uncertainty on the part of the analyst as to how the appropriate values of the quantities should be assigned.⁸

Scientific versus statistical significance: *Statistically significant* refers to a mathematical calculation that verifies that two quantities are likely to be the same or different. *Scientifically significant* refers to whether the difference is large enough to be important.

Uncertainties in the Design Process and the Problem of Switchover

Of practical significance is that direct measurement of the fire safety performance of a building or building system is not usually possible; therefore, we must rely on the technical predictive ability of scientific tools, such as existing fire models. The problem is that the numerous uncertainties in the application of these fire safety design tools often go unrecognized or ignored. Many of these uncertainties are inherent in the design process itself. Variations in analysis parameters, assumptions, or model inputs may cause output criteria to change. *Switchover* occurs when outcome criteria change enough so as to cause a change in the design decision (e.g., the acceptability of a final design). It is critical to know if different sets of reasonable inputs, scenarios, or parameters used in a fire safety engineering design have potential to cause switchover and lead to different acceptable designs.

The Society of Fire Protection Engineers (SFPE) *Engineering Guide to Performance-Based Fire Protection Analysis and Design of Buildings* details several steps in the design process.⁹ These are shown in Figure 5-4.1, adapted from the SFPE engineering guide. The stated intent of the guide is to “provide guidance that can be used by both design engineers and approving authorities as a means to

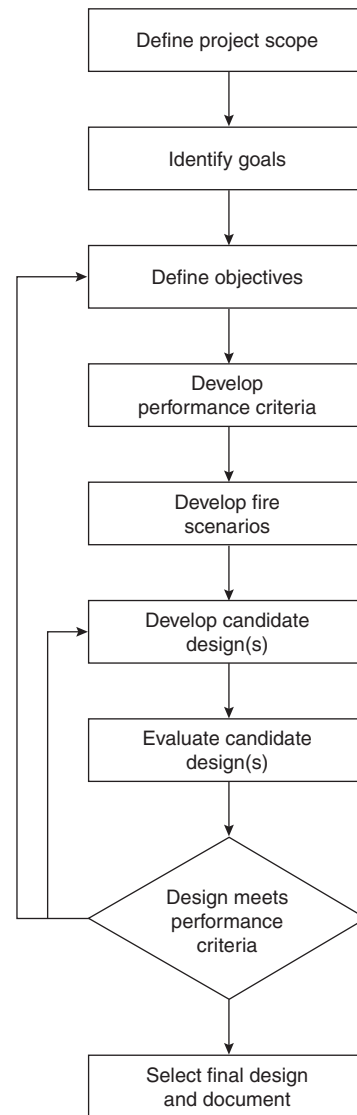

Figure 5-4.1. Overview of the performance-based design process.⁹

determine and document achievement of agreed upon levels of fire safety for a particular project” (emphasis added).

A review and analysis of the performance-based design process for fire safety engineering outlined in the guide along with a review of several case studies of performance-based, fire safety engineering designs for actual buildings was conducted.¹⁰ This review uncovered seven major barriers to determining and documenting achievement of agreed-upon levels of fire safety for a particular project. All seven barriers involve various types of uncertainty. Thus, there is a well-defined and strong role for uncertainty analysis in improving the ability to document achievement of agreed-upon levels of fire safety. The seven barriers identified are presented below along with a discussion of how they might lead to switchover of a design from acceptable to unacceptable.

1. Performance criteria are not established or no agreement exists: There is uncertainty in the selection of performance criteria. In fact, performance criteria have not been established or agreed upon by the fire safety community, and current policy allows the stakeholders themselves to select the criteria to be used for each design. Discussions occur around questions such as the following: Is the set of performance criteria sufficient? What do the numerical values actually represent? Should different criteria be used for different subpopulations, such as for people who are sick, elderly, or have disabilities? At one recent international conference, two engineers presented their performance-based case studies conducted for real clients on actual buildings. They had each followed the current design guidelines; however, they had selected very different performance criteria.^{11,12} Differences existed on three levels: (1) the parameters included in the set of performance criteria, (2) numerical values selected as the critical or cut-off values for these parameters, and (3) the presence or absence of a time element for reaching the cut-off values. Since predictions of fire models are compared to selected performance/life safety criteria in order to determine if a design is acceptable, variations in criteria can cause the same design to pass or fail.

2. The design fire selection process is unspecified: Design fires are descriptions of fire events (e.g., a grease fire on the stove, a smoldering cigarette fire on the sofa). Along with design fires, several fire scenarios, or descriptions of possible fires that could occur, are developed. For each design fire evaluated, the goal is to provide a fire safety design that would mitigate unwanted fires from developing.

Since it is impossible to evaluate physically the performance of building systems in response to all design fires that might occur, one does not have confidence that design fires and the resulting fire scenarios chosen adequately represent the range of fires that might occur in the building. Usually a designer will try to select worst-case or reasonable worst-case scenarios.* However, it is not always intuitive which scenarios present a worst-case situation or how likely (or unlikely) a particular scenario is. It is debatable whether we should be designing for the one-in-a-million fire and how many design fires and fire scenarios are sufficient. A methodology is needed that would incorporate the likelihood of a design fire and/or associated design fire scenario. It is easy to see how the same design may be deemed acceptable if based on a limited number and type of design fires, or deemed unacceptable if based on an expanded set of scenarios or a different set of scenarios.

3. Assumptions are made about human behaviors during fire: During several critical steps in the design process, assumptions are made about human behaviors during fire. For example, some egress models used by fire protection engineers to predict the time required for

safely evacuating a building (or part of a building) make many assumptions about how humans behave. Two assumptions are stated in one internationally used egress model: (1) 100 percent of the occupants are readily mobile and (2) occupants begin leaving the building immediately upon hearing an alarm.¹³ Experience demonstrates that this is often not the case.^{14,15}

Other behavior assumptions may not be explicitly stated but can be inferred from an analysis of model outputs. For example, results from a recently published study of a performance calculation using the egress model in FASTlite reveal that assumptions are made about human behavior during fires.¹³ A decrease in the number of exits by one-third increases the egress time by exactly one-third. This suggests an implied assumption that an equal number of people egress through each available exit. More typically, actual human behavior will be to exit following the path one normally uses to enter and exit the building. Existing egress calculations and models need to be evaluated so that unrecognized and/or unstated uncertainties resulting from assumptions regarding human behavior can be identified. Once revealed, the implications of these assumptions need to be explored quantitatively.

4. Predictive fire models have limitations that are not well documented or widely understood: Fire models and other calculation methodologies are often inappropriately used to develop and evaluate trial designs for buildings and/or scenarios outside of the predictive capabilities of the models. This occurs because limitations of fire models are not well documented or widely understood. For example, computer fire models don't model fire directly and only predict fire effects based on user-selected input data. Because many existing fire model and calculation methodologies were originally developed as research tools, model conditions, defined as "fundamental requirements for the model's validity,"¹⁶ are often unknown or unstated. Estimates provided by a model are technically credible only when model conditions have not been violated.

5. Outputs of fire models are point values that do not directly incorporate uncertainty: Even when the model is used within its intended limitations, fire model outputs are point values that do not reflect inherent input uncertainties (e.g., fire growth rates, initial conditions). Without knowledge of the uncertainty surrounding a prediction, it is impossible to be certain of a design's acceptability. One example is modeling the response of fire protection equipment such as sprinklers, heat detectors, and smoke detectors. Predictions of the time to activation of such devices would specify, for example, 121 s. However, the actual time to activation may be higher or lower depending on uncertain inputs or also on any number of factors not modeled, such as individual detector characteristics and distance below the ceiling.

6. The design process often requires engineers to work beyond their areas of expertise: Problems can also occur when fire protection engineers are required to work in domains outside their expertise. Conservative assumptions

*The term *worst-case scenario* is used in this chapter to represent both worst-case and reasonable worst-case scenarios as understood in the fire protection design field.

made by well-intentioned engineers may not be as conservative as intended. For example, a design engineer intending to be conservative may assume that tenability would be violated if, out of a set of criteria, any one particular criterion, such as temperature or carbon monoxide, exceeded its minimum value. However, toxicity experts might argue that temperature and gas interactions cause tenability to be violated even when every individual species is in acceptable ranges. Likewise, a design engineer may assume that the time needed for a resident to react to an alarm be conservatively set equal to the travel time needed to go from one remote corner of the unit to the other most remote corner of the same unit. However, this may not be that conservative since even a fully ambulatory occupant may stop to gather belongings, rescue a pet, call a neighbor, and so forth.

7. No standardized methods exist to incorporate reliability of systems: The last barrier identified is the uncertainty surrounding both the reliability of a given fire protection device, system, or characteristic and the lack of a standardized method to incorporate reliability into performance-based engineering calculations and decisions based upon these calculations. We may be uncertain about the reliability of a given fire suppression system. Sometimes a fire suppression system is proposed as an alternative to passive fire protection, such as compartmentalization. However, these two alternatives have different reliabilities. There is uncertainty (e.g., no agreement) on how to account for these differences.

These seven barriers to determining and documenting achievement of agreed-upon levels of fire safety for a particular project must be addressed fully in order for all stakeholders to have a known level of confidence in the science-based predictions and the resulting final design. All seven barriers involve various types of uncertainty. Thus, there is a well-defined and important role for uncertainty analysis in fire safety engineering calculations. Although this clear role for uncertainty in improving the development and implementation of performance-based fire safety regulations exists, uncertainty analysis is clearly an uncomfortable topic for many of the stakeholders in the process.

Difficulties with Uncertainty Analysis

Discussion of the proper treatment of uncertainty in a fire safety engineering calculation is difficult for several reasons:

1. *Magnitude of the problem.* It is widely assumed that a mixture of conservative assumptions and factors of safety can be used to explain away uncertainties. However, the magnitude of the problem is not clearly understood. Factors of safety that are applied at various stages of the analysis are not necessarily linearly related to the critical output parameters, potentially resulting in a reduced (or nonexistent) factor of safety in the results.
2. *Uncertainties that go unrecognized or ignored.* These types of uncertainties include those in variables hard-wired in scientific tools, those in tenability/performance crite-

ria, those surrounding the selection of design fires, and those in human behaviors and values.

3. *Effect on the implementation of performance regulations.* It is feared that identification and treatment of uncertainty would show that our current ability to predict the buildup of heat and toxic products of combustion is not accurate enough to judge the acceptability of a proposed design with a high enough confidence level. This would delay implementation of the entire performance process until predictions of critical outcome criteria can be more certain.
4. *Quantitative methodology.* No quantitative methodology exists for treating uncertainty in performance-based designs. A methodology is needed that is both rigorous and user friendly.
5. *Impracticality.* It is feared that the mathematical rigor needed to conduct such an analysis would render the process impractical.
6. *Paucity of data.* To quantify uncertainty adequately, a large quantity of data would be needed to determine ranges of values for input parameters such as heats of combustion, rates of production of various gaseous species, and other important inputs. A large quantity of data would also be needed to validate predicted values with empirical data from real burn scenarios.

It should be pointed out that these are real and valid concerns due to the combination of poorly defined and unstructured problems, and the lack of a user-friendly methodology. Current common practice for conducting uncertainty analyses involves completing a series of single-variable sensitivity studies. Application of these techniques to a complete performance-based design containing hundreds of variables is impractical. The following sections focus on practical ways to identify and account for uncertainties in fire protection engineering design.

Identifying Uncertainties in Fire Protection Engineering

When considering uncertainty in a fire protection engineering calculation, fire protection engineers typically consider first the uncertainties associated with the calculation inputs, usually empirically measured quantities such as heat-release rate. However, there are many other types of uncertainty integral to fire safety engineering design.

In a complete uncertainty analysis, not all uncertain parameters are treated quantitatively, only parameters or combinations of parameters with the potential to cause switchover in the final decision on the acceptability of a design. Others are negligible and best-guess values of these parameters can be used in the calculations. Still others, such as societal values, become policy or regulatory issues, not engineering issues. The intelligent use of safety factors can often cover more than one type of uncertainty. Still, it is useful to first identify sources and types of uncertainty from a broad perspective. Without first adequately identifying the sources of uncertainty, we cannot understand how best to handle them.

This section presents a taxonomy useful in developing a framework for understanding, identifying, and in-

investigating uncertainties as a function of the steps in a fire safety engineering calculation. The taxonomy builds upon earlier published work.^{4,10}

Scientific Uncertainties

Scientific uncertainties are due both to lack of knowledge (e.g., in the underlying physics, chemistry, fluid mechanics, and/or heat transfer of the fire process) and to necessary approximations required for operational practicality of a model or calculation. Of the many types of uncertainty found in performance-based fire safety design calculations, scientific uncertainties are typically the most easily recognizable and quantifiable. The many types of scientific uncertainty can be roughly divided into five subcategories: (1) theory and model uncertainties, (2) data and input uncertainties, (3) calculation limitations, (4) level of detail of the model, and (5) representativeness of the design fire scenarios.

Theory and model uncertainties arise when physical processes are not modeled due to lack of knowledge of how to include them, processes are modeled based on empirically derived correlations, and/or simplifying assumptions are made. These types of uncertainties are present in most compartment fire models, where each of these factors lead to uncertainties in the results. Most compartment fire models are zone models, which make the simplifying assumption that each room can be divided into two volumes or layers, each of which is assumed to be internally uniform and that changes in energy or state are implemented immediately throughout the layers. Current zone models do not contain a combustion model to predict fire growth, forcing the model user to account for any interactions between the fire and the pyrolysis rate. Many compartment fire models also use an empirical correlation to determine the amount of mass moved between the layers.

Data and input uncertainties arise from both lack of knowledge of specific input values and variations in input values as a function of many factors, such as time, temperature, or region of the country. For example, the rate of heat release of a three-cushion upholstered sofa may be uncertain due to lack of available data for sofas with the same dimensions, stuffing, and cover materials. It may also be uncertain because the test method by which the heat-release rate was measured could not specify all combinations of ignition source and strength, and because there are inaccuracies inherent in the instrumentation used in the test. Other inputs such as concentrations of toxic gases produced vary with time as the fire develops and are uncertain. The species production rates used to predict concentrations are a function of the material or combination of materials actually burned. This is unknown a priori at the design stage.

For most fire models and calculation procedures, very different answers can result depending on the calculation limitations, control volume selected for modeling, the level of detail of the model, and the model-domain parameters specified. Model-domain parameters set the scope of the system being modeled and define the model's level of detail and/or baseline properties. Though these

parameters or quantities are often ignored during uncertainty analysis, they have the potential for considerable impact.¹ This has been shown for fires in high bay spaces. Differences in the outcome criteria such as maximum temperature, and time to activation of fire detectors and sprinklers are found when a large space is modeled with a simple zone fire model versus a more detailed computational fluid dynamics model.¹⁷ Differences in the outcome criteria are also found when a large space, which is typically subdivided by draft curtains,^{*} is modeled. If a control volume is drawn around a single draft-curtained area (as opposed to drawing the control volume around multiple draft-curtained areas or around the entire building), higher temperatures and faster activation times of installed fire protection devices will be predicted. Also, significant to the uncertainty in the outcome parameters are the index variables of the model. Index variables are used to identify a location in the domain of a model or to make calculations specific to a population, geographic region, and so forth.

Uncertainty arises in both the number and type of design fire scenarios that need to be modeled for a given design/building. There may be significant differences between reality and the design fire scenarios that were used to judge the adequacy of the performance-based design. Variations in the ignition source, rate of growth, and/or the materials burned affect confidence in the results. It is unclear whether all statistically significant fire scenarios must be modeled or whether worst-case or reasonable worst-case scenarios are adequate. Furthermore, a worst-case scenario may be defined in terms of many different variables. A scenario may be worst-case because it is most likely to cause death, because it has potential for large property loss, or for other reasons.

Uncertainties and Variability in Behavior

Human behavioral uncertainties concern both the way in which people act in a fire and how these actions should be considered during steps in the design process (e.g., definition of project goals, selection of performance criteria, and development and evaluation of trial designs). Behavioral scientists tell us that human actions can range from somewhat predictable to unpredictable. Actions are more predictable when choices are limited, procedures are practiced, the situation is not novel, and little chaos is present. Unfortunately, during a typical fire, few if any of these conditions occur. Brannigan discusses what he calls *intentional uncertainty* in relationship to human behavior.¹⁶ Brannigan states, "human decision making does not follow the same kind of well understood rules that control the physical science variables used in models. Human decisions represent intentional uncertainty."

Human behavior in response to a fire alarm must be modeled in terms of time to respond to the alarm and type of response. Does the person immediately begin evacuating the building? Does he/she take the stairs or

*A draft curtain is a barrier that extends a certain vertical distance down from the roof or ceiling. Draft curtains are installed to subdivide a large area with the intent of corralling the heat and smoke.

the elevator? What factors into that choice? Does the person try to fight the fire? Does the person stop to gather personal possessions or call a neighbor? Another area of human behavior relevant to performance-based calculations is behavior during egress. Do people use the best exit or the most familiar one? How long do people take to start to exit?

Human factors also affect the analysis needed for identifying goals and objectives and developing performance criteria. Fire safety goals typically include levels of protection for people, with performance criteria being a further refinement of these objectives. Performance criteria are numerical values to which the expected performance of trial designs can be compared. What range of occupant characteristics, such as age or disability, should be considered? How do human behaviors, for example, during egress, influence the numerical values chosen for performance criteria?

When developing and evaluating trial designs, the efficacy of the proposed fire safety measures mitigating all likely fire scenarios should be determined. This involves varying human behavioral elements. For instance, two very different fire scenarios could develop from the same cooking-initiated design fire: (1) a grease fire from cooking sets off a smoke detector that alerts the occupant who reacts and properly extinguishes the fire while it is still small; or (2) the occupant forgets and leaves a pot simmering on a burner, takes a sleeping aid, and goes to bed. The overheated pot ignites and the fire spreads to one or more adjacent items. The First International Symposium on Human Behaviour in Fire was held in 1998. Proceedings from this conference provide information useful in addressing these issues.¹⁸

Uncertainties and Variability in Risk Perceptions and Values

There is both variability and uncertainty in the way people perceive and value risk. Capturing differences that people have in their perceptions of risk and values related to risk is a necessary step in the design process. Research has shown that although people typically view consequences from voluntary risks less severely than equal consequences resulting from an unknown and/or involuntary risk, there is variability.¹⁹ For example, while some people would agree that an increase in risk to fire fighters (people who accept risk as part of their job) is justifiable if a corresponding decrease in risk to the public could be achieved, others would not. Few studies have been conducted that clearly demonstrate how society values fire safety risks at the level needed to support performance-based trade-offs. Some work on incorporating risk concepts and identifying levels of acceptable risk is discussed in Section 5, Chapter 12 of this handbook, "Building Fire Risk Analysis." It is important to identify where value judgments enter into a performance-based calculation and to make any assumptions explicit regarding values and the impact of different values on the final design.

Another important factor is the concept of *equivalency*. Equivalency can mean different things to different stakeholders. For example, one person may determine

that noncombustible construction is equivalent to an installed sprinkler system if they are both shown to provide time to fully egress the building. Another may argue that they are not equivalent—that the reliability of the sprinkler system is less. Designs may be equivalent in terms of life safety, property protection, business interruption, injuries, and/or prevention of structural collapse, but they are most likely not equivalent in all regards. It is, therefore, important to make explicit the assumptions that equivalency depends on.

Uncertainties Related to the Life-Cycle Use and Safety of Buildings

Many factors change over the lifetime of a building. The uncertainties surrounding future use, occupancy, and other factors contribute to the difficulty in conducting a structured, performance-based design. Even daily fluctuations in these design parameters can affect the safety of a building. For example, a building or area of a building that is normally occupied 24 hours per day may become unoccupied (or occupied by very different people) for extended periods of time due to extraneous factors (e.g., business closing, maintenance, renovation). The characteristics of the different occupants can lead to very different design considerations. Other changes that may affect the life-cycle safety of the building are fire service characteristics such as location, expected response time, and operating procedures and capabilities.

Uncertainties Related to Providing for Equity and Incorporation of Societal Values

Providing for equity and incorporating societal values involves determining what is important to the stakeholders and to what degree protection should be provided. A mechanism should be provided to ensure equal outcomes for subgroups. Since most projects have many stakeholders, such as building owner, design engineer, architect, code official, and the public (users of the building), it is difficult to assign worth to the usefulness or importance of something and apply it across all individual and societal issues. The key here is that decisions that change when a value, attitude, or risk perception varies must be made explicit in the design. Agreement on these key decisions by all stakeholders is critical to the success of a performance-based design.

Relation to Steps in the Design Process

Several types of uncertainty will be encountered at each step in a performance-based design process or during the process of setting a new prescriptive requirement. For example, when developing performance criteria, one will have to deal with scientific uncertainty, such as determining what level of carbon monoxide will cause unacceptable consequences, and how to account scientifically for interactions between products of combustion. One will also have to deal with issues of equity and societal values. At present, performance criteria are not established nor agreed upon. Changes to the set of performance criteria

selected could cause the same design for the same building to be deemed acceptable in one jurisdiction and deemed unacceptable in another jurisdiction. Uncertainties related to life-cycle use and safety of buildings also arise when selecting performance criteria. Over the life cycle of the building, many factors, such as use and occupant characteristics, change.

Nature and Sources of Uncertainty

In conclusion, uncertainty is a broad and general term used to describe a variety of concepts including, but not limited to, lack of knowledge, variability, randomness, indeterminacy, judgment, approximation, linguistic imprecision, error, and significance. Many of these uncertainties are inherent in the design process itself. Variations in analysis parameters, assumptions, or model inputs, may cause output criteria to change. Switchover occurs when outcome criteria change enough so as to cause a change in the design decision (e.g., the acceptability of a final design). It is critical to know whether different sets of reasonable inputs, scenarios, or parameters used in a fire safety engineering design have potential to cause switchover and to lead to different acceptable designs. This section provided an overview of terminology used to describe uncertainty; described aspects of the design process that introduce uncertainty; and presented a taxonomy useful as an aid in identifying uncertainties.

Treatment of Uncertainty

Treatment of Uncertainty with Safety Factors

Safety factor and margin of safety are two commonly used terms in the field of engineering. The dictionary defines factor of safety in terms of stress: "The ratio of the maximum stress that a structural part or other piece of material can withstand to the maximum stress estimated for it in the use for which it is designed." Safety factors do not just apply to stress, however. The idea of a safety factor is that the design values are multiplied by the factor of safety and the design is checked to ensure that the design is safe at the larger value (i.e., the product of the design value and the safety factor). Safety margins are a slightly different concept. A safety margin is additive and not multiplicative. A safety margin is defined as the difference between the design value and the value that would no longer be safe.

Implied versus Explicit Safety Factors

Safety factors are used with both prescriptive and performance codes. These factors of safety can be implied or explicit. Implied safety factors generally are found at various substages or components of a design. Implied safety factors provide for an extra margin of safety simply attributable to the choice of a component of a system. Implied safety factors may also take the form of conservative assumptions or worst-case scenarios. Explicit safety factors are multipliers applied to critical analysis parameters, often (and preferably) the final outcome criteria used

to judge the acceptability of a design. Both types of safety factors are used to increase safety by lowering the probability that critical values of analysis parameters will be reached or exceeded.

Use of Safety Factors in Prescriptive and Performance Codes

An example of an implied safety factor in a prescriptive code is use of a pipe material or thickness that exceeds the strength and durability needed to meet the requirements of a sprinkler system. Pipe schedules have implied safety factors. An example of an explicit safety factor incorporated into a prescriptive code provision is a requirement to use a sprinkler flow density 1.5 or some other multiple higher than the minimum shown experimentally to control a given type of fire. In this example, the safety factor is used to cover for uncertainties in the measurement of the needed flow density, variations in the actual fuel package versus the fuel package tested, and uncertainties and variations in geometry, building characteristics, and so forth. An example of an implied safety factor in a performance code is an assumption that the rate of production of carbon monoxide for a given fuel package is equal to the rate of production of the component fuel with the highest production. An example of an explicit factor of safety incorporated into a performance-based design is to directly multiply the time necessary for egress by a factor of 2.

Selecting an Appropriate Factor of Safety

The first step in the use of safety factors is to determine which analysis parameters would be appropriate for the application of a safety factor. When a factor of safety is applied to measures of the final outcome criteria, it is most clear what margin of safety has actually been achieved; however, it is least clear how to alter the design specifications when a higher factor of safety is desired.

Safety factors may also be applied to different judgment parameters at various stages of the analysis. Careful judgment must be used, however, when applying these intermediate safety factors, because the quantity to which they are applied may not be linearly related to the final outcome criteria. Even if the quantity is linearly related to the final outcome criteria, it may not possess a 1:1 relationship. Specifically, a 1:1 relationship exists when a unit change in the analysis parameter causes a proportional unit change in the outcome criteria. In fire protection engineering calculations, input variables and analysis parameters are not often linearly related to outcome criteria such as upper-layer temperature. Also, they usually do not share common units of measure. In fire protection engineering calculations, time is the only common measure. It is likely that a safety factor of 2 applied to an intermediate quantity will not allow for a safety factor of 2 in the final design. In some cases, a safety factor of 2 applied to an intermediate quantity may not allow for *any* factor of safety design.

This is particularly true for implied factors of safety often found in the form of conservative assumptions. For example, an assumption that a fast growth rate fire is a

worst-case scenario is not true in all cases. A fast-flaming fire may not pose the greatest danger if it activates the sprinkler more quickly. A slower developing fire may be more able to overpower the sprinkler in some circumstances, and a fire originating in an unprotected or shielded space, even though slower growing, may also be more deadly. Therefore, if we wish to provide a safety factor of 2 to the time available to safely egress a building, we cannot assume that doubling the fire size (heat release rate) will achieve this goal. Heat release rate is not linearly related to time to critical temperature.

When an explicit factor of safety is applied, one may choose a value of 1.5, 2, or even higher. How much of a margin of safety is appropriate is as much a function of how much confidence we have in the predictive equations (i.e., are we using a factor of safety as a factor of uncertainty?) used in the calculations as it is of the stakeholders' risk tolerance. It should be noted, however, that increasing the margin of safety usually corresponds to an increase in cost of the project. When historical performance data is available, it can be used to set factors of safety. Otherwise, safety factors are usually set by expert judgment or mandated in policy. Safety factors are set to reflect confidence in the design equations as well as to reflect the stakeholders' acceptable risk tolerance. New specialized methods are being developed for deriving appropriate factors of safety.

Combining Safety Factors

First, it must be stated that there are no official rules, that is, none published and agreed upon by the fire safety community at large, for combining safety factors. The following list of suggestions and potential pitfalls was compiled by the author. After a fairly thorough review of the literature, specific numbers and justifications for safety factors were found lacking. To get good quantitative numbers for safety factors, historical data are needed.

Track the effect of each factor of safety: The effect of each factor of safety on the outcome criteria can be determined by changing the value of the safety factor and observing the net change in the outcome criteria relative to the net change in the safety factor. When the equations are not overly complicated, it may be possible to derive this relationship directly using partial derivatives. For conservative assumptions, the effect of the assumption should be tested by repeat calculations.

Watch for variance: If the normal variation in the population is sufficiently large, a factor of safety applied to the mean will not cover all or even most of the people who will be in the building. For example, if the baseline walking speed is estimated as the walking speed of a young, healthy individual and a safety factor of 2 is used, that would not cover the walking speed of an elderly person or person with physical disabilities if their speed was less than half the average.

Don't assume safety factors are additive: Factors of safety applied to two individual parameters in the analy-

sis will not necessarily provide a total factor of safety equal to the sum of each individual safety factor. The total safety factor could be more or less than the sum of the two individual safety factors. As was discussed earlier, analysis parameters are often not linearly related to outcome criteria. They are most likely in different units of measure, and analysis parameters are likely not linearly related to each other. For these reasons, safety factors cannot be assumed to be additive.

Account for both positive and negative effects on safety:

An explicit factor of safety or design assumption may have either a positive or negative contribution towards safety. Careful thought, engineering judgment, and testing using the calculation procedure must be used to test for the effects of each factor of safety and/or design assumption made. For example, doubling the heat of combustion may be conservative in predicting upper-layer temperature whereas doubling the radiative fraction will have the opposite effect.

Evaluate for multiple performance criteria: Also, since most fire safety engineering designs are judged on multiple performance criteria, what might constitute an implied factor of safety for one outcome criterion might constitute a reduction in safety for another parameter. For example, if a soot yield value is conservative for smoke detector activation, then it could not simultaneously be conservative for life safety.²⁰

Realize effects may change with time: The relative importance of individual input variables, and thus the factors of safety applied to them, may be a function of time. In particular, variables may be limiting factors in the analysis during the time period of preflashover, and in the postflashover time period have little or no effect. Since in fire protection engineering we often deal with two distinct phases of the fire represented by different physics and mathematics, we must be careful to be aware of changes in the effects of a parameter in these very different phases of fire development.

Derivation of Safety Factors

Researchers at the University of Lund^{21,22} have been conducting research on the application of the FOSM (first-order second-moment) methodology for fire safety engineering design. They have applied the FOSM method to derive safety factors for use in fire safety engineering design calculations. The safety index is represented by β , the distance from the origin to a failure line (limit state). β is also referred to as a reliability index where reliability is defined as the probabilistic measure of assurance of performance. β can also be thought of as the overall safety factor for the design.

The overall concept for conducting a design is to specify input data, choose a target reliability index β (they suggest 1.4, which is approximately equivalent to a probability of failure of 8 percent on condition that a fire has started), and vary the design parameters to be determined until the chosen value of β has been obtained. In

this type of analysis, design parameters include design door width and time to detection.²¹

They have also applied the FOSM methodology to derive the safety factor, β , for a design. In this case, design parameters such as door widths and time to detection are already known. An example is worked out for a shopping center.²² There are some admitted shortcomings to applying this methodology to an actual design problem. First, the importance of the uncertainties in the input parameters needs to be investigated via a sensitivity analysis. A method of incorporating this uncertainty would then need to be standardized.

Techniques for the Quantitative Treatment of Uncertainty

It is important not only to recognize the various types of uncertainty, but also the different types of quantities for which the uncertainty exists, since they need to be treated in different ways. There is a standard procedure for quantifying uncertainty in empirical quantities. This procedure, sometimes referred to as classical uncertainty analysis, is based on the mathematics of probability and statistics. However, as shown by the taxonomy, in any fire safety engineering calculation or decision, there are many nonempirical parameters and assumptions used in the calculations. It is not always appropriate, meaningful, or even possible to treat the uncertainty in these nonempirical parameters by these same probabilistic methods. It has been argued that "probability is an appropriate way to express some of these kinds of uncertainty but not others."¹ The next sections present quantitative methods appropriate for the expression of uncertainty in various types of quantities.

Techniques for Quantifying Measurement Uncertainty

Many calculation and model inputs are empirical in nature. To be empirical, variables must be measurable and have a true value. Empirical quantities in the domain of fire protection engineering include the heat-release rate, the burning rate, and the radiative fraction of a given fuel. Classical uncertainty analysis refers to a statistical method of determining the random and systematic errors (and from them the total error) for a set of measurements. Random error and statistical variation results because no measurement of an empirical quantity can be absolutely exact. Imperfections in the measuring instruments and observational technique will inevitably give rise to variations from one observation to the next. The resulting uncertainty depends on the size of the variations between observations and the number of observations taken.

Classical statistical techniques such as standard deviation, confidence intervals, and others can be used to quantify this uncertainty. These statistical techniques are presented in Section 1, Chapters 11 and 12 on probability and statistics, respectively. A full discussion on uncertainty in measurement is found in the U.S./ISO guide² and in the NIST guide.²³ The NIST guide describes two

types of evaluations of uncertainty. A Type A evaluation of standard uncertainty may be based on any valid statistical method for treating data. Three examples are (1) calculating the standard deviation of the mean of a series of independent observations; (2) using the method of least squares to fit a curve to data in order to estimate the parameters of the curve and their standard deviations; and (3) carrying out an analysis of variance (ANOVA) in order to identify and quantify random effects in certain kinds of measurements.

A Type B evaluation of standard uncertainty is usually based on scientific judgment using all the relevant information available, which may include previous measurement data, experience, manufacturer's specifications, and calibration reports. There is not always a simple correspondence between the classification of uncertainty components into categories A and B and the commonly used classification of uncertainty components as random and systematic.

The nature of an uncertainty component is conditioned by the use made of the corresponding quantity, that is, on how that quantity appears in the mathematical model that describes the measurement process. When the corresponding quantity is used in a different way, a random component may become a systematic component and vice versa. The NIST guide also differentiates between uncertainty and error. It is assumed that a correction is applied to compensate for each recognized systematic effect that significantly influences the measurement result. The relevant uncertainty to associate with each recognized systematic effect is then the uncertainty of the applied correction.

Techniques for Assessing Uncertainty in Analysis Parameters, Assumptions, and Value Parameters

Probabilistic techniques used to quantify measurement uncertainties are not applicable to uncertainties in establishing performance criteria or uncertainties regarding values such as the value of life. These uncertainties should be evaluated with techniques that make explicit the effect of the uncertainty on the value of all decision variables. Decision variables in fire protection engineering are such things as level of acceptable fire safety and installation of fire protection devices. If a quantity is a decision variable, then by definition it has no absolute, true value. It is up to the decision maker who exercises direct control to decide its value. Morgan and Henrion state that, "*The question of whether a specific quantity is a decision variable, an empirical quantity, or some other type of quantity depends on the context and intent of the model, and particularly who the decision maker is*" (emphasis added).¹ For example, in performance-based design, the minimum, permissible escape time during a fire may be a decision variable for the regulatory body, but it may be an empirical quantity from the viewpoint of the fire protection engineer.

Value parameters represent preferences of individuals. One controversial value parameter is the value of premature death avoided, often referred to as the value of life. Another is risk tolerance or risk preference, a parameter used to specify a degree of risk aversion when comparing

uncertain outcomes. The effect on the outcome of an analysis caused by differences in value parameters should be demonstrated explicitly. This is done by repeating the analysis for a range of possible inputs of the value parameter(s) to determine if a change in the outcome occurs that someone would care about. Several techniques that aid in the evaluation of uncertainty in these types of quantities are presented below. For all these techniques, the effect of various values of analysis parameters, assumptions, and value parameters is made explicit.

Bounding: Evaluating the extremes of the range of possible values of an uncertain quantity. If the extreme values at both ends are acceptable, a more complex and costly analytical uncertainty analysis may be avoided. For example, suppose we bound the ambient room temperature between a low and a high value. If we are trying to predict carbon monoxide buildup in a room, we may find that the results are either not sensitive to ambient temperature, or the range of predicted values of carbon monoxide, based on the range of ambient temperatures, is completely acceptable. We may either eliminate ambient temperature as a variable or set it to our best-guess estimate. We do not need to quantify the uncertainty in the ambient temperature any further.

Sensitivity/sensitivity analysis: Sensitivity of a design to modest variability and uncertainty must be explicitly understood. Sensitivity analysis is useful in assessing the consequences of uncertainty in data and in assumptions. By testing the responsiveness of calculation results to variations in values assigned to different parameters, sensitivity analysis allows the identification of those parameters that are most important to the outcome criteria. It does not tell the decision maker the value that should be used, but it can show the impact of using different values.

Parametric analysis: A parametric analysis is a particular type of sensitivity analysis. In parametric analysis, detailed information is obtained about the effect of a particular input on the value of the outcome criterion. This is done by evaluating and plotting the outcome criterion for a sequence of different values for each input, holding the others constant.

Importance/importance analysis: An importance analysis is a particular type of sensitivity analysis that determines which of the uncertain input variables contributes most to the uncertainty in the outcome variable. The results are used to focus on getting more precise estimates or building a more detailed model for the one or two, or small group of, most important inputs. Importance here is defined as the rank-order correlation between the output value and each uncertain input. Each variable's importance is calculated on a relative scale from 0 to 1. An importance value of 0 indicates that the uncertain input variable has no effect on the uncertainty in the output.

Comparative analysis: Comparative analysis is a technique used to evaluate risks, and the costs to mitigate them, by means of comparison to other similar risks. This

technique is useful in evaluating perceptions of risk tolerance. Researchers²⁴ conducted a comparative analysis of the cost of mandating residential fire sprinklers with the cost of mandating other methods of reducing residential deaths such as radon remediation and ground fault interrupters.

Expert elicitation: Where hard data does not exist and is not possible to create experimentally, an expert elicitation is often conducted in order to obtain expert judgment of an uncertain quantity. An excellent discussion of the techniques for conducting an expert elicitation is provided in Chapter 6 of *Uncertainty*.¹

Switchover: Variations in analysis parameters, assumptions, or model inputs, will cause output criteria to change. Switchover occurs when outcome criteria change enough so as to cause a change in the design decision (e.g., the acceptability of a final design).

Techniques for Assessing Uncertainty and Sensitivity in Complex Models

Several of the scientific uncertainties discussed in the taxonomy presented above can only be evaluated by examining the structure of the fire model. These include theory and model uncertainties, calculation limitations, and level of detail of the model. Uncertainties arise when physical processes are modeled based on empirically derived correlations, and/or simplifying assumptions are made. Other physical processes are not modeled due to lack of knowledge of how to include them. As stated earlier, most compartment fire models are zone models, which make the simplifying assumption that each room can be divided into two volumes or layers, each of which is assumed to be internally uniform. Current fire models do not contain a combustion model to predict fire growth, and many compartment fire models use an empirical correlation to determine the amount of mass moving between the layers.²⁵ There are uncertainties introduced by these modeling approximations.

Fire model validation: Fire model validation has become a much-discussed topic since fire models have become relied upon as a means of verifying that a fire safety engineering design meets a set of performance objectives. Work is being done to characterize the additional output uncertainty due to modeling approximations. Part of this work is focused on aiding the user in selecting a model, or set of models, appropriate to the type of prediction(s) needed. Some researchers have suggested a Bayesian framework where each available model is treated as a source of information that can be used in a prediction.^{26,27}

In addition, work is ongoing to evaluate computer fire models by comparison of model predictions to predictions of other models or with experimental data. These comparisons are helpful to the user in determining the level of uncertainty likely from a model prediction for a similar set of conditions. However, these comparisons are difficult since they involve comparing two time-series curves, the exper-

imental measurements, and the predicted values. Historically these comparisons have been largely qualitative. The use of a branch of mathematics called functional analysis to make comparisons of these time-series curves is being investigated. This allows lengths, angles, and distances between two arbitrary curves to be defined and quantified.²⁸ Further validation issues that must be addressed were discussed among various groups of fire safety professionals at the Conference on Fire Safety Design in the Twenty-First Century.²⁹ Jones discusses issues that must be addressed in a report entitled, "Progress Report on Fire Model Validation."³⁰ Once a model is selected, it is useful to know the sensitivity of that model's output predictions to the values selected for the inputs.

Sensitivity of output predictions to input values: When selecting and using a fire model, it is important to know the sensitivity of the predicted outcome criteria to the model inputs. In order to facilitate this, several quantitative methods for determining the sensitivity of model predictions to model inputs are described below along with a brief discussion of their positive and negative attributes and limitations of application. These are also discussed in ASTM 1355-92, *Standard Guide for Evaluating Predictive Capability of Computer Fire Models*.³¹

A differential/direct method: For a system of time-dependent, ordinary differential equations, it is possible to solve directly for the partial derivative of the predicted values with respect to each of the input variables. This set of partial derivatives measures the sensitivity of the solution with respect to changes in the input parameters:

$$Y_i = f_i = (c_1, c_2, \dots, y_1, y_2, \dots, t)$$

where c_k are rate parameters.

We simultaneously solve for both y_i and a set of sensitivity functions, $\delta y_i / \delta c_k$, over all times t . These partial derivatives measure the sensitivity of the solution with respect to uncertainties in the parameters c_k and in initial conditions. Often these parameters are not accurately known. Dickson provides an example of a direct solution of a set of ordinary differential equations that composes a large computational model of atmospheric chemical kinetics.³²

Response surface replacement: Multiple runs, n , of the computer model are made. The model output Y_i and inputs X_{1i}, \dots, X_{ki} , $i = 1, \dots, n$, are used to estimate the parameters of a general linear model of the form:

$$Y = \beta_0 + \sum_j \beta_j X_j$$

The estimated model is known as a fitted response surface, and this response surface is used as a replacement for the computer model. All inferences with respect to uncertainty analysis and sensitivity analysis for the computer model are then derived from this fitted model.³³ Construction of a response surface without specification of the probability distributions for all input variables is discussed by Iman.³⁴ It is suggested, in fact, that when

using certain sampling techniques to build a response surface, it may be desirable to ignore probability distributions and use only the ranges of the variables. Iman provides a good discussion of using a response surface method to conduct a sensitivity analysis and provide a ranking of input variables in a second paper.³⁵ Beller has discussed the use of response surfaces for modeling upper-layer temperature and layer height.³⁶

Monte Carlo sampling: In uncertainty analysis employing Monte Carlo sampling,* it is desired to estimate the distribution function and the variance for the particular output variables under consideration. The uncertainty surrounding each input is represented mathematically and often probabilistically by its individual distribution. When all probability distributions for all uncertain quantities are put together, a simulation model is built that is believed to capture the relevant aspects of the uncertainty in the problem. After running the simulation many times, an approximation of the probability distribution of the output variables is generated. The more simulations that are carried out, the more accurate the approximation becomes.

Advantages and Disadvantages of Each Technique

Iman and Helton state in their paper, "Investigation of Uncertainty and Sensitivity Analysis Techniques for Computer Models," some of the characteristics of large and complex computer models.³³

- There are many input and output variables.
- The model is time consuming to run on the computer.
- Alterations to the model are difficult and time consuming.
- It is difficult to reduce the model to a single system of equations.
- Discontinuities exist in the behavior of the model.
- Correlations exist among the input variables, and the associated marginal probability distributions are often nonnormal.
- Model predictions are nonlinear, multivariate, time-dependent functions of the input variables.
- The relative importance of the individual input variables is a function of time.

Fire models often possess many and sometimes all of these characteristics. Iman and Helton evaluated the above three techniques as applied to large, complex models having many of the above characteristics. Their evaluation included ease of implementation, flexibility, estimate of the cumulative distribution function (CDF) of the output, and adaptability to different methods of sensitivity (analysis). Their findings clearly show that the technique that had the best overall performance was Monte Carlo sampling. They found that a differential analysis provides good local information about the inputs but does not extend well to a global interpretation. Also, a very real problem with

*There are many sampling techniques. Monte Carlo is one, well-accepted sampling method that has certain statistical advantages but may not be the best choice in all cases.

differential analysis lies in the difficulty of implementation. Response surface replacements were not recommended because the underlying models are often too complex to be adequately represented by a simple function.

The following section describes a methodology for application of uncertainty analysis to fire safety engineering calculations. This methodology employs Monte Carlo sampling. It also incorporates many of the techniques described in previous sections for quantifying measurement uncertainty, and assessing uncertainty in analysis parameters, assumptions, and value parameters.

Application of Uncertainty Analysis to Fire Safety Engineering Calculations

The fire safety community needs to begin to move forward from discussing a set of issues and concerns relating to uncertainty in fire protection engineering to agreeing as a community on practical steps to execute an uncertainty analysis. This section demonstrates a suggested methodology that quantitatively treats variability and uncertainty and applies it to a complex fire protection engineering problem. The methodology suggested is a generic methodology that is applicable to a wide range of fire protection engineering calculations and fire safety design issues. For example, application of the methodology is appropriate for engineering calculations such as those that predict upper-layer temperatures and concentrations of products of combustion. The methodology may also be applied to calculations of time needed to egress. It ties together the issues discussed above regarding uncertainties in the design process and the problem of switchover. Here, a brief introduction to and overview of the methodology is presented. A full description of the methodology and a worked case study of an actual building can be found in Notarianni.³⁷

Overview of the Performance-Based Design Process with Uncertainty

The methodology is rigorous but comprehensible. It breaks up the process of conducting an engineering design calculation with uncertainty analysis into identifiable steps, each of which can be expanded or contracted to fit specific design problems. Table 5-4.1 shows the steps in conducting a performance-based fire protection engineering design. The column labeled Performance-Based Design Process lists the steps in the performance-based design process as detailed in the SFPE guide.¹¹ The right column lists the steps in the performance-based process with uncertainty. Steps or parts of steps in bold signify suggested modifications to the current design process. Steps 1–3 are modified by incorporating treatment of uncertainties noted in parentheses and detailed in the taxonomy presented earlier. The intent of each step does not change; however, the process is made explicit and standardized.

The quantitative methodology for the application of uncertainty analysis is applied throughout Steps 4–8. In Step 4 a probabilistic statement of performance is developed. In Steps 5–7, candidate designs are developed and a process for evaluating these designs through simulation

with uncertainty analysis is described. Step 8 now includes a decision of acceptability that makes use of the results of the quantitative uncertainty analysis. Steps 9 and 10 remain the same. It should be noted that performance-based designs may require an iterative process. If in Step 8 the candidate designs are deemed unacceptable, the process returns to Step 6 to develop new candidate designs. If no acceptable design is found to meet the goals and objectives, Steps 1–3 must be revisited.

Steps 1–3: Define Scope, Goals, and Objectives

Many of the types of uncertainties discussed in the taxonomy are important to consider during the process of setting the scope, goals, and objectives of a project. These three steps are described below; for each step, one example of a type of uncertainty to consider is provided.

The first step in the performance-based design process is to define the scope of the project. The project scope is an identification of the boundaries of the performance-based analysis or design. The SFPE guide suggests consideration of several aspects of scope such as occupant and building characteristics and intended use of the building. In the first section of this chapter, indeterminacy was discussed as well as uncertainties related to the lifecycle use and safety of buildings. Indeterminacy affects the scope in that it is impossible to know what the occupancy and furnishings will be in a building at some point in the future. Therefore when assumptions are made regarding occupant and building characteristics, some investigation of the sensitivity of the final design to changes in occupant and building characteristics should be made and documented. If switchover occurs for a particular value of one or a combination of analysis parameters, assumptions, or values, this needs to be made explicit.

The second step in the design process is identifying and documenting fire safety goals of various stakeholders. These include levels of protection for people and property and provide for continuity of operations, historical preservation, and environmental protection. For example, when identifying goals of various stakeholders, a mechanism needs to be provided to ensure equal outcomes for subgroups, including the building owner, design engineer, architect, code official, and the public (end users). Because it is difficult to assign worth in the usefulness or importance of something and apply it across all individual and societal issues, the key here is that decisions that change when a value, attitude, or risk perception varies must be made explicit in the design documentation.

The third step in the design process is the development of objectives, which are essentially the design goals that have been further refined into values quantifiable in engineering terms. Objectives might include mitigating the consequences of a fire expressed in terms of dollar values; loss of life; or maximum, allowable conditions such as the extent of fire spread, temperature, or spread of combustion products. Uncertainties arise here in risk perceptions and values. There is both uncertainty and variability in the way people perceive and value risk.

Capturing differences people have in their perceptions and values related to risk is a necessary step in the design process. For example, it may be a goal of the stake-

holders to protect historical features of the building or to protect against business interruption or loss of operating capability. Stakeholders with different values may see these needs differently. It is important to identify where value judgments enter into a performance-based calculation and to make any assumptions explicit regarding values and the impact of different values on the final design.

The following discussion is focused on incorporating uncertainty directly into Steps 4–8. Here, we develop a probabilistic design statement, develop a distribution of statistically significant fire scenarios, calculate a set of values for critical outcome criteria, and evaluate each candidate design to determine whether the design meets the performance criteria within acceptable uncertainty bounds.

Step 4: Develop Probabilistic Statement of Performance

The fourth step in the design process is the development of probabilistic statement(s) of performance, that is, criteria by which to judge the acceptability of the design. These criteria are a further refinement of the design objectives and contain numerical values to which the expected performance of the candidate designs can be compared. Each probabilistic design statement contains a minimum of four elements: probability, time, performance criteria, and threshold value. For example, an objective may be to maintain tenable gas concentrations in the corridor. A corresponding probabilistic design statement for life safety might specify that the design must allow for a 0.9

probability of having 4 min or more before a temperature of 65°C is reached in the corridor. Thus all four elements are included: probability, time, performance criteria, and threshold value. A location is also specified.

There are many issues to be addressed when establishing probabilistic statements of performance. For example, which criterion should one evaluate? One could select, instead of or in addition to temperature, levels of carbon monoxide, heat flux, or obscuration. There is disagreement in the literature as to what values of each of these cause negative consequences. The negative consequences must be defined; that is, should the threshold values represent incapacitation or lethality? Also, the probability element involves determining the level of acceptable risk to the stakeholders, and establishing criteria for time to untenability involves understanding behavioral patterns of people in fire as well as making value judgments as to which subpopulations one is trying to protect. The sensitivity of the design to each element of the probabilistic statement of performance is evaluated in Step 7b.

Based on this type of sensitivity analysis, a two-tiered probabilistic statement of performance may be developed based on any of the four elements as well as location. For example, the probabilistic statement of performance may say that the design must allow for a 0.9 probability of having 4 min or more before untenability based on a temperature of 65°C is reached *and* a 0.9 probability of having 6 min or more before 100°C is reached. The design statement may be specified in other ways:

- Include two probability levels, such as the design must have greater than or equal to a 0.95 probability of *X* *and* less than or equal to a 0.1 or more probability of *Y*.
- Provide a variation such as the design must provide for a 0.9 probability of providing 4 min before 65°C is reached and a 0.9 probability of having 8 min or more before untenable gas conditions are reached.

These are just a few of the possible specification options. Also, the location of evaluation matters. Untenability can be evaluated as a minimum anywhere in any room, including the room of origin, or it can be evaluated along the egress path. These two analyses may give different results in terms of acceptability.

Step 5: Develop a Distribution of Design Fire Scenarios

One of the most important pieces of the methodology is how to generate a set of realistic input scenarios. It is important that this set include a combination of scenarios that represent statistically both the types of fires and the frequency at which they occur in a given occupancy. The input scenario generator should integrate information about the uncertainty, variability, and correlational structure of the input parameters. Using an appropriate sampling method (e.g., Monte Carlo method), a set of any given number of fire scenarios may be constructed. This distribution of scenarios generated will contain the typical cases as well as the worst-case scenarios in the tails of the distribution. The steps involved in developing a distribution of design fire scenarios are (a) selecting a

calculation procedure; (b) identifying the uncertain and crucial input parameters; (c) generating a distribution of design fire curves; (d) defining distributions of and modeling correlations among input parameters; and (e) selecting a sampling method and determining the number of scenarios.

Step 5a: Select Calculation Procedure(s)

There are a range of calculation tools and models currently available from which to select the calculation procedure(s) to be used in the performance-based design. The *Fire Protection Handbook* provides a good overview of the various types of fire models.³⁸ Which model or type of model is selected depends on several factors, including the application of interest. Fire models can be used to predict a hazard, predict a risk, reconstruct a fire, interpolate between or extrapolate beyond test results, or evaluate a parametric variation. The application of fire models for each of these purposes is discussed by Nelson.³⁹ Each of these applications may have purpose at some stage of the performance-based design process.

Step 5b: Identify Uncertain and Crucial Input Parameters

Once a calculation procedure is chosen and candidate designs have been selected, the input parameters necessary for the calculation are evaluated. Which input parameters will be treated as uncertain must be determined. Ideally, only parameters or combinations of parameters with uncertainty great enough to change decisions regarding the final design are treated as uncertain. These are referred to as the crucial variables. Unfortunately, we do not always know a priori which of the input parameters possess crucial uncertainty. Therefore, we must use a combination of judgment and results of previous analyses. The uncertainty importance of each of the uncertain input parameters is determined so that future analyses may be simplified. Eventually, only a few key parameters may be needed to capture the uncertainty in each calculation.

Step 5c: Generate a Distribution of Design Fires

Design fire scenarios are made up of both possible fire events (heat-release rate curves) and characteristics of the material burning, of the building, and other relevant information such as weather conditions. A set of design fires is established to mimic the type and frequency of fires expected for that occupancy. These design fire curves are based on statistically collected data, judgments, and the goals of the design. Each design fire is assigned a likelihood of occurrence.

Step 5d: Define Distributions of and Correlations among Other Inputs

The uncertainty and variability surrounding each variable must be captured in the mathematical description of that variable. Any and all available knowledge

regarding the value of that parameter should be incorporated into the input scenario generator. This includes empirically measured values, known variations, and statistically compiled data. For example, for a given occupancy type, the NFPA publishes statistical data on the percentage of fires that start in each potential room of fire origin. This information should be incorporated into the random scenario generator so that the generator mimics these statistics. Distributions can be constructed for variables such as temperature, wind, and relative humidity from regional data published by the national weather service data. Methods for quantifying measurement uncertainty² are used to capture uncertainty and variability in empirically measured parameters such as rates of production of products of combustion. In many cases, where hard data do not exist and are not possible to create, expert elicitation is needed to quantify the uncertainty.

When two or more variables are correlated, knowledge of the value of one variable tells one something about the value of the other variable(s). Correlation among variables is modeled so that the input scenario generator will not generate unrealistic scenarios. For example, if the design incorporated a weather module, a month of the year would be randomly selected. For that given month, a value is sampled from an outdoor temperature distribution based on National Weather Service data for that region. Outdoor temperature is correlated to external pressure, wind, relative humidity, likelihood of windows/doors being open, indoor temperature and pressure, and initial fuel temperature. This prevents the software from generating, for example, a scenario where there is a fire on a below-freezing day in August, in California, and all the windows are open.

Step 5e: Select Sampling Method and Determine Number of Scenarios

A sampling method, such as Monte Carlo, Latin Hypercube, or quasi-random must be selected. By sampling a single value from each of the distributions in the input scenario generator and combining those numbers with the values of input parameters that are being treated as certain, any number of independent fire scenarios may be generated.

A large number of scenarios increases the statistical significance of the results. However, this relationship is dependent on the sampling method chosen and is not linear. Using 2000 runs may not provide any more insight than using 500. The number of scenarios chosen depends on (1) the number of uncertain input parameters, (2) the average calculation time per scenario for the calculation procedure chosen, and (3) the statistical significance needed. When conducting correlational analyses between inputs and outputs, one obtains importance or correlation coefficients, c , between 0 and 1. Hald provides a formula for determining the relationship between the number of runs, n , and the statistical significance (as measured by a t -test) of the correlation coefficient.⁴⁰

$$t = \frac{c}{\sqrt{1 - c^2}} (\sqrt{n - 2})$$

The value for t is related to the confidence level, which is typically chosen as 95 percent.

Step 6: Develop Candidate Designs

The candidate design is intended to meet the project requirements. A candidate design includes proposed fire protection systems, construction features, and operations that are provided in order to meet the performance criteria when evaluated using the design fire scenarios.

Step 7: Evaluating Candidate Designs— Introduction

Each candidate design must be evaluated using each design fire scenario. The evaluations indicate whether the candidate design will meet the elements of the probabilistic statements of performance. Only candidate designs that meet the performance criteria may be considered as final design proposals. Without the quantitative treatment of uncertainties in the design, each calculation will provide a point estimate only of the important outcome criteria. For example the performance criteria for a design may be a 100°C maximum temperature reached in the upper layer. The time to an upper-layer temperature of 100°C may be predicted as 175 s, and the time to activation of a sprinkler may be predicted as 171.2 s by a given computer model. Because the sprinkler is predicted to activate before the performance criteria is exceeded, this would be deemed an acceptable design. However, the uncertainty in the prediction of time to 100°C may be ± 20 s. This would mean that the temperature in the room may reach 100°C at 155 s or before activation of the sprinkler. Also, the predicted time to activation of the sprinkler has an uncertainty surrounding it as does the temperature at which untenability might actually occur.

The performance-based design process with uncertainty will aid in the calculation of a range of possible values for each key outcome criterion instead of a single point value. This methodology is useful for and may need to be applied to several parts of the design calculations. For example, it could be applied to the calculation of upper-layer temperatures, to the prediction of time to response of devices, and to the prediction of time needed to egress a building.

Step 7a: Calculate a Set of Values for Each Outcome Criterion

A single value will be determined for each outcome criterion calculated for each design fire scenario run. Much information can be obtained from observation of both the range of values for criteria of interest and from cumulative distribution functions generated from the set of all values.

If criteria are time-series values, each scenario will predict a different curve of the key outcome criteria versus time. For example, if upper-layer temperature is the criterion of interest, four design fire scenarios would produce four curves of upper-layer temperature versus time.

Figure 5-4.2 shows a representative graph of the value of outcome criterion A plotted against time from ignition (in seconds). For any given design, there will be as many curves as there are design fire scenarios calculated. One can see that the curves vary both in the magnitude of the peak value and in the time to the peak value.

The range of values predicted from the set of design fire scenarios represents the uncertainty in the value of the outcome criterion. From the set of predicted values of a single outcome criterion, a cumulative distribution function may be generated. This is done by graphing the value of the criterion against its rank order. For example, for n design fire scenarios, n values of a given criterion are generated. These values are then sorted in descending order. The largest value is graphed versus $1/n$, the second largest against $2/n$, ..., and the smallest value against n/n or 1.

An example of a cumulative distribution function (CDF) is shown in Figure 5-4.3. The time to reach a threshold value of 1 or more of the tenability criteria, that is, a value determined to cause injury or death, can be determined from the time-series predictions. The threshold value may be a particular temperature or carbon monoxide level or a parameter used to represent some synergistic effect of a combination of the tenability variables. One value of time to untenability is obtained for each scenario run. The set of all possible values provides a distribution of the outcome criteria.

Figure 5-4.3 shows that for the distribution of design fire scenarios, there is almost a 1.0 probability that the time to a critical value of criterion A is 30 s or more. Likewise, there is a 0.75 probability that the time to this value

is 120 s or more, a 0.50 probability that it is 180 s or more, and a 0.1 probability that it is 390 s or more.

Step 7b: Determine Sensitivity of Outcome Criteria to Elements of Probabilistic Statement of Performance

The sensitivity of key outcome criteria to each of the four elements of the probabilistic statement of performance upon which a design is judged must be known before good policy and good design practice can be established. Elements such as criteria, threshold values, probabilities, and times are not mandated nor agreed upon by fire safety and health professionals, nor the public. Therefore, major conclusions of all designs should be checked in order to demonstrate the sensitivity to uncertainty in each of these elements. This might include checking for times to untenable temperature, carbon monoxide, carbon dioxide, and reduction in oxygen. It may include checking for synergistic effects of the presence of these substances. It may also be appropriate to evaluate for heat flux and visibility.

The same design may be judged on two different performance criteria or by two different critical values of the same performance criterion. Figure 5-4.4 shows an example of time to untenability based on different values of upper-layer temperature. This type of presentation could also be used to determine the effect on time to untenability by selecting a group of tenability criteria or by including different sets of components in the specification of tenability criteria.

Figure 5-4.2. Variation in prediction of time-series values of outcome criterion A.

Figure 5-4.3. *Cumulative distribution function of time to the critical value of criterion A.*

Figure 5-4.4. *Probability of having X seconds or more before untenable upper-layer temperatures are reached for three different values of untenable temperature.*

This type of evaluation is a good way to focus discussions among stakeholders on deciding which tenability criteria should be included, what effect the selection of different threshold values of tenability criteria has, what

probability level is acceptable to the stakeholders, and how to select the final design. At the end of this step, final performance criteria must be selected for use in judging acceptability of designs and choosing a final design.

Step 7c: Evaluate Base Case

Depending upon the needs and the scope of the project, it is helpful to compare a candidate design to a base-case design. The base case can be the design that meets the prescriptive code, the design that includes the fire protection options currently in the building, or the design with no active fire suppression systems. The purpose of having a base case is to benchmark the effects of fire on the building and on the building conditions against each of the designs.

In Figure 5-4.5, the results of multiple scenario runs are used to show the probability of safe egress graphed against the time to untenable conditions for two different designs. Design 1 and Design 2 may represent two different performance designs or a performance design and a prescriptive design. Reiss discusses the need for this comparative approach.⁴¹ The graph shows two design curves that exhibit crossover. Design 1 provides a higher probability of tenability out to 50 s; however, Design 2 provides a higher probability of tenability at longer times.

Another way that the acceptability of a design is judged is by comparison of the level of safety provided to that provided by the corresponding prescriptive design. There is uncertainty associated with the prescriptive design also. The prescriptive code will mandate certain building materials and fire detection and suppression schemes. However, uncertainty and variability remain in the weather, ventilation conditions, human behavioral aspects, and where and how the fire will start. Thus, multiple scenarios can be constructed in a parallel manner to that shown above, holding as constants those factors required by the prescriptive code. Thus, a CDF for the prescriptive code can be generated and compared to the CDF for the performance code.

Step 7d: Determine the Effect of Each Candidate Design on Each of the Scenarios

To compare two different candidate designs, we may want to look at the distribution of differences between the two designs based on the final selected performance criteria. One may consider differences between a design and the reference base case or differences in time to untenability provided by Design 1 versus Design 2. For example, Figure 5-4.6 is a cumulative distribution function of the difference in time to untenability provided by Design 1 minus the time to untenability provided by Design 2.

Figure 5-4.6 shows that there is a 0.25 probability that Design 1 will provide a longer time to untenable conditions than will Design 2. Conversely, there is a 0.75 probability that Design 2 will provide a longer time to untenability than will Design 1 and a 0.25 probability that the difference will be 100 s or more better. In selecting a final design, it may be helpful to investigate what factors might lead to Design 1 providing more time to untenability than Design 2, which could highlight ways to improve the design.

Step 7e: Evaluate Uncertainty Importance

An importance analysis is a particular type of sensitivity analysis that determines which of the uncertain input variables contributes most to the uncertainty in the outcome variable. The results are used to simplify future performance-based designs by identifying the one or two, or small group of, most important inputs. Importance here is measured by the correlation between the output value and each uncertain input. Each variable's importance is calculated on a scale from 0 to 1 (or -1). A correla-

Figure 5-4.5. Comparison of cumulative distribution functions of time to untenable conditions for two different designs.

Figure 5-4.6. Cumulative distribution function of time to untenability of Design 1 – Design 2.

tion of 0 indicates that uncertainty in the input variable has no effect on the uncertainty in the output parameter. The input parameters can be correlated to composite or derived outcomes (i.e., an outcome that is not directly an output of the model but one that is derived from the output data). Likewise, input variables can be combined (for example, the volume of a room can be determined from the dimension). Room volume may be correlated with key outcome criteria, for example, peak temperature or time to peak temperature.

Importance analysis can be used to simplify a future uncertainty analysis by determining the input uncertainties that are most crucial. This can simplify the process for a class of buildings and can demonstrate where additional research would be effective in reducing uncertainty and ensuring a safer, more predictable building. It must be remembered, however, that correlation does not equal causation. Thus, any apparent, strong correlation that is counterintuitive should be investigated with good engineering judgment. Also, for each design, the value of the correlation coefficient that is statistically significant will depend on the number of scenarios run and the sampling method used.

Step 8: Judging a Design’s Acceptability Based on All Four Elements of Probabilistic Statement of Performance

There are two ways to judge acceptability of a design. The first is based on the minimum time to untenability anywhere in the building, including the room of origin. The second is the time to untenability along the egress path. In general, for both cases, cumulative distribution functions are used to judge acceptability of a design. For example, Figure 5-4.3 is a cumulative distribution function

of the time to a specific value of criterion A in the room of origin. If the probabilistic statement of performance required a 0.9 probability of having 30 s or more before reaching this value, it can be determined from the CDF that this criterion is met. In fact, Figure 5-4.3 shows that there is a 0.9 probability of having 80 s or more. However, if the probabilistic statement of performance requires a 1.0 probability of having 50 s or more, Figure 5-4.3 shows that this criterion is not met because the CDF demonstrates a 1.0 probability of having only 30 s or more.

Another way of judging the acceptability of a performance-based design is with a time-to-egress analysis. The time needed to egress a building is often represented in the literature as the time to detect the fire, plus the time to react, plus the time to travel to a safe place. This is represented mathematically as

$$time_{egress} < time_{untenability}$$

$$time_{egress} = time_{detect} + time_{react} + time_{travel}$$

One problem with this approach is that it is very difficult to predict human behavior in terms of reaction time and travel time during a fire. There is both variability due to age and health of the individual and uncertainty as to individual goals and concerns (e.g., will the person try to fight the fire, locate valuables, rescue pets, or notify other occupants about the fire?). The methodology described in this chapter may be applied to egress calculations; however, since these are difficult to predict, it is suggested that perhaps these are best handled as societal and policy decisions. Regulatory decisions may be made as to the available, safe egress time. For example, more time may be mandated for a healthcare facility, where patients may be nonambulatory and/or asleep at the time of the fire, than in an office building where occupants are generally awake and healthy.

Steps 9-10: Select Final Design and Prepare Documentation

Candidate designs that satisfy the probabilistic design statement(s) may be considered for selection as the final design. When more than one candidate design meets all four elements of the probabilistic statement of performance, other factors such as cost and preference are considered. When considering multiple designs or designs with very different features, a multicriteria decision analysis model may be developed to aid in selecting the final design.

Proper documentation of a performance design is critical and should be written so that all parties involved understand what is necessary for the design implementation, maintenance, and continuity of the fire protection design. *The SFPE Engineering Guide to Performance-Based Fire Protection Analysis and Design of Buildings* suggests that the documentation have four parts: the fire protection engineering design brief, the performance design report, the detailed specifications and drawings, and the building operations and maintenance manual.¹¹ It is important that the performance-based design report convey the expected hazards, risks, and performance over the entire building life. It should include the project scope, goal, and objectives, the probabilistic design statements, a discussion of the design fires and design fire scenarios, and any critical design assumptions.

Treatment of Uncertainty

In conclusion, incorporating uncertainty in a fire safety engineering design calculation aids in ensuring performance. The methodology described in the above section can be used in combination with standard performance-based design procedure. Each step in the methodology may be expanded or contracted to fit the needs of a given calculation. In the future, one may be able to construct libraries of models with families of input scenario generators and develop reusable models for classes of buildings. Ultimately, a fire safety engineering model should be developed that directly incorporates uncertainty.

Application of Uncertainty to Cost-Benefit Models and Decision Analysis Models

Decision Making under Uncertainty

The importance of making good decisions under conditions of uncertainty is becoming better understood in many fields, including fire safety design. The recently released National Science Policy study, "Unlocking Our Future: Toward a New National Science Policy," states that "decision makers must recognize that uncertainty is a fundamental aspect of the scientific process." Good decisions can be made under uncertain conditions; however, one must capture the nature and magnitude of the uncertainty in order to make a good decision.⁴²

There is uncertainty involved in deciding among fire safety options, such as whether to install smoke detectors, sprinklers, or both. Another example is deciding whether the cost of redundant pumps or entire redundant systems is justified. These types of decisions are typically modeled using fire safety trees.⁴³ However, average or best-guess estimates typically are used for parameters in the decision model, and uncertainty and variability in these are rarely considered.

Decisions made by municipalities on whether to mandate fire safety systems, such as residential sprinklers, are likewise often made based on economic analyses using best-guess and national average values. Integration of uncertainty and variability into these types of cost-benefit studies would provide the decision maker more insights into the issues at hand. It would also highlight where engineering technology is able to reduce risks and where regulatory solutions might be more helpful.

This is becoming more complex because implementation of any form of a performance-based standard will require more decisions to be made. These decisions will be more difficult, more complex, and more uncertain than under a prescriptive-based code. Robert Clemen discusses in his book, *Making Hard Decisions*, four reasons why making decisions is so difficult.⁴⁴

- *First, decisions can be difficult simply because of their complexity.* In the case of decisions regarding fire protection features, one must consider the potential for property protection, life safety, injury mitigation, and business continuity. One must also consider the diverse impacts on people with special needs, such as the very young, the elderly, or persons with limited mobility.
- *Second, decisions can be difficult because the decision maker may be working toward multiple or competing objectives.* In fire protection analyses, typically competing objectives are low cost and high level of safety. Progress in one direction, such as installing automatic fire sprinklers for increased fire safety, may impede progress of a competing objective, such as designing an economical building.
- *Third, a problem may be difficult if different perspectives lead to different conclusions.* In a fire protection decision, the perspective of the building owner, designer, and authority having jurisdiction may very well differ.
- *Finally, decisions can also be difficult because of the inherent uncertainty.* Uncertainties may arise in the model physics, the values of the inputs, the reliability of the devices, and the frequency of events. Yet a decision must be made without knowing for sure what these uncertain values will be. In fact, the most important decisions are often those that must be made under the greatest uncertainty, have the highest complexity, and involve multiple perspectives and goods.

The quantitative treatment of variability and uncertainty using the tools and techniques presented earlier in this chapter can help in identifying important sources of uncertainty and representing that uncertainty in a quantitative way.

The following section introduces an analytical approach that allows quantitative models and decisions models to be built with the integrated treatment of uncer-

tainty. The final section demonstrates how these tools were used in a cost-benefit model of the decision to mandate residential fire sprinklers from a municipal standpoint.

Available Software That Incorporates Uncertainty

Decision analysis applications often use generic modeling software such as spreadsheets, statistics packages, and financial modeling languages. Specialized software is also available for modeling decision problems using decision trees, influence diagrams, belief networks, multi-attribute utility functions, hierarchical value structures, Monte Carlo simulation, and multicriteria optimization.

Two such pieces of software that allow for direct treatment of uncertainty are Analytica™ by Lumina and @Risk™ by Palisade. These are just two software options. They are described here for informational purposes only, intended to provide the reader with an idea of the capabilities of currently available software. The reader is encouraged to evaluate the full range of available software before selecting a package.

@RISK is a risk analysis and simulation add-in for Microsoft Excel or Lotus 1-2-3. @RISK adds the power of Monte Carlo simulation to your spreadsheet models. It allows the user to replace uncertain values in their spreadsheet with probability functions, which represent a range of possible values. @RISK will recalculate your spreadsheet hundreds or even thousands of times, each time selecting random numbers from the functions entered. The result is distributions of possible outcomes and the probabilities of getting those results. This identifies not only what could happen in a given situation, but how likely it is that it will happen.

Analytica is another program that allows for the direct treatment of uncertainty. A model built in Analytica uses a graphical interface that resembles an influence diagram. This diagram conveys the model structure. A complicated model can be easily organized into a hierarchy of comprehensible and simple modules. The influence diagram format easily distinguishes between decision variables (those you can control), chance variables (uncertain quantities that cannot be controlled), and objectives (criteria to maximize).

Other distinctive features of Analytica are what the company terms *intelligent arrays* and also turn-key importance analysis. With intelligent arrays, data may be entered as an array indexed by several parameters. The software handles operations on these multidimensional values, such as adding, multiplying element by element, or summing over a dimension. Examples of intelligent arrays are presented in the following section.

In Analytica uncertainty can be treated explicitly with probabilities. The user can express uncertainty about any variable, selecting a probability distribution using a graphical browser; propagate uncertainties with the model using Monte Carlo sampling; and display uncertain results as standard statistics, probability bands, probability density functions, or cumulative probability functions. Analytica conducts rank-order and importance analyses. These tools help one decide which uncertainties make a difference to help determine whether getting better data or expanding the model is worthwhile. Analytica also al-

lows for parametric analysis by graphing model behavior as one or more inputs are varied.

Example of Cost-Benefit Model with Variability and Uncertainty

In the United States, approximately 3500 people die each year in residential fires. The number of residential fire deaths, however, varies with the type of housing, area of the country, and community size. The cost of installing residential fire sprinklers varies with areas of the country and house age. Thus, the true cost-benefit will be different for each combination of the above parameters. However, cost-benefit models typically use average costs and probabilities and do not incorporate uncertainty.

A model was built using Analytica that incorporated variability and uncertainty to determine the societal benefits and costs of mandating residential sprinklers. A full description of the mathematical model and the results is beyond the scope of this chapter but can be found in "A Municipal Model of the Cost of Mandating Residential Sprinklers."⁴⁵ A brief overview of that study is presented in order to demonstrate the techniques used in the treatment of variability and uncertainty and the implications for fire protection analyses.

Treatment of Variability and Uncertainty

Interyear variability in fire loss statistics: To conduct a cost-benefit study of residential fire sprinkler systems, many fire statistics (e.g., death rates, injury rates, and average direct dollar losses) are needed as inputs. National average values of these numbers are often used in these analyses. For example, the national average value for the residential death rate would be equal to the number of residential fire deaths nationally divided by the number of occupied residential units. The actual fire death rate will vary with a number of parameters.

The U.S. National Fire Protection Association publishes death rates discretized by three of four index variables: region of the country, community size, and house type.⁴⁶ The fourth index variable, house age, is accounted for in the cost functions as it is more expensive to retrofit sprinklers than it is to install them during the construction phase. There are four regions of the country, eight community sizes, and three house types. Thus, the death rate used in these calculations is a $4 \times 8 \times 3$ matrix consisting of 96 values for death rate. Two examples would be the death rate in mobile homes in a small community (2500 or less) in the South and the death rate in a one- or two-family dwelling in a community size of 25,000 to 50,000 in the West.

Yearly variability in fire loss statistics: It is important to differentiate between variability and uncertainty. Variability in fire statistics from year to year arises because of the randomness of the occurrence of fires. For instance, in one particular year, several large-loss fires may occur followed by few or none the next year. In this study, since there is an interest in benefits and costs over the life of a fire sprinkler system, mean yearly values were chosen. Yearly variance in deaths, injuries, property loss, and

indirect losses due to fires is thus accounted for by taking mean yearly values over a five-year period. Mean values were calculated from the 1989–1993 data.

Uncertainty in the fire statistics: Uncertainty in fire loss statistics exists due to the impossibility of a full and accurate accounting of all fires and all fire losses. Mathematical techniques are thus used to provide estimates.⁴⁷ Uncertainty in the fire data is represented as uncertainty about the mean values. An expert elicitation of the chief statistician of NFPA was conducted to set the uncertainty bands for the fire statistics.⁴⁸

Uncertainty in other (empirical) model inputs: Uncertainty in the cost data and parameters such as the sprinkler reduction factor were determined by bounding. For example, uncertainty in the sprinkler reduction factor arises because of the small number of fires occurring in homes with automatic sprinklers installed. Data from other occupancies were used to bound the uncertainty.

Propagation of uncertainty: Once the uncertainties in the model inputs have been expressed, the question becomes, How can we propagate these uncertainties through the model to discover the uncertainty in the predicted consequences? In this analysis a Monte Carlo simulation was used. A value for each input is randomly selected from its actual probability distribution. From these values, a value for the outcome criteria is calculated. This process is repeated many times, resulting in a probability distribution for each outcome variable.

Value/cost of death averted: For any cost-benefit analysis regarding health and safety, one of the most highly contentious points is setting a value of life. Economists have come up with various ways of estimating the value of a life. These include willingness to pay for safety devices, and income-based estimates.⁴⁹ All these methods

are highly debated. For this study, the problem of establishing a value of life was avoided by means of careful selection of the outcome criteria. By selecting the outcome criteria to be dollars per premature death averted and dollars per life-year saved, no explicit value of life needs to be specified.

Results—national average calculation versus indexed calculations: When variability due to region, community size, house type, and house age are accounted for, the net cost of residential sprinklers varies tremendously. The net cost for installing residential sprinklers varies by greater than a factor of 35 times. From a low of \$1.4 million per premature death averted (for a new mobile home in a small community in the South) to a high of \$35.1 million (for a retrofit of a one- and two-family dwelling in a medium-size community in the West). Based on a national average calculation, our model predicts that residential fire sprinklers have a median net cost of \$7.3 million dollars per premature death averted.

Comparison to other lifesaving interventions: An article in *Risk Analysis* identified over 500 lifesaving interventions, reporting their net cost in terms of dollars per life-year saved.⁵⁰ The accuracy of the results is limited by the accuracy of the data and assumptions in each original analysis, but the results are believable within an order of magnitude. In this study the cost per life-year saved for residential fire sprinklers was compared to the cost per life-year saved for chlorination of drinking water, banning urea-formaldehyde insulation in homes, installing oxygen depletion sensors for gas space heaters, conducting radon remediation, mandating child-resistant cigarette lighters, and installing ground fault interrupters. Figure 5-4.7 below shows this comparison. The heights of the bars represent the relative costs per life-year saved and have all been normalized to the cost of chlorination of drinking water.

Figure 5-4.7. Comparison of net cost of fire sprinklers in manufactured homes with other residential lifesaving interventions.

Uncertainty in Cost-Benefit and Decision Analysis Models

This example demonstrates how uncertainty and variability may be treated in a cost-benefit or decision analysis model. It also showed that effectively treating variability and uncertainty, and use of tools such as importance analysis and comparative analysis, can lead to greater insights. The cost of mandating residential fire sprinklers in new mobile homes was shown to be as low as five times less than the cost of mandating residential fire sprinklers using national average values for fire risk and costs. The cost of mandating residential fire sprinklers in existing single family homes was shown to be up to five times more than using national average numbers. The comparative analysis provides lawmakers a frame of reference by comparing the cost of mandating residential fire sprinklers to the costs of mandating other residential safety options with lifesaving potential.

Conclusion

The treatment of uncertainty is key to ensuring and maintaining an appropriate level of public safety while allowing the flexibility necessary to reduce costs. This is true for all fire safety engineering calculations, whether conducted to meet a performance-based code, to aid in the establishment of a prescriptive requirement, or to compare a performance option to its prescriptive counterpart. Beyond being just another step in the process of getting a building approved, properly determining and documenting a level of confidence in the design will have numerous benefits. It will facilitate cooperation among stakeholders by increasing the overall understanding of risks and costs.

Distributions of outcomes are a much richer description of what is possible than the typical point value answers. Though stakeholders and/or policy decisions must still determine how much risk to accept, with thorough uncertainty analyses, this decision will be informed and free of the uneasiness that typically surrounds acceptance of a deterministic performance calculation. The information provided in this chapter is intended to help the fire protection community to understand the nature and sources of uncertainty, to aid in the selection of a calculation procedure, to apply a methodology for the treatment of uncertainty, and to incorporate uncertainty into cost-benefit models and decisions.

CHAPTER 5

Data for Engineering Analysis

John R. Hall, Jr., and Martha J. Ahrens

This chapter addresses sources of input data required for deterministic (e.g., fire hazard) or probabilistic (e.g., fire risk) engineering analysis, such as performance-based design, code change analysis, product evaluation analysis, or major fire reconstruction. An overview of types of analysis engineers may perform, with a brief discussion of the kinds of engineering problems that should be addressed using those kinds of analysis, is given in the list below. Table 5-5.1 then translates each type of analysis into a list of fire or fire-related phenomena that must be characterized to perform the analysis. Each phenomenon is then translated into a list of types of data required to model the phenomenon as part of the analysis.

- (General) fire risk analysis refers to a comprehensive analysis of fire risk associated with a range of situations, whether or not there is a particular focus for the analysis, and is set up in a classic risk analysis format, using scenarios and requiring data on probabilities and consequences for each scenario.
- Fire hazard or risk analysis of a burnable product is needed for evaluation and possibly certification for acceptability (possibly for equivalence to a product regulation) of a product, material, assembly, component, and so on whose role in fire is as something that burns, either the first item ignited or a major fuel source during fire development.
- Fire hazard or risk analysis of a design for an occupiable space is needed for assessment and possibly approval of a design for an entire building (possibly under equivalence or relative to a performance-based code).
- Fire hazard or risk analysis is also appropriate for evaluation and possibly approval of products whose roles in fire are as heat sources that initiate fires.
- Engineering analysis can be appropriately applied to the performance of automatic detection/alarm or

suppression systems or of other active fire protection systems.

- Engineering analysis can be appropriately applied to the performance of passive fire protection, such as walls, doors, and structural members.
- Engineering analysis can be appropriately applied to the performance of features designed to ensure safe evacuation of occupants from a building with a developing fire.

As Table 5-5.1 shows, regardless of the type of analysis required, the same generic types of data are typically needed, which may be organized into these few sources:

- Fire incident and field observation (i.e., nonincident event) data
 - Probabilities of ignition or of reliability, given naturally occurring variation in conditions
 - Fire size and consequences, given specified values of certain conditions, factors, or characteristics of interest and naturally occurring variation in all others
 - Characteristics and behavior of people
- Usage or exposure data
 - Denominators for probability calculations from event data (e.g., number of portable electric heaters versus wood stoves in use, to support estimates of fires per year per unit; number of gasoline service stations, to support estimates of probability of fire per service station per year; number of square feet of office space, to support estimates of probability of fire per square foot of office space per year)
- Laboratory test results
 - Fire size (e.g., heat release rate) as a function of time, given planned variation in certain conditions (e.g., fuel load) and unplanned variation in those not recognized or measured (e.g., exact location of fuel items and their proximity to each other)
 - Probabilities of ignition or of reliability, given planned variation in conditions (measured as

Dr. John R. Hall, Jr., is NFPA's assistant vice-president for Fire Analysis and Research.

Martha J. Ahrens is a fire analysis specialist at NFPA.

Table 5-5.1 Types of Analysis and Associated Data Needs

Type of Analysis	Phenomena	Data Needs
General fire risk analysis	Ignition—probability of fire, by scenario	Fire incident data, exposure data
	Consequence—measures of severity of fire, by scenario	Fire incident data, laboratory test results
Burnable product fire hazard or risk analysis	Ignition—probability of fire, by scenario, for different versions of the product	Laboratory test results (related to scenarios, including specific ignition sources), fire incident data, product usage data
	Burning characteristics of product once ignited—time curve for heat release rate, peak heat release rate, flame spread rate, effective heat of combustion, rate of production of smoke or toxic species	Laboratory test results
	Reliability of product—probability, mode or nature, and magnitude of “failure,” defined as any deviation from nominal product performance	Field observations (e.g., probability of poor quality control in manufacture of product), usage data (e.g., age effects related to performance, degradation due to wear or vandalism)
	Contribution to harm to people—toxic species production by mass loss ratio or mass loss rate, toxic potency of species, time rate of production of vision-reducing products of combustion	Laboratory test results (of characteristics and effects of fire conditions produced when product burns)
Design for occupiable space fire hazard or risk analysis	Contribution to harm to property—mass loss rate by combustion product, corrosivity or other chemical characteristics by combustion product	Laboratory test results (of characteristics and effects of fire conditions produced when product burns)
	Ignition and burning characteristics	Laboratory test results (related to scenarios, including specific ignition sources), fire incident data, product usage data
	Transition to flashover	Design specifications (e.g., compartment dimensions, thermal properties of compartment surface linings, venting), laboratory test results, other measured or estimated conditions
	Burnout time	Field surveys (fuel load or fuel mass available, compartment geometry, ventilation), laboratory tests (mass burning rate, heat of combustion)
	Space to space fire spread—flame spread rate	Design specifications (e.g., measures of barrier integrity), laboratory test results, other measured or estimated conditions (e.g., paths of fire spread such as HVAC), fire duration (see burnout time)
	Structural performance—collapse or damage making use of building unsafe	Laboratory test results, field observations
Heat source product fire hazard or risk analysis	Contribution to harm to people	Same as for burnable product analysis
	Contribution to harm to property	Same as for burnable product analysis
	Ignition—probability of fire, by scenario, for different versions of the product	Laboratory test results, fire incident data, product usage data
Active fire protection performance	Reliability of product—probability, nature, and magnitude of deviations from nominal product performance	Field observations (e.g., probability of poor quality control in manufacture of product, testing and maintenance records), usage data (e.g., component failure due to age, degradation due to usage or vandalism)
	Time of activation	Laboratory test results (e.g., physical conditions leading to system activation), fire incident data
Passive fire protection performance	System effect—measures of system output (e.g., sound, suppression agent)	Laboratory test results, fire incident data
	Reliability—probability, nature, and magnitude of deviations from nominal system performance	Field observations (e.g., probability of poor quality control in manufacture of product, testing and maintenance records), usage data (e.g., component failure due to age, degradation due to usage or vandalism)
	Time performing function (e.g., time blocking spread of fire, time providing structural integrity while subjected to fire conditions)	Laboratory test results (on passive fire protection element, reflecting materials and type of design or construction), fire incident data, burnout time (see previous reference to burnout time as a phenomenon; it is a calculated time for fire duration exposing passive fire protection element)
Evacuation and other human behavior	Feature effect—degree to which function is performed (e.g., quantity of fire effects permitted to pass barrier)	Laboratory test results, fire incident data
	Reliability—probability, nature, and magnitude of deviations from nominal feature performance	Field observations (e.g., impairment prior to fire, such as poke-through holes in wall or doors blocked open, probability of poor quality control in manufacture of product), usage data (e.g., component failure due to age, degradation due to usage or vandalism), laboratory test results
	Occupant characteristics	Field observations, laboratory test results, design specifications and estimated conditions

numbers of ignitions or numbers of failures divided by numbers of trials, although fire and equipment failure tend to be such rare events that measurement of probabilities in the laboratory can be impractical)

Fire consequences, including specific effects on people (actually data for estimation of effects on people, for example, via animal tests or toxic effects models based on species concentrations and exposure times) or on property, as a function of time and of specified or measured conditions

Discussion of data types and sources will be organized, therefore, around incident data, field observation data, usage or exposure data, and laboratory test results. The last type will be addressed only briefly, as it is the type most familiar already to fire protection engineers and most thoroughly discussed in the other chapters of this handbook.

Incident Data

How often do certain items catch fire, or certain types of equipment start fires, or certain types of occupancies have fires? The first component in all these calculations is data on event frequencies per unit time. If the focus is on products, occupancies, or other subjects of analysis that are well established in widespread use, then fire experience data will include a number of fires involving those items, and those data can be used with usage data to calculate event frequencies.

If the product is new, it will not be reflected in current fire experience data. It may be necessary to use laboratory tests in a full range of relevant scenarios to calibrate the likelihood of ignition for the new product against the likelihood of ignition for a typical established product or mix of products. The performance of the typical product or mix of products indicates the level of performance producing today's product fire problem, which means the degree of difference in the new product's laboratory performance should predict the new product's field performance as a change in the product's fire problem.

There are no standard test protocols for such a calibration and, because ignition is typically a rare event, it may be difficult and expensive to obtain test-based estimates of these relative likelihoods. Subjective estimation and interpretive judgment will likely be required and may in some instances be the only basis available for ignition probability estimates for new products. (For example, experts might agree that a new product will be roughly a third to a half less likely to be involved in fire ignitions than a typical product now in use.)

If fire experience history is relevant, it is important that estimates be drawn from suitable, statistically representative databases and procedures. In the United States, this means starting with national estimates of fire experience using data from the U.S. Fire Administration's National Fire Incident Reporting System (NFIRS) for detail and from the National Fire Protection Association's annual survey of fire departments for projection of NFIRS to national estimates.¹

NFIRS is the largest and most detailed fire incident database in the world, capturing roughly a million indi-

vidual fire incidents a year, but it collects only an estimated one-half of the fires reported to U.S. fire departments per year. Historically, since 1980 NFIRS has had participation from some or all communities in roughly 40 of the 50 states, plus the District of Columbia, although not all participating communities have been able to submit data every year. It captures data about the fixed property use or occupancy, the form and type of material first ignited, general type of equipment involved in ignition, form of heat of ignition, ignition factor, and presence of automatic detection and suppression systems.

To project NFIRS results to national estimates, one needs at least an estimate of the NFIRS fires as a fraction of the total so that the fraction can be inverted and used as a multiplier or scaling ratio to generate national estimates from NFIRS data.² But NFIRS is a sample from a universe whose size cannot be inferred from NFIRS alone. (*Universe* is the statistical term for the complete set from which a sample is drawn, in this case, the universe of all reported fires.)

Also, participation rates in NFIRS and practices regarding the types and severity of incidents reported are not necessarily uniform across regions and sizes of community. For example, some communities do not report fires with zero property damage. Both region and community size, in turn, are correlated with frequency and severity of fires. This means NFIRS may be susceptible to systematic biases.

No one at present can quantify the size of these deviations from the ideal, representative sample, so no one can say with confidence that they are or are not serious problems. But there is enough reason for concern so that a second database—the NFPA survey—is needed to project NFIRS to national estimates and to project different parts of NFIRS separately. This multiple calibration approach makes use of the annual NFPA survey where its statistical design advantages are strongest. The NFPA survey is a stratified random-sample survey that captures roughly one-tenth of all U.S. fire departments, including most departments protecting a population of at least 100,000. This stratification preserves randomness, hence representativeness, in the sample but reduces total variance, for more precise answers with less sampling uncertainty.

There are separate projection formulas for four major property classes (residential structures, nonresidential structures, vehicles, and other) and for each measure of fire severity (fire incidents, civilian deaths, civilian injuries, and direct property damage).

For example, the scaling ratio for 1996 civilian deaths in residential structures is equal to the total number of 1996 civilian deaths in residential structure fires reported to fire departments, according to the NFPA survey (4080), divided by the total number of 1996 civilian deaths in residential structure fires reported to NFIRS (1504). Therefore, the scaling ratio is $4080/1504 = 2.71$.

The scaling ratios for civilian deaths and injuries and direct property damage are often significantly different from those for fire incidents. Except for fire service injuries, average severity per fire (e.g., average number of deaths per 100 fires, average property damage per fire) is generally higher for NFIRS than for the NFPA survey. Use of different scaling ratios for each measure of severity is equivalent to assuming that these differences are due

either to NFIRS underreporting small fires, resulting in a higher-than-actual loss-per-fire ratio, or possible biases in the NFIRS sample representation by region or size of community, resulting in severity-per-fire ratios characteristic only of the oversampled regions or community sizes.

Most analyses of interest involve the calculation not just of the estimated total number of fires per year within a particular occupancy but more specifically of the estimated number per year of a certain type of fire in the particular occupancy. The types that are most frequently of interest are those defined by some ignition-cause characteristic. The six cause-related characteristics most commonly used to describe fires are two characteristics related to the source of heat of ignition (form of the heat that caused the ignition, equipment involved in ignition), two characteristics related to the first fuel item ignited (form or type of material first ignited), the ignition factor that brought heat source and ignited material together, and area of origin. Other characteristics of interest are victim characteristics, such as ages of persons killed or injured in fire, victim location at ignition, and victim activity at time of injury.

For any characteristic of interest in NFIRS, some reported fires have that characteristic unknown or not reported. If the unknowns are not taken into account, then the propensity to report or not report a characteristic may influence the results far more than the actual patterns on that characteristic. For example, suppose the number of fires remained the same for several consecutive years, but the percentage of fires with cause unreported steadily declined over those years. If the unknown-cause fires were ignored, it would appear as if fires due to every specific cause increased over time while total fires remained unchanged. This, of course, does not make sense.

Consequently, most national estimates analyses allocate unknowns. This is done by using scaling ratios defined by NFPA survey estimates of totals divided by only those NFIRS fires for which the dimension in question was known and reported. This approach is equivalent to assuming that the fires with unreported characteristics, if known, would show the same proportions as the fires with known characteristics. For example, it assumes that the fires with unknown ignition factor contain the same relative shares of child-playing fires, incendiary-cause fires, short-circuit fires, and so forth, as are found in the fires where ignition factor was reported.

It may be useful at this point to summarize sources of error and uncertainty in NFIRS-based national estimates, both those that can be readily quantified and those that cannot:

- Sample-size-based uncertainty—negligible from NFIRS itself because of its enormous size, unless the problem being examined accounts for hundreds of fires per year or less, and modest from the calibrating NFPA survey (about 10% for deaths and much less for other measures of fire loss)
- Sample-bias-based uncertainty—negligible from the NFPA survey because of its design, and unknown for NFIRS, where poorer communities (large or small) are proportionally less well represented but differences in proportional representation appear to be modest; large

for any other incident data source, which will tend to be limited to more severe fires and possibly to specially selected victim groups

- Uncertainty due to missing data—the percentage of NFIRS cases with blank or unknown data is addressed, as noted above, by proportional allocation but can also be used to estimate the uncertainty, which in extreme ranges from all the unknowns being relevant to none of the unknowns being relevant
- Uncertainty due to coding inconsistencies—more difficult to address because few coding combinations are truly inconsistent (unusual fires are possible) but can be analyzed as with missing, blank, or unknown data in terms of elimination of a range of suspect cases
- Uncertainty due to error in determining the facts of the case—unmeasurable in the absence of some indicator within the incident record (e.g., inconsistency in coding two or more data elements) or access to a more reliably accurate source of incident data (few incidents have a second source of data, and second sources of data are not necessarily more reliable)

Fire incident commanders provide NFIRS data using a standardized coding system after a fire to complete an incident report. The strengths of the system are also limiting factors. By utilizing a standard classification system to capture the circumstances at all types of fires, data can be captured easily about a wide variety of events. However, the data will not be as detailed as many people would like. The fire service personnel collecting the data are generalists, not specialists. They can usually identify that a particular piece of equipment was the source of ignition, but they are unlikely to know which part of the equipment was involved. Information on brand, model, or component of equipment involved is not coded and typically is not captured. Nor does NFIRS capture very specific types of equipment that are used in only a small number of industries. And even at the level of detail addressed by the database coding, there are many gray areas of interpretation.

To illustrate these points on the limitations and complexities of applying the data to a particular product, consider the steps you might have to go through just to fully capture the detail that is available in NFIRS in order to estimate fires involving a particular type of carpet. Carpet is one of several products that falls within the NFIRS category of floor covering. The NFIRS Form of Material First Ignited code 14 for floor covering includes carpet but also tile, rugs, hardwood flooring, resilient (e.g., vinyl) flooring, and even stairs. The NFIRS database can be checked for number of fires coded as starting with floor covering. However, floor covering will also account for a share (usually estimated as proportional) of fires with Form of Material First Ignited unknown. Floor covering will also account for a share (usually estimated as proportional) of fires under Form of Material First Ignited code 10, which is structural component or finish of unknown type. The standard references on developing national estimates provide guidance on these steps and the specific statistical methods needed to execute them.

To distinguish carpets from other floor coverings, consider the Type of Material First Ignited data. This data
